Although endoscopy is diagnostic for UGIB, it is also therapeutic in the majority of cases and should be performed within 24 hours of admission. It should be carried out without delay when patients remain unstable despite initial fluid and blood product resuscitation. Although many guidelines stress the need for 'haemodynamic stability' prior to endoscopy, in cases where this is difficult to achieve, consideration must be given to achieving haemostasis by endoscopic means as part of the ongoing resuscitation process. A recent development has been the use of capsule endoscopy in the ED for low-risk patients to allow rapid decision making and facilitate early discharge and outpatient management. There are few published studies so far, with small patient numbers, but further developments in this technology are likely to occur rapidly as the technology for capsule endoscopy improves further. At present, therapeutic capsule endoscopy is not possible.

Specific therapy

Peptic ulcer disease

Bleeding ceases spontaneously in 80% of cases and the mortality rate is approximately 5% to 6%, significantly less than with variceal bleeding.

Drug therapy

Haemostasis is known to be a pH-dependent process; therefore it has been hypothesized that medications that inhibit acid secretion will also reduce the rates of re-bleeding, need for surgery and mortality. The two main drug classes are the histamine (H_2) antagonists and the PPIs.

H_2 antagonists A large meta-analysis in 2002 reported that H_2 antagonists had only modest effects on bleeding gastric ulcers, reducing re-bleeding by 7.2%, surgery by 6.7% and death by 3.2%, with no effects on bleeding duodenal ulcers. H_2 antagonists are not recommended in the contemporary management of UGIB.

Proton pump inhibitors The PPIs are the most common class of drugs used for peptic ulcer disease based on their profound and persistent acid suppression. Current guidelines recommend that intravenous PPIs should be given by bolus followed by continuous infusion in high doses. There is little evidence to support routine pre-endoscopy use of intravenous PPIs, but local guidelines should be followed. The use of PPI infusion should not delay early endoscopy for patients. The use of PPIs for high-risk bleeding ulcers has been demonstrated to reduce re-bleeding within 7 days. High-dose oral PPIs are also effective and may be used when intravenous administration is not possible. Oral doses of PPIs

should be at least four times the standard oral dose. Reversible risk factors, such as *H. pylori* and NSAIDs, should be eliminated where possible.

Somatostatin/octreotide Studies have found conflicting results in the use of somatostatin and octreotide in peptic ulcer disease. A meta-analysis suggested that there may be a reduction in re-bleeding and the need for surgery in patients with bleeding ulcers, but there was no effect on mortality. Somatostatin and octreotide are no longer recommended in the acute management of peptic ulcer disease.

Endoscopy

Endoscopic therapy is at the core of all modern management of UGIB. The ongoing development of new endoscopic techniques for haemostasis means that endoscopy has almost completely replaced surgery as the definitive therapy. Combination therapy using submucosal adrenaline injections combined with cautery or mechanical clips is the best option for ulcers requiring endoscopic treatment.

Surgery

Surgery is required in less than 2% of patients. Surgery is indicated for intractable or recurrent active bleeding, especially in patients aged over 60, in whom early surgery produces significant benefits in terms of mortality. Other indications include massive blood transfusion, refractory shock and failure to respond to endoscopic therapy. Salvage surgery is associated with poor outcomes; therefore early surgical consultation should be considered, particularly for patients aged over 60 years, those with significant co-morbidities, those with evidence of active bleeding (active bright red haematemesis, haematochezia), when there is a significant risk of re-bleeding or when there is continuing haemodynamic instability. Trans-arterial embolization, although it is rarely used, appears to offer selected patients a good alternative to open surgery when bleeding is not manageable by conventional endoscopic means. Success rates of up to 69% have been reported, which is comparable to the results of open surgery.

Gastro-oesophageal varices

Although haemorrhage from gastro-oesophageal varices accounts for 2% to 15% of all UGIB, it represents a significant therapeutic challenge. Bleeding ceases spontaneously in only 20% to 30%, but as bleeding is often more severe and recurrent, mortality approaches 25% to 40% for each episode of variceal haemorrhage. Factors influencing mortality include the stage and rate of deterioration of the underlying liver disease, the presence of co-morbidities, variceal size and specific endoscopic criteria. Patients with known severe varices should be considered for early transfer to a specialist hepatology centre with expertise in dealing with acute massive variceal bleeding.

Drug therapy

Drugs should be used when endoscopic expertise is not available, if massive bleeding prevents immediate sclerotherapy or as an adjunct to further treatment if continued variceal haemorrhage is suspected. However, it must be emphasized that endoscopic haemostasis procedures are still the mainstay of treatment for varices and that endoscopy is required for all cases despite drug therapy.

Somatostatin, octreotide, vasopressin and terlipressin have all been used in this situation. Somatostatin/octreotide therapy produces dramatic reductions in splanchnic arterial blood flow and portal venous pressure while preserving cardiac output and systemic blood pressure. Treatment results in the control of bleeding in 74% to 92% of cases, with endoscopic evidence of cessation of bleeding in 68% of patients within 15 minutes. Vasopressin increases peripheral vascular resistance and mean arterial pressure, with reduced cardiac output and coronary blood flow; it is therefore contraindicated in patients with coronary artery disease. Vasopressin results in the control of bleeding in 50% to 75% of cases. Terlipressin is a synthetic analogue of vasopressin. It can be given by bolus intravenous injection and has been shown to have a 34% relative risk reduction in mortality from acute variceal haemorrhage and a much lower incidence of side effects than vasopressin. Where available, terlipressin (2 mg IV bolus) is therefore recommended for patients with known or highly suspected oesophagogastric varices with UGIB.

There is evidence that patients with oesophageal varices who have chronic liver disease have higher survival rates if given broad-spectrum antibiotics on admission. Intravenous antibiotics should be started early and local advice should be sought on the most appropriate antibiotic. In the absence of local guidance, intravenous cephalosporins or quinolones are a reasonable initial choice.

Endoscopy

Endoscopy is essential to confirm the diagnosis of variceal haemorrhage, as an alternative bleeding site is found in up to 81% of patients with known varices. Endoscopy is also therapeutic in many cases. Endoscopic variceal ligation (EVL) has been shown to be more effective than endoscopic sclerotherapy in the control of variceal haemorrhage, with significantly fewer complications, less re-bleeding and lower mortality; it also requires fewer treatment sessions. Control of bleeding can be achieved subsequently in up to 95% of cases, with a reduction in the risk of re-bleeding. Therefore EVL should be considered first-line therapy in the control of bleeding from oesophageal varices. Sclerotherapy remains an option if EVL is technically impossible due to massive bleeding at the time of endoscopy.

It is very difficult to perform EVL on gastric varices, so injections of cyanoacrylate are recommended. This should be combined with drug therapy.

Balloon tamponade

Compression of fundal and distal oesophageal varices by balloon tamponade results in control of bleeding in 70% to 90% of cases. Balloon tamponade may be used as a temporary means of controlling bleeding that is refractory to medical or endoscopic treatment or when bleeding is too massive for endoscopy to be performed successfully.

Because of the problems of pooling of secretions in the oesophagus (thereby increasing the risk of pulmonary aspiration), the standard Sengstaken-Blakemore tube has been modified to incorporate an oesophageal aspiration channel. Further modifications have been made with the Linton-Nachlas tube, which incorporates a single large (600 mL) gastric balloon for the tamponade of gastric varices. The principal use of balloon tamponade now is to act as a bridge to facilitate transfer to a specialist hepatology or endoscopy centre for ongoing care. Endoscopy at the earliest opportunity remains the treatment of choice for UGIB.

There are a number of problems with balloon tamponade:

- It can be used for a maximum of only 48 to 72 hours. As up to 50% of patients re-bleed when the tube is deflated, further definitive procedures (EVL, sclerotherapy, surgery) must be performed.
- There is a significant (25%–30%) risk of complications, particularly pulmonary aspiration and oesophageal perforation and rupture.
- Balloon tamponade requires skilled staff and monitoring in an intensive care setting for the initial insertion and maintenance of balloon position and function.
- Owing to the risks of pulmonary aspiration, endotracheal intubation should be considered in all patients requiring balloon tamponade.

Transjugular intrahepatic portosystemic stent-shunt

Transjugular intrahepatic portosystemic stent-shunt (TIPSS) involves the insertion of a stent under radiological guidance via the jugular vein, forming a portosystemic shunt between the hepatic and portal veins. This technique is effective, achieving control of bleeding in up to 90% of patients, and it is less invasive and faster to perform (30 minutes–3 hours) than other

surgical shunt procedures. However, it requires an experienced operator and often results in complications similar to those seen after other portosystemic shunts, particularly encephalopathy and deteriorating liver function.

The main role of TIPSS, therefore, appears to be in patients who continue to bleed in spite of EVL or sclerotherapy and who do not have hepatic encephalopathy, preterminal liver failure, portal vein thrombosis, intrahepatic sepsis or significant cardiac disease. TIPSS then acts as a bridging procedure until other definitive surgical procedures can be performed (such as liver transplantation, shunt surgery or, rarely, oesophageal transection).

Surgery

Since the advent of EVL and sclerotherapy, the role of surgery in the control of acute variceal bleeding has decreased, and it is now largely confined to the small number of patients who continue to bleed despite endoscopic intervention. Shunt surgery and oesophageal transection have been shown to reduce bleeding. However, these techniques require specialist surgical skills and have not been shown to improve survival.

Disposition

The primary decision in most cases is whether the patient is to be admitted to the general ward or to an intensive care unit (ICU) or high-dependency unit (HDU). Ideally, patients with UGIB should be admitted under the joint care of a gastroenterologist and a surgeon in a specific GI bleeding unit.

The main indications for ICU/HDU admission include

- known or suspected variceal bleeding.
- haemodynamic instability.
- significant co-morbidities, including cardiac, renal, pulmonary or hepatic dysfunction.

The threshold for ICU/HDU admission should be lowered in patients over 60 years of age owing to the high incidence of co-morbidities and poor physiological compensatory reserve. Lower-risk patients may be admitted to the general ward. The usual length of stay is 2 to 3 days, as the major risk of re-bleeding is during the first 24 to 48 hours.

Evidence for outpatient management of upper GI bleeding is less clear. Most UGIB ceases spontaneously and most patients compensate well, not requiring transfusion or surgery. Some authors have suggested outpatient management for selected patients. To minimize the risk of adverse events if the patient is managed as an outpatient, early endoscopy has been advocated. Early discharge is then suggested for those who are found to have clean-based ulcers or non-bleeding Mallory-Weiss tears. In the United Kingdom, studies have recommended outpatient management for patients with a score of two or less on the GBS. It would be interesting to see if this can be applied in clinical settings to determine its plausibility for recommendation in future guidelines.

Likely developments over the next 5 to 10 years

- There is likely to be a continuing increase in the incidence of UGIB as the population ages, particularly variceal bleeding, as the incidence of liver disease rises in most developed countries, particularly in those below 60 years of age.
- Further studies on doses, route of administration, timing and duration of therapy for PPIs after UGIB will help to clarify the optimum treatment.
- Improvements in delivery of critical care may help to improve survival in patients with UGIB by improving care of co-morbid conditions.
- Diagnostic capsule endoscopy in the ED to rule out active bleeding and allow outpatient-based care will be further studied and evaluated.
- Clinical risk-evaluation tools facilitating outpatient management will be further validated in different settings and become part of routine clinical practice.

CONTROVERSIES

- The optimum dose, route of administration, timing and duration of therapy for PPIs after UGIB has not yet been clarified and requires further study.
- Despite improvements in re-bleeding rates and a reduction in the requirement for surgical intervention, mortality rates have not improved, probably because of growing elderly populations and more co-morbidity.
- Increasing co-morbidities and the growing elderly population may require more intensive critical care to improve survival rather than further improvements in endoscopic haemostasis.
- The pressure to manage more patients safely in the outpatient setting means that there is a need to validate and further refine scoring systems to evaluate risk or adverse outcomes in UGIB, both with and without early endoscopy.
- A better understanding of the optimal use of the restrictive transfusion strategy for acute UGIB is needed as well as method to identify patients with exsanguinating bleeding who may need to be managed differently.

7.7 Peptic ulcer disease and gastritis

Win Sen Kuan • Shirley Ooi

ESSENTIALS

1 ***Helicobacter pylori*** **is responsible for 70% to 90% of peptic ulcers, with non-steroidal anti-inflammatory drugs (NSAIDs) accounting for most of the remainder.**

2 **Emergency presentations of peptic ulcer disease vary from mild indigestion to severe life-threatening complications.**

3 **Endoscopy is the investigation of choice for definitive diagnosis.**

4 **Most patients can be managed medically with a combination of anti-secretory drugs and antibiotics as indicated.**

5 **Surgical treatment may be indicated for complications, such as haemorrhage, perforation and obstruction.**

6 **A 'negative' erect chest x-ray does not exclude ulcer perforation.**

Introduction

Peptic (gastroduodenal) ulcers are defects in the gastrointestinal mucosa that extend through the muscularis mucosa. The term 'gastritis' is used to denote inflammation associated with mucosal injury. *Gastropathy* is defined as epithelial cell damage and regeneration without associated inflammation.

The discovery of the organism *Helicobacter pylori* has resulted in a dramatic change in our understanding of the aetiology and pathophysiology of peptic ulcer disease. What was once a chronic disease prone to relapse and recurrence has now become eminently treatable and curable.

Patients presenting to emergency departments may do so with 'classic' ulcer symptoms, undifferentiated abdominal or chest pain or, more dramatically, with life-threatening complications, such as perforation or haemorrhage.

Aetiology, genetics, pathogenesis and pathology

Aetiology

Peptic ulcer disease is associated with two major factors: *H. pylori* infection and the consumption of NSAIDs. Smoking is also an important contributory element but does not appear to be a risk factor for *H. pylori* recurrence or ulcer relapse following eradication of *H. pylori*.

Gastritis is usually due to infectious agents (such as *H. pylori*), autoimmune conditions and hypersensitivity reactions. In contrast, gastropathy is usually caused by irritants, such as drugs (e.g. NSAIDs and alcohol), bile reflux, hypovolaemia, ischaemia or chronic congestion.

Genetics

There seems to be a distinct familial aggregation of peptic ulcer disease in pre–*H. pylori* studies, suggesting a polygenic inheritance of peptic ulcer disease. It remains uncertain whether genetic factors predispose to *H. pylori* infection or whether the genetic factors function independently.

Pathogenesis and pathology

H. pylori disrupts the mucous layer of the gastroduodenal tissue, adheres to the gastric epithelium and releases enzymes and toxins. This causes the underlying mucosa to be susceptible to acid damage and incites an inflammatory response by the host.

NSAIDs cause ulcers by inhibiting the production of prostaglandins in the stomach and duodenum. The decreased synthesis of prostaglandins leads to the generation of increased amounts of gastric acid, decreased production of bicarbonate and glutathione and reduced blood flow to the gastric mucosa. NSAIDs are more commonly associated with gastric ulceration.

Epidemiology

H. pylori infects about 50% of the world's population. There are significant regional differences in the prevalence of peptic ulcer disease not explained by *H. pylori* alone, purportedly due to dietary variations. Populations with poor hygiene and low socioeconomic status are predisposed to a higher prevalence of *H. pylori* infection.

The vast majority of patients harbouring *H. pylori* are asymptomatic. Although decreasing in incidence in developed regions, *H. pylori* is the major cause of peptic ulceration or, at least, a major cofactor in its development. *H. pylori* has been isolated from 20% to 50% of patients with symptoms of dyspepsia. More importantly, 90% to 95% of patients with duodenal ulcers and 70% of those with gastric ulcers are infected with the organism. Eradication of *H. pylori* has been shown to markedly reduce the recurrence rate for ulceration. At least 50% of patients taking NSAIDs will have endoscopic evidence of erythema, erosions or ulcers even if they are asymptomatic.

Several risk factors influence gastrointestinal toxicity due to NSAIDs, the most important being a prior history of clinical ulcer disease or ulcer complications. Other risk factors are the dose and duration of therapy with NSAIDs, age above 75 years and cardiovascular disease. The risk of peptic ulcer disease is highest on commencement of NSAIDs. Combined therapy of NSAIDs with corticosteroids, anticoagulants, other NSAIDs or low-dose aspirin dramatically increases the risk of ulcer complications.

Some NSAIDs are more likely to produce ulcers than others. In general, shorter-acting agents, such as ibuprofen and diclofenac, are less likely to lead to ulcers than longer-acting agents. Even though cyclo-oxygenase (COX)-2 selective inhibitors (coxibs) have shown a reduction in the risk of peptic ulcers and their complications compared with traditional NSAIDs, this risk is increased compared with placebo. Studies have shown that the combination of a proton pump inhibitor (PPI) with a coxib decreases the incidence of peptic ulcers.[1] However, there is no evidence that coxibs have advantages over other NSAIDs for patients with unhealed ulcers. Coxibs appear to inhibit the healing of peptic ulcers.

The interaction between NSAIDs and *H. pylori* is controversial and complex, but evidence from two meta-analyses of case-controlled trials identified synergism between *H. pylori* and NSAIDs in producing peptic ulcers and ulcer bleeding.[2] Traditional risk factors—such as smoking, alcohol and stress—may increase the risk of ulceration and delay healing, but their relative importance as aetiological agents has fallen considerably with the discovery of *H. pylori*. Other causes of peptic ulceration, such as Zollinger-Ellison syndrome, are rare.

Clinical features

History

Peptic ulcers may present with a wide variety of symptoms, and over two thirds may be completely asymptomatic until complications, such as haemorrhage or perforation, occur. 'Indigestion' is the most common symptom in patients found to have peptic ulcer disease. Patients classically describe a burning or gnawing pain in the epigastrium that may radiate into the chest or straight through to the back. This may be associated with belching, early satiety, nausea and vomiting. Food may either exacerbate or relieve the pain. The pain is classically both fluctuating and periodic, with bouts of discomfort of variable severity interspersed with symptom-free periods.

The symptoms 'indigestion' or 'dyspepsia', however, have relatively poor sensitivity and specificity for diagnosing the various peptic syndromes. Less than 25% of patients with dyspepsia have peptic ulcer disease proven by gastroscopy and 20% to 60% of patients presenting with complications of ulcer disease report no antecedent symptoms.

Other presentations include chest or abdominal pain that must be differentiated from conditions such as myocardial ischaemia, biliary tract disease, pancreatitis and other abdominal emergencies.

Patients also present with the two most common complications of ulcer disease: acute gastrointestinal haemorrhage and acute perforation. The former gives symptoms of melaena with or without haematemesis, and the latter presents with sudden, severe abdominal pain.

Examination

In uncomplicated peptic ulcer disease, abdominal findings may be limited to epigastric tenderness without peritoneal signs. If perforation has occurred, patients experience severe pain and look unwell. Abdominal findings include generalized tenderness, widespread peritonism and 'board-like' rigidity. Those with gastrointestinal bleeding will usually have melaena on rectal examination.

Differential diagnosis

The differential diagnosis of upper abdominal pain is broad. Functional (idiopathic, non-ulcer) dyspepsia is the commonest (up to 60%), and the diagnosis is one of exclusion. Other important differential diagnoses include gastric, oesophageal or pancreatic cancer; pancreatitis; biliary tract disease; gastro-oesophageal reflux disease; ischaemic bowel disease; and metabolic diseases such as hypercalcaemia and hyperkalaemia.

Clinical investigations

The extent of investigations depends greatly on the patient's presentation and the degree of severity of symptoms. There are no blood tests that can reliably predict the presence of peptic ulcer disease. Pathology investigations are aimed primarily at eliminating alternative diagnoses or identifying the complications of peptic ulceration.

Full blood examination

Anaemia is most likely to represent chronic rather than acute blood loss unless bleeding is particularly heavy and hence clinically obvious. A microcytic, hypochromic anaemia suggests chronic blood loss with iron deficiency and can be confirmed with iron studies. Unexplained anaemia warrants a detailed evaluation and may raise concern for an underlying malignancy.

Blood cross-match

Patients with active bleeding may need replacement with blood products. Several units of blood may be required.

Clotting studies

These are indicated in patients taking anticoagulants and those with massive bleeding and/or a history of liver disease or alcoholism.

Liver function tests/amylase/lipase

Biliary tract disease and pancreatitis are important differential diagnoses in patients presenting with upper abdominal pain. Pancreatitis may also be the consequence of ulcer penetration through the posterior wall of the stomach.

Radiology

Radiological imaging has a very limited place in the diagnosis of uncomplicated peptic ulcer disease. However, an erect chest x-ray (CXR) is an important investigation when perforation is being considered. Gas is usually visible under the diaphragm, but its absence does not rule out perforation, with sensitivity of erect CXR for detection of pneumoperitoneum ranging from 70% to 80%. Upright lateral CXR has been shown to be more sensitive than posterior-anterior CXR in detecting pneumoperitoneum. Lateral decubitus abdominal x-rays may be needed to demonstrate free gas in patients unable to sit erect. Computed tomography (CT) scans of the abdomen are regarded as the criterion standard in detecting small pneumoperitonea.

Contrast studies are no longer considered first-line investigations in the assessment of patients with dyspeptic symptoms. Abdominal x-ray and ultrasound studies are useful to exclude alternative diagnoses, as indicated.

Criteria for diagnosis

Endoscopy

Endoscopy is the investigation of choice. It allows direct visualization of the mucosa of the oesophagus, stomach and proximal duodenum. It provides a definitive diagnosis, which forms the basis of drug therapy and allows biopsies to be taken to exclude malignant disease and to isolate *H. pylori*. Endoscopic intervention may also be therapeutic in some cases of upper gastrointestinal haemorrhage.

H. pylori status

Currently, a number of tests are available, both invasive (endoscopic) and non-invasive, although their exact role in the emergency department (ED) setting has not been defined. It should be remembered that the majority of patients infected with *H. pylori* do not in fact have peptic ulcer disease and that the identification of *H. pylori* infection often bears little relation to presenting symptoms. Non-invasive tests can only make a diagnosis of *H. pylori* infection, not of peptic ulcer disease. A negative test in a patient not taking NSAIDs makes the likelihood of peptic ulcer disease low.

The invasive tests for *H. pylori* include histology of mucosal biopsies and biopsy urease testing in patients without recent PPI, bismuth or antibiotic use. The non-invasive tests include urea breath tests and stool antigen assay. Urea breath tests are highly sensitive and specific for the presence of *H. pylori*. They are most useful in assessing *H. pylori* eradication without the need for further gastroscopy. The urea breath test should be done early, as an important limitation is its decreased sensitivity with prolonged antisecretory therapy.

Treatment

The treatment of peptic ulcer disease depends on the underlying cause and clinical presentation. Traditional management of patients with dyspeptic symptoms requires the exclusion of other diseases, the removal of known precipitants—such as NSAIDs, alcohol and cigarettes—the institution of simple treatment measures aimed at symptomatic relief and referral for further investigation and management.

Cost-effectiveness analysis and consensus statements support the treatment of *H. pylori*–positive dyspeptic patients with antimicrobial and anti-secretory therapy, followed by endoscopic study only in those with persistent symptoms, so it would also be reasonable to begin symptomatic therapy, order testing for *H. pylori* and refer for early follow-up with a primary care provider for initiation of antibacterial therapy if the test results are positive.

The choice of approach is open to debate. Early treatment prior to endoscopy may cure some patients without the need for expensive invasive procedures. However, this plan of action may hinder subsequent *H. pylori* isolation and delay definitive diagnosis, including the diagnosis of malignant disease.

It should be noted that the prevalence of *H. pylori* is lower in patients with complicated duodenal ulcers (complicated by bleeding or perforation) than in those with uncomplicated disease. Patients with *H. pylori*–negative ulcers appear to have significantly worse outcomes, especially if treated empirically for infection. Thus documenting infection is important prior to initiating antimicrobial therapy.

For patients with mild symptoms of recent onset, empirical treatment with antacids and/or histamine receptor antagonists aimed at symptomatic relief is reasonable. A review of the literature concluded that for patients with non-ulcer dyspepsia, H_2-receptor blockers were significantly more effective than placebo at reducing symptoms, whereas PPIs and bismuth salts were only marginally so. Antacids and sucralfate were not statistically superior to placebo.

Given the poor correlation between dyspeptic symptoms and gastro-oesophageal disease, gastroscopy should be considered, particularly if symptoms are not controlled or promptly recur. Early endoscopy has been advocated in patients above 45 years of age presenting with alarm symptoms, such as dysphagia, recurrent vomiting, weight loss or bleeding.

Antacids

'Antacids' containing combinations of calcium, magnesium, local anaesthetics and alginates are useful in providing symptomatic relief for patients with relatively mild symptoms. In many instances, patients have already tried these agents prior to presentation. Relief of symptoms with antacids is, however, not a diagnostic indicator.

Histamine-receptor antagonists

The H_2-receptor antagonists—such as cimetidine, ranitidine, famotidine and nizatidine—all have similar efficacies with regard to ulcer healing. All are well absorbed orally, but their absorption may be reduced when used with antacids but not with food. Eighty to 90% of duodenal ulcers will be healed in 4 to 8 weeks and 70% of gastric ulcers within 8 weeks. Relapse rates of 80% over the course of 1 year are to be expected if *H. pylori* eradication is not also undertaken in appropriate cases. H_2 antagonists are also useful in the treatment of gastro-oesophageal reflux disease and the management of dyspepsia. Because of renal excretion, dosage adjustments must be made in patients with renal dysfunction.

Proton pump inhibitors

The PPIs—omeprazole, lansoprazole, rabeprazole, pantoprazole, dexlansoprazole and esomeprazole—effectively block acid secretion by irreversibly binding to and inhibiting the H^+/K^+ ATPase pump of the gastric parietal cells, thereby inhibiting the cells' proton pump. Acidic compartments within the stimulated parietal cell are essential for activation of a PPI. Thus PPIs work poorly in fasting patients or those with simultaneous dosing with other anti-secretory agents (H_2-receptor antagonists, anticholinergic agents or somatostatin). PPIs are most effective when taken with or shortly before meals. Compared with H_2-receptor antagonists, these agents result in more rapid ulcer healing and pain relief over 2 to 4 weeks, although differences at 8 weeks are not significant. Again, relapse rates are high, particularly if *H. pylori* is present and eradication therapy is not used.

Cytoprotectants

Cytoprotective agents include colloidal bismuth subcitrate (De-Nol) and sucralfate. Both act by binding to or chelating with proteins in the base of the ulcer. Bismuth compounds also suppress *H. pylori*.[3] A 6- to 8-week course is recommended and relapse rates are high. Bismuth compounds lead to the formation of black stools, which may be confused with melaena. The primary concern with bismuth is bismuth intoxication. Sucralfate should not be taken with antacids, as it requires an acid environment to achieve its optimal effects. Sucralfate has minimal adverse effects other than possible aluminium toxicity.

Prostaglandin analogues

Misoprostol (a synthetic analogue of PGE_1) interferes with histamine-dependent gastric acid secretion as well as being cytoprotective. It is particularly useful in the prevention of NSAID-induced ulcers, although it is probably no better than the other agents in actually treating such ulcers.

Misoprostol significantly reduces the risk of endoscopic ulcers. Standard doses of H_2 blockers were effective at reducing the risk of duodenal but not gastric ulcers. Double-dose H_2 blockers and PPIs were effective at reducing the risk of both duodenal and gastric ulcers and were better tolerated than misoprostol.

H. pylori eradication

All patients with duodenal ulcers associated with *H. pylori* infection should undergo therapy to eradicate the organism, as cure of *H. pylori* infection reduces ulcer recurrence and complications, such as bleeding.[4] A number of eradication therapies have been postulated, all with very high eradication rates (>80%) and low relapse rates (<5%). The 2017 American College of Gastroenterology guidelines suggest considering previous antibiotic exposure before selecting the appropriate first-line treatment.[5] Bismuth quadruple therapy consisting of bismuth, metronidazole, tetracycline and a PPI is strongly recommended in the presence of risk factors for macrolide resistance (prior exposure to macrolides and local clarithromycin resistance rates ≥15%) or penicillin allergy. In the absence of macrolide resistance or penicillin allergy, clarithromycin, amoxicillin, metronidazole and a concomitant PPI is recommended. The duration of treatment for the aforementioned regimens is 10 to 14 days. Salvage treatment for failed first-line therapy should not include previously used antibiotics. Newer proposed regimens, such as the hybrid and sequential therapies are more complex to administer and have not generated markedly superior eradication rates, thus they are not widely adopted or recommended.

Treatment of NSAID-induced ulcers

The American College of Gastroenterology issued a guideline in 2009 for the prevention of NSAID-related ulcer complications.[6] It recommends that all patients who are to commence long-term NSAID therapy should first be tested for *H. pylori*. Those testing positive for *H. pylori* should discontinue NSAID use where clinically feasible and undergo *H. pylori* eradication therapy. Patients who are at moderate risk for peptic ulcer complications and at high risk of cardiovascular disease should avoid NSAIDs or COX-2 inhibitors entirely and receive alternative therapy.[7] Treatment of NSAID-induced ulcers should consist of a minimum 8-week course of a PPI.

Surgical management

With the success of medical treatment for peptic ulcer disease, surgical intervention has been restricted to the management of complications rather than that of the primary disease.

Complications

There are four major complications of peptic ulcer:

- haemorrhage
- perforation
- penetration
- obstruction

Haemorrhage

Peptic ulceration is a common cause of upper gastrointestinal (GI) bleeding, occurring in 10% to 20% of ulcer patients and accounting for approximately 50% of all upper GI bleeds. Urgent endoscopy is usually indicated. Surgical intervention may be required in a small proportion of

patients. A meta-analysis concluded that the use of acid-reducing agents was associated with a statistically significant decrease in re-bleeding but not in mortality. Assessment and management of haematemesis and melaena is discussed in detail in Chapter 7.6.

Perforation

Perforation occurs in approximately 5% of ulcers, with duodenal, antral and gastric body ulcers accounting for 60%, 20% and 20% of perforations, respectively. One-third to one-half of perforated ulcers are associated with NSAID use; these usually occur in elderly patients. Chemical peritonitis develops suddenly, with acute, severe generalized abdominal pain. Examination reveals a sick patient with a rigid, quiet abdomen and rebound tenderness. Delay in presentation and treatment, which may occur in the elderly and debilitated, can lead to the rapid development of bacterial peritonitis and subsequent sepsis and shock.[8] The overall mortality rate is about 5%.

Rapid diagnosis is essential, as the prognosis is excellent if the condition is treated within the first 6 hours, but it deteriorates to probable death after more than a 12-hour delay. Diagnosis should be confirmed with an erect CXR, bearing in mind its sensitivity of 70% to 80%. If free air is found, no other diagnostic studies are necessary. If there is diagnostic uncertainty, CT or ultrasound can be useful to detect small amounts of free air or fluid.

Judicious fluid resuscitation should be instituted and renal function (via urine output) closely monitored. Initial empiric antibiotic therapy to cover for enteric gram negative rods, mouth flora and anaerobes should be given, along with adequate analgesia. Intravenous PPIs should be started early. Cardiac and respiratory support may be needed in some cases.

As the standard of care, patients with perforation should undergo surgery for decontamination and repair (e.g. Graham patch) after resuscitation. Non-operative management—including intravenous fluids, nasogastric suction, antibiotics and anti-secretory drugs—may be successful in some patients in whom the leak seals quickly in response to medical management. It may also be considered in patients who have severe comorbidities precluding surgery and those with delayed presentations.

Penetration

Posterior ulcers may perforate the gastric or duodenal wall and continue to erode into adjacent structures, most commonly the pancreas, without free perforation and leakage of luminal contents into the peritoneal cavity. Patients may describe their pain as becoming more severe and constant, radiating to the back and no longer eased by antacids and food. There is also loss of cyclicity of pain with meals. The serum amylase level may be mildly raised but clinical pancreatitis is not common. Endoscopy may reveal ulceration, but 'penetration' is difficult to confirm.

Gastric outlet obstruction

This is the least frequent complication. It may arise acutely secondary to inflammation and oedema of the pylorus or duodenal bulb or, more commonly, as a consequence of scarring due to chronic disease.

Prognosis

The prognosis for peptic ulcer disease is excellent when the underlying cause is identified and treated. The mortality rate is approximately 1 death per 100,000 cases, which is a modest decrease from a few decades ago, contributed mainly by an improved mortality rate from bleeding peptic ulcers using intravenous PPIs after endoscopic therapy.

Poor prognostic factors for peptic ulcer perforation include shock at the time of admission, presence of renal impairment, delayed presentation for more than 12 hours, age over 70 years, liver cirrhosis, immunocompromised state and perforated gastric ulcer (twice the mortality of perforated duodenal ulcer).

Disposition

Patients without complications can usually be managed as outpatients.

Likely developments over the next 5 to 10 years

- Vaccination for *H. pylori* infection to benefit populations in unfavourable socioeconomic environments.
- Future research should focus on understanding of the pathophysiology and treatment of non-*H. pylori* and non-NSAID-associated peptic ulcers.
- Studies to tackle the increasing incidence of antimicrobial resistance in *H. pylori*.

CONTROVERSIES

- Elimination of *H. pylori* in all infected individuals or only in symptomatic patients.
- Conservative versus surgical management of perforated ulcer.
- Interaction between *H. pylori* infection and low-dose aspirin.

7.8 Biliary tract disease

Stacy Turner

ESSENTIALS

1 More than 95% of biliary tract disease is attributable to gallstones.

2 Most patients with gallbladder disease present with abdominal pain.

3 Investigations are directed to confirming the diagnosis and detecting the presence of complications.

4 The management of acute biliary pain (biliary colic) is supportive and discharge from the Emergency Department is often possible.

5 The management of cholecystitis and other complications of gallbladder disease is both supportive and surgical.

6 Acalculous cholecystitis occurs in the absence of gallstones.

7 Antibiotics are indicated for the treatment of cholangitis and for a subset of patients with cholecystitis.

8 Ultrasound is the imaging test of choice for most biliary tract disease.

Introduction

Biliary tract disease is common and the vast majority of disease is related to gallstones. Stones may cause acute or chronic cholecystitis, acute biliary pain (biliary colic), pancreatitis, cholangitis or obstructive jaundice. Acute biliary pain is the most common presentation, caused by a gallstone impacting within the cystic duct. The second most common presentation is acute cholecystitis, caused by distension of the gallbladder with subsequent necrosis and ischaemia of the mucosal wall. Other diseases of the biliary tree include tumours and acalculous cholecystitis, which occurs in the absence of gallstones and often complicates critical illness.

Gallbladder disease is diagnosed by a combination of clinical features, laboratory investigations and imaging.

Gallstones and acute biliary pain

Aetiology, genetics, pathogenesis and pathology

Most biliary pathology is secondary to gallstones. Eighty percent of gallstones in the Western world are composed primarily of cholesterol, but stones may also be formed from bile pigment (due to haemolysis) or may be of mixed origin. These components precipitate out to form crystals when bile is concentrated in the gallbladder. The crystals, if trapped in the gallbladder mucus, can grow, producing gallbladder sludge and then stones. Infection can play a role in the precipitation of stones, with bacteria—long dead—often found inside gallstones, as is explicit in the well-known aphorism of Lord Moynihan: 'A gallstone is a tomb stone erected to the memory of organisms that lie dead with in them'. Symptoms occur when the gallbladder contracts, often after a meal, resulting in occlusion of the cystic duct by a stone and causing visceral pain (biliary colic). On relaxation of the gallbladder, the stone falls back into the gallbladder and symptoms subside. More prolonged gallbladder outlet obstruction leads to acute cholecystitis. Gallbladder distension and increased intraluminal pressure lead to inflammation, ischaemia and subsequent necrosis of the mucosal wall. Infection is not thought to play an initial part in the development of acute cholecystitis, but secondary infection may occur in up to 50% of cases. The main difference between acute cholecystitis and biliary colic is the inflammatory component, leading to ongoing pain, fever, localized peritonism and an elevated white cell count (WCC). Secondary bacterial infection is usually caused by aerobic bowel flora (such as *Escherichia coli*, *Klebsiella* species and, less commonly, *Enterococcus faecalis*). Anaerobes are found infrequently, usually in the presence of obstruction.

Cholangitis requires the presence of two factors: biliary obstruction and infection.

Epidemiology

Around 10% to 15% of Western adults have gallstones (cholelithiasis). Stones are less common in African and Asian populations. In young adults, four times more females are affected than males, but the disparity narrows with age. The lifetime risk of gallstones is 35% in women and 20% in men. In women, the risk is increased further during and after pregnancy and with oral contraceptive use. This is likely due to endogenous sex hormones that enhance cholesterol secretion and increase bile cholesterol saturation.

Other risk factors for the development of gallstones include increasing age, diabetes, obesity, rapid weight loss, drugs (most notably exogenous oestrogens, octreotide, clofibrate and ceftriaxone), genetic predisposition, diseases of the terminal ileum and abnormal lipid profile.

Two-thirds of gallstones are asymptomatic. Gallstones may be present for decades before symptoms develop. Asymptomatic patients become symptomatic at a rate of 1% to 4% per year, but the risk decreases with time. Risk factors for stones becoming symptomatic are smoking, pregnancy and obesity. Stones may cause acute or chronic cholecystitis, acute biliary pain (biliary colic), pancreatitis or obstructive jaundice.

Biliary colic is the most common presentation (56%), followed by acute cholecystitis (36%), obstructive pancreatitis and cholangitis. Less common presentations include empyema, perforation, fistula formation, gallstone ileus, hydrops or mucocele of the gallbladder and carcinoma of the gallbladder.

Prevention

Many of the risk factors for gallstones, such as age and gender, are fixed. There is limited evidence to support preventive strategies, but maintaining a healthy weight and following a low-fat, high-fibre diet may reduce the risk. Patients on long-term statins also appear to be protected from gallstones. Ursodeoxycholic acid is useful in preventing high-risk patients (e.g. morbidly obese patients undergoing rapid weight loss following bariatric surgery) from developing gallstones. However, ursodeoxycholic acid has no effect on the reduction of symptoms once stones have formed.

Clinical features

History

The pain of biliary colic characteristically starts suddenly in the epigastrium or right upper

quadrant (RUQ) and may radiate round to the interscapular region of the back. Despite the use of the term *biliary colic*, pain is usually constant. Pain develops in the hours after a meal, most commonly starting at night, waking the patient from sleep and usually lasting from 1 to 5 hours, then subsiding spontaneously or with analgesics. Ongoing pain suggests cholecystitis. Nausea and vomiting are often present. Complaints of fevers and chills may be indicative of either cholecystitis or cholangitis. Rigors are suggestive of cholangitis.

Examination

RUQ tenderness is the most common examination finding. Patients with biliary colic have relatively normal vital signs. Significant fever is uncommon.

Jaundice is usually absent. Its presence suggests cholangitis or obstruction of the common bile duct (CBD)—choledocholithiasis. The presence of pain, jaundice and high fever with rigors (the Charcot triad) is indicative of cholangitis.

Differential diagnosis

The differential diagnosis of RUQ pain includes the following:

- Peptic ulcer disease, including perforation
- Acute pancreatitis
- Coronary ischaemia, especially involving the inferior myocardial surface
- Appendicitis, especially retrocaecal or in pregnancy
- Renal disease, including renal colic and pyelonephritis
- Colonic pathology, such as irritable bowel syndrome
- Hepatic pathology, especially hepatitis
- Right lower lobe pneumonia

Clinical investigations

Investigations in biliary pain are aimed at confirming the diagnosis, establishing the presence of gallstones and detecting complications.

Imaging

Ultrasound is the investigation of choice and can be used to confirm the presence of gallstones, measure the thickness of the gallbladder wall and the diameter of the CBD and detect the presence of any local fluid collection. On ultrasonography, gallstones appear as echogenic foci that cast an acoustic shadow; they are usually mobile and gravitationally dependent. Ultrasound has high sensitivity and specificity (84% and 99%, respectively) for the detection of gallstones, is non-invasive and requires little preparation of the patient. However, ultrasound is not as good at visualizing stones in the CBD, identifying about half. Also, it is operator dependent, but bedside ultrasound examination has satisfactory diagnostic capability.

Abdominal x-ray. In the majority of cases, plain radiographs are not helpful in the diagnosis of gallbladder disease. On occasion they may be useful to rule out other potential diagnoses, but only 10% of biliary calculi are visible on plain radiographs.

Computed tomography (CT) should not be used as a first-line test. It is not sensitive for detecting gallstones, but is useful in diagnosing acute cholecystitis and in patients with complicated disease. CT may better demonstrate dilatation of the bile duct and pneumobilia, gangrene and perforation. In non-specific abdominal pain, it can detect acute cholecystitis and identify extrabiliary disorders.

Magnetic resonance imaging (MRI) with magnetic resonance cholangiopancreatography (MRCP) is usually reserved for cases in which choledocholithiasis is suspected but has not been detected on ultrasound.

Blood tests

In acute biliary pain, blood tests are non-specific. Bilirubin and alkaline phosphatase levels should be normal. In acute cholecystitis, mild derangement may be seen in around 25% of cases. Amylase/lipase assays are useful to evaluate the presence of pancreatitis. Amylase may also be mildly elevated in cholecystitis. Full blood examination shows a leucocytosis and left shift in the majority of cases of cholecystitis and cholangitis; however, up to 40% of patients do not have a leucocytosis at the time of presentation.

Complications

Complications of gallstone disease include the following:

- Cholecystitis
- Obstructive jaundice
- Cholangitis and gram negative septicaemia
- Gallstone ileus
- Perforation (the elderly and diabetics are at particular risk of rapid necrosis and perforation)
- Pancreatitis

Treatment

General measures

The management of biliary colic focuses on pain control, which can be achieved with oral analgesics, titrated intravenous opioids or parenteral non-steroidal anti-inflammatory drugs (NSAIDs). The choice will, in part, be guided by pain severity. NSAIDs may provide equivalent analgesia to opioids with fewer side effects. There is also some evidence that NSAIDs may help reduce the progression of acute biliary pain to cholecystitis owing to the inhibition of prostaglandin release from the gallbladder wall. Patients with prolonged attacks should also receive intravenous fluids, especially if there is associated vomiting. Keeping the patient starved may prevent the release of cholecystokinin, thus reducing gallbladder contraction.

Antibiotics

Antibiotics are indicated for the treatment of cholangitis, but it is not clear whether they are required routinely for the treatment of uncomplicated cholecystitis, as complication rates may not be affected. That said, if there are clinical, laboratory of radiological findings suggesting infection, antibiotics should be given. Choice of antibiotic should be guided by local policy.

Definitive care

Cholecystectomy is the definitive treatment of choice for symptomatic stones. It provides symptomatic relief in up to 99% of patients. Minimally invasive surgery (either laparoscopic or using a small-incision technique) is preferred to the classical open operation technique as recovery is more rapid. Laparoscopic technique and the small-incision operation are equivalent. Early cholecystectomy (immediate or within 7 days) is the preferred approach for biliary colic or acute cholecystitis requiring hospital admission. Early cholecystectomy for biliary colic appears to decrease morbidity during the waiting period, conversion rate to open removal of the gallbladder and operating time and hospital stay.

Dissolution methods and lithotripsy are of limited utility due to restricted indications for their use and gallstone recurrence in approximately 50% of cases at 5 years.

Prophylactic cholecystectomy is not recommended in asymptomatic patients as the risks of the procedure outweigh the potential benefits.

Bile duct clearance as well as cholecystectomy is indicated for the treatment of biliary obstruction. Bile duct clearance can be achieved surgically at the time of cholecystectomy or with endoscopic retrograde cholangiopancreatography (ERCP) before or at the time of cholecystectomy.

Disposition

In the absence of cholecystitis or other complications, many patients with biliary colic can be discharged for outpatient surgical follow-up if pain settles and if an early operative route is not being pursued. Most patients with complications, such as acute cholecystitis, cholangitis or pancreatitis, require hospital admission. Admission may also be indicated in some cases because of recurrent severe pain.

Acute cholecystitis

Epidemiology

Distribution parallels that of cholelithiasis. Acute cholecystitis develops in 1% to 3% of patients with symptomatic stones.

Clinical features

RUQ pain and fever are the most common features. Usually patients have experienced previous episodes of biliary pain. Nausea and vomiting are often present. Local peritonism and the Murphy sign (pain on inspiration during palpation of the right subcostal region) may be present but are not specific. A distended, tender gallbladder is not usually evident: the RUQ mass palpated in approximately 20% of patients represents omentum overlying the inflamed gallbladder. Approximately 20% of patients are jaundiced. The presence of hyperbilirubinaemia suggests CBD obstruction. Neutrophilia may be present.

Clinical investigations

Blood tests

No single test or combination of tests is sufficiently sensitive or specific to rule in or rule out the diagnosis. A leucocytosis is usually present. Elevated bilirubin and alkaline phosphatase concentrations are not common in uncomplicated cholecystitis, since biliary obstruction is limited to the gallbladder. If present, they should raise concerns about complications, such as cholangitis, choledocholithiasis or the Mirizzi syndrome (a gallstone impacted in the distal cystic duct or Hartmann pouch causing extrinsic compression of the CBD).

Ultrasound

Findings on ultrasound are often diagnostic, showing cholelithiasis with concomitant gallbladder wall thickening (5 mm or greater), pericholecystic fluid or a positive ultrasonographic tenderness over the gallbladder.

Complications

Complications include bacterial superinfection leading to cholangitis or sepsis, gallbladder perforation leading to local abscess formation or diffuse peritonitis, biliary enteric (cholecystenteric) fistula, with a risk of gallstone-induced intestinal obstruction (gallstone ileus) and deterioration in pre-existing medical illness.

Treatment

General measures and antibiotics

Treatment requires hospital admission and includes supportive care (in particular analgesia), antibiotics and cholecystectomy. It is recommended that antibiotics be given if infection is suspected on the basis of laboratory and clinical findings (WCC >12,500 × 10^9/L or a temperature of more than 38.5°C) and imaging findings (e.g. air in the gallbladder or gallbladder wall). Antibiotic choice should be guided by local policy and should include coverage against aerobic bowel flora such as *E. coli* and *Klebsiella* spp. (e.g. amoxicillin 1g IV q 6 h plus gentamicin 4–6 mg/kg IV qd). Antibiotics are also recommended for routine use in patients who are elderly or have diabetes or immunodeficiency. Most patients will respond to conservative management, with the gallstone dis-impacting and falling back into the gallbladder, thereby allowing the cystic duct to drain. If the gallstone does not disimpact, gangrenous cholecystitis (2%–30% of cases), empyema of the gallbladder or gallbladder perforation (10% of cases) may occur.

Surgery

Minimally invasive cholecystectomy is recommended within 7 days for acute cholecystitis to prevent recurrence or other complications. Early surgery appears safe and shortens the total hospital stay. In severe cholecystitis, urgent cholecystectomy or cholecystostomy (percutaneous drainage of the gallbladder) with deferred cholecystectomy is required. Cholecystostomy may also be used in patients who are not candidates for surgery.

Acute acalculous cholecystitis

Acute inflammation of the gallbladder in the absence of gallstones generally occurs in the severely ill patient and accounts for 5% to 10% of cases of acute cholecystitis. It is associated with greater morbidity and mortality than gallstone cholecystitis and is most commonly observed in the setting of critically ill patients often recovering from trauma, burns or major surgery. Acalculous cholecystitis may also occur in elderly patients with coexisting vascular disease, in patients with diabetes, human immunodeficiency virus infection/acquired immunodeficiency syndrome (HIV/AIDS) or patients on long-term total parenteral nutrition (TPN).

Pathophysiology is thought to be due to increased bile viscosity and stasis because of critical illness, fever, dehydration and lack of enteral feeding.

Diagnosis can be difficult, as patients usually have other life-threatening illnesses and may be sedated and ventilated in an intensive care setting. The usual finding on imaging studies is a distended acalculous gallbladder with thickened walls and with or without pericholecystic fluid.

Management consists of urgent cholecystectomy or cholecystostomy with treatment of the underlying illness. Compared with acute calculous cholecystitis, there is a much higher incidence of empyema, gangrene and perforation of the gallbladder and consequently a higher mortality rate (up to 50%).

Choledocholithiasis

Pathology and clinical features

Gallstones within the biliary tree almost all originate in the gallbladder, but primary choledocholithiasis (formation of stones within the CBD) can occur. Between 10% and 18% of patients have stones in the CBD at the time of cholecystectomy, and the incidence of choledocholithiasis increases with age. Stones may be asymptomatic or cause pain as well as liver test abnormalities with or without evidence of complications. The common complications are acute cholangitis and acute pancreatitis.

Imaging

Transabdominal ultrasound is less reliable in choledocholithiasis than in gallbladder stones, but it is still the preferred initial imaging modality. As well as gallbladder stones, ultrasound can evaluate for CBD stones and CBD dilatation. CBD dilatation is suggestive of CBD stones but not specific. Sensitivity for CBD stones varies and is poor for stones in the distal duct. ERCP is more accurate and is also therapeutic, but it is invasive and associated with complications, such as pancreatitis. Therefore transabdominal ultrasound is reserved for patients with confirmed CBD stones.

MRCP, endoscopic ultrasound, and intraoperative cholangiography during cholecystectomy are considered the tests of choice for the evaluation of possible CBD stones, as suggested by CBD dilatation on ultrasound or deranged liver function tests with an obstructive pattern.

Treatment

CBD stones pose a high risk for complications and nearly always warrant treatment. Various options are available, including pre- or post-operative ERCP, open surgery or laparoscopic bile duct exploration. Which is best is not yet clear.

Cholangitis

Pathology

Cholangitis is defined as an infection of the biliary tree. It most commonly occurs due to biliary obstruction because of choledocholithiasis or a benign or malignant stricture. Infection can also flow in a retrograde direction up the CBD as a result of instrumentation, such as ERCP.

Bacteria are usually gram negatives, such as *E. coli*, *Klebsiella*, *Bacteroides* and *Enterobacter* spp., enterococci or group D streptococci. There is also a subset of Asian patients who develop cholangitis mainly secondary to parasitic infection (recurrent pyogenic cholecystitis).

Clinical features and investigations

Fifty to 70% of patients present with the classic Charcot triad of jaundice, fever and RUQ pain. Patients may also have features of severe sepsis or septic shock. WCC is raised in the majority of cases. Liver function tests are typically elevated in a cholestatic pattern. One-third of patients have a raised amylase. Blood cultures are positive in 20% to 30% of cases. If bile fluid is available (e.g. if biliary drainage through intervention has occurred), it should also be cultured. Transabdominal ultrasonography is the recommended primary imaging study. Ultrasonography should be followed by ERCP, CT of the biliary tree or MRCP.

Treatment

Resuscitation may be required for patients with severe sepsis or shock. Parenteral antibiotics should be administered once blood cultures have been taken. Antibiotic choice should be guided by local policy but should be effective against anaerobes and gram negative organisms (e.g. amoxicillin 1g IV q 6 h plus gentamicin 4 to 6 mg/kg IV qd). Around 20% of patients fail to respond to antibiotics or have a rapidly deteriorating clinical picture. These patients require urgent biliary decompression, which is achieved through ERCP, either percutaneously or via open surgical decompression.

CONTROVERSIES

- Timing of cholecystectomy.
- Appropriate use of antibiotics in acute cholecystitis.
- The optimal management of choledocholithiasis.

7.9 Acute pancreatitis

Kenneth Heng

Introduction

The twin challenges of acute pancreatitis are to establish the diagnosis and stratify severity. The difficulty in diagnosing pancreatitis lies in its non-specific symptomatology, which is shared by a number of other gastrointestinal diseases. The 2012 revised Atlanta classification[1] definition of acute pancreatitis requires two of the following three features: (1) abdominal pain consistent with acute pancreatitis; (2) serum lipase or amylase activity equal to or greater than three times the upper limit of normal; and (3) characteristic features of acute pancreatitis on radiological (computed tomography or magnetic resonance) imaging. Patient outcomes depend in part on the prompt recognition of severe pancreatitis. Patients with severe pancreatitis require aggressive treatment to reverse organ failure as well as admission to intensive care or a high-dependency area for ongoing management. The hunt for the aetiology is the next priority, but this may be deferred to the inpatient team.

Aetiology and pathogenesis

The pathogenesis of acute pancreatitis relates to inappropriate activation of trypsinogen to trypsin, which, in turn, releases digestive enzymes causing pancreatic injury. Mild pancreatitis occurs 80% of the time, causes interstitial oedema and transient organ failure before spontaneous resolution.[2] In 20% of cases, pancreatic necrosis and persistent organ failure occur. This necrotic tissue remains sterile in 70% of cases and eventually gets walled off, whereas secondary infection due to the translocation of gut bacteria affects the remaining 30%. A cytokine cascade ensues, resulting in systemic inflammatory response syndrome, multi-organ dysfunction syndrome (MODS) and, in some cases, death.

The commonest risk factor for recurrent pancreatitis in males is prolonged alcohol use (4–5 drinks daily for more than 5 years) through direct toxicity and immunological mechanisms. Binge drinking without long-term heavy alcohol use does not appear to precipitate acute pancreatitis.[2] In females, gallstone disease is the most common underlying cause. The other aetiological factors are listed in Box 7.9.1.

Box 7.9.1 Aetiology of acute pancreatitis

Common
- Gallstone (including microlithiasis)
- Alcohol
- Idiopathic
- Associated conditions: type 2 diabetes, morbid obesity, smoking

Uncommon
- Hypertriglyceridaemia
- Hypercalcaemia (hyperparathyroidism, metastatic bone disease, sarcoidosis)
- Drugs (azathioprine, valproate, pentamidine, didanosine, co-trimoxazole)
- Post-ERCP
- Postoperative

Rare
- Trauma
- Toxins
- Vasculitis
- Infective (Coxsackie virus, mumps, HIV, parasitic, ascariasis)
- Autoimmune (systemic lupus erythematosus, Sjögren syndrome)
- Gene mutations and polymorphisms (e.g. cationic trypsinogen [PRSS1]; cystic fibrosis transmembrane conductance regulator [CFTR])

Epidemiology

The incidence of pancreatitis is rising, reflecting an increase in alcohol consumption and gallstone disease. Approximately 80% of patients with pancreatitis have mild, self-limiting disease. The overall in-hospital mortality is 2%. Risk factors for death are older age, obesity, secondary infection and persistent multi-organ failure.

Clinical features

Gallstone pancreatitis typically presents with a sudden onset of severe, constant epigastric pain radiating to the back. In contrast, pain in pancreatitis from other causes (e.g. alcohol) has a more insidious onset and may be poorly localized. Pain is often accompanied by nausea and vomiting.

Upper abdominal tenderness is usually present, but guarding and rebound tenderness are rare. Abdominal signs are often surprisingly few, given the severity of the abdominal pain. Abdominal wall ecchymosis around the umbilicus (Cullen sign), flanks (Grey Turner sign) and inguinal ligament (Fox sign) are uncommon findings. They are due to retroperitoneal bleeding from pancreatic necrosis and do not occur till 36 to 72 hours after the onset of pain. Severe pancreatitis is characterized by tachycardia, hypotension, abdominal distension and shallow respiration from diaphragmatic irritation and associated pleural effusion.

Differential diagnosis

The most important differential diagnoses to exclude are perforated viscus, ischaemic colitis, leaking abdominal aortic aneurysm and myocardial ischaemia.

Clinical investigations

Biochemical tests

Amylase rises in 2 to 12 hours and normalizes in about a week. In 10% of cases of pancreatitis, amylase is falsely negative due to depleted acinar cell mass. False positives may occur with salivary gland disease, macroamylasaemia, some cancers and decreased renal clearance of amylase in chronic renal impairment.

Lipase rises in 4 to 8 hours and normalizes in 1 to 2 weeks. It has superior sensitivity and specificity compared with amylase, as it is produced only in the pancreas. Amylase or lipase levels more than three times the upper limit of normal are among the diagnostic criteria of acute pancreatitis. Lesser elevations must be interpreted against the timing of the test from symptom onset. The peak amylase and/or lipase level does not correlate with severity of disease. Alanine aminotransferase (ALT) equal to or greater than 150 IU/L is 96% specific and 48% sensitive for gallstone pancreatitis.

Serial assays of haematocrit, urea, and creatinine track progress,[3] whereas other tests that aid severity scoring include C-reactive protein, lactate dehydrogenase, alanine aminotransferase, blood gas analysis, calcium and procalcitonin.

Imaging studies

When clinical signs and biochemical tests are equivocal, a contrast-enhanced computed tomography (CT) scan of the abdomen is the radiological investigation of choice, as it can establish the diagnosis, exclude most of the differential diagnoses listed earlier, stage the disease[4] and detect complications.

The use of ultrasound is not as helpful, because the pancreas is poorly seen in 25% to 50% of patients. It may, however, show gallstones and/or a dilated common bile duct, giving a clue to its aetiology. Magnetic resonance cholangiopancreatography (MRCP) has a strong correlation with contrast-enhanced CT, with the advantage of a lower risk of nephrotoxicity and greater ability to characterize fluid collections, necrosis, abscess, haemorrhage and pseudocyst formation.

Plain radiography of the chest and abdomen has limited utility in diagnosing pancreatitis, but it may show pleural effusions or features of acute respiratory distress syndrome (ARDS), gallstones, sentinel bowel loops, calcified pancreas or peripancreatic retroperitoneal gas signifying infection of the pancreas.

Severe pancreatitis scoring systems

Severe acute pancreatitis is defined as persistent single or multiple organ failure lasting more than 48 hours. Various scoring systems using clinical, laboratory and radiological parameters to try to predict severe pancreatitis have been developed and are described in Table 7.9.1.

Table 7.9.1 Comparison of severity scoring systems for acute pancreatitis

Scoring systems	*Details*	*AUC* for SAP**/ Mortality*[5]	*Comments*
Ranson[6]	Measure at admission (age, WCC, glucose, AST, LDH) and at 48 h (calcium, haematocrit, PaO_2, urea, base deficit, fluid sequestration). Score ≥3 indicates severe pancreatitis (AUC = 0.83).	0.85/0.84	Well established. Cannot score risk early as it is completed only at 48 hours.
Modified Glasgow	Measure PaO_2, age, neutrophilia, calcium, urea, LDH, albumin, glucose over 48 h. Score ≥3 indicates severe pancreatitis.	0.75/0.83	Simpler than Ranson but cannot score risk early as it is completed only at 48 hours.
Systemic inflammatory response syndrome (SIRS)	Measures temperature, heart and respiratory rates, WCC at any time.	0.73/0.76	Easy to use. High sensitivity but low specificity.
Acute Physiology and Chronic Health Examination (APACHE II)	Measures age and 12 physiological parameters in first 24 h. Score ≥8 indicates severe pancreatitis (AUC=0.82).	0.88/0.86	Allows scoring at presentation. Complicated but online calculators exist.
Bedside Index of Severity in Acute Pancreatitis (BISAP)	Measure urea, impaired mental status, SIRS, age, pleural effusion in the first 24 h. Score ≥3 indicates severe pancreatitis (AUC=0.87).	0.80/0.83	Simple to use. Allows scoring at presentation.
Pancreatitis outcome Prediction (POP) score[7]	Measure pH, age, urea, mean arterial pressure, PaO_2/FiO_2, calcium in first 24 h. Score of 10 predicts 10% probability of death.	-/0.83	Simple to use. Allows scoring at presentation.
Harmless Acute Pancreatitis Score (HAPS)[8]	Measure signs of peritonism, haematocrit, creatinine at presentation. Score of 0 indicates non-severe pancreatitis.		Very easy to use at presentation to identify low-risk pancreatitis. Specificity for non-severe pancreatitis 96.3%; positive predictive value of 98.7%.
Balthazar[4]	Computed tomography severity index (CTSI) measures fluid collection, inflammation and degree of necrosis. Score >6 indicates severe pancreatitis.	0.66/0.57	Radiological scoring system. Identification of pancreatic necrosis does not necessarily predict organ failure or mortality.

*AUC = area under receiver operating characteristic curve

**SAP = severe acute pancreatitis

Treatment

The treatment for acute pancreatitis is supportive, with emphasis in the emergency department on fluid replacement, prevention of hypoxia and analgesia.

- Supplemental oxygen. Hypoxia may indicate ARDS or significant pleural effusions. Mechanical ventilation may be required in patients with respiratory distress.
- Fluid resuscitation. Significant third-space losses may occur. Vigorous fluid replacement with balanced crystalloids[2] should be administered in the first 24 hours, titrated to blood pressure and normalization of urine output, urea and haematocrit. Central venous monitoring should be considered in severe cases.
- Analgesia. An intravenous opioid (e.g. morphine or fentanyl) is the agent of choice and dose should be titrated against response. Patient-controlled analgesia may be appropriate. There are no human studies to support the belief that morphine causes spasm of the sphincter of Oddi.

Other important aspects of treatment include the following:

- Antibiotics. Prophylactic antibiotics are not indicated in pancreatitis. Antibiotics (e.g. carbapenems) should be given only for documented infection (fever, leucocytosis, increasing abdominal pain or CT evidence of pancreatic emphysema, indicating infected necrotic tissue).
- Nutritional support. In mild pancreatitis, complete resolution of pain is not necessary before starting a low-fat, low-calorie diet, as early feeding is associated with shorter hospitalization. In severe pancreatitis, current evidence supports early nasoenteral tube feeding over total parenteral nutrition (TPN), as it is more physiological, prevents gut mucosal atrophy and eliminates the risk of TPN-associated line sepsis. Nasogastric feeding has been found to be as effective as using the nasojejunal route.
- Surgery. Debridement of infected necrotic pancreatic tissue should be delayed for 4 weeks to allow it to wall off properly. However, unstable patients may require early drainage with radiological guidance or minimally invasive laparoscopy. Sterile pseudocysts do not require treatment unless they obstruct an adjacent viscus.
- Treatment of the cause. In mild gallstone pancreatitis, cholecystectomy and bile duct clearance should occur during the initial hospitalization to prevent a potentially severe and fatal recurrence. In severe gallstone pancreatitis, especially where there is suspicion of cholangitis, current evidence supports endoscopic retrograde cholangiopancreatography with sphincterotomy within the first 24 hours.
- Octreotide, aprotinin and glucagon have not been shown to improve outcome.

Disposition

Patients with pancreatitis require admission for treatment and observation of disease progression. Mild pancreatitis can be managed in the general ward, but severe pancreatitis should be managed in an intensive care or high-dependency unit.

Prognosis

The majority of patients with acute pancreatitis experience a mild, self-limiting course with recovery in 5 to 7 days. Twenty percent of patients develop severe pancreatitis, which has a mortality of 20%. Death is biphasic, with 50% occurring in the first week from MODS and 50% after 2 weeks from infective complications. If organ failure is reversed within 48 hours, the prognosis is good.

Complications

Local complications include pancreatic pseudocyst, abscess, splenic vein thrombosis, duodenal obstruction and progression to chronic pancreatitis. Systemic complications include hypocalcaemia, pleural effusion, ARDS and MODS.

Likely developments over the next 5 to 10 years

New early markers of severe pancreatitis are being developed, such as adipokines and urinary trypsinogen-activating peptide, the level of which correlates with severity. Other markers being investigated include interleukins 6 and 8, polymorphonuclear elastase and phospholipase A2. Mutations in genes for serine protease 1, pancreatic secretary trypsin inhibitor and cystic fibrosis transmembrane conductance regulator have been identified in patients with recurrent idiopathic pancreatitis. Therapeutic implications are yet to be established.

Chronic pancreatitis

Introduction

Patients with chronic pancreatitis usually present with recurrent abdominal pain radiating to the back. This may be associated with weight loss because of fear of eating due to postprandial exacerbations of pain. There may be symptoms of pancreatic exocrine insufficiency (steatorrhoea) or endocrine insufficiency (diabetes mellitus). Physical examination may reveal a mass in the epigastrium, suggesting a pseudocyst, and the patient may assume a characteristic pain-relieving posture of lying on the side with the knees drawn up to the chest.

Aetiology and pathogenesis

The aetiology of chronic pancreatitis is usually metabolic in nature, with excessive alcohol consumption accounting for 60% to 90% of cases. The primary process is chronic irreversible inflammation, fibrosis and calcification of the pancreas, affecting both its exocrine and endocrine functions.

Clinical investigations

In chronic pancreatitis, serum amylase and lipase levels are not as elevated as in acute pancreatitis. Occasionally enzyme levels may be normal due to atrophy of the gland. Endoscopic retrograde cholangiopancreatography (ERCP) is the gold standard for the diagnosis of chronic pancreatitis. Contrast-enhanced CT and MRCP are non-invasive and provide additional information about the pancreatic parenchyma.

Treatment

The key issues in the management of chronic pancreatitis are as follows:

- Continued alcohol intake is associated with an increased risk of painful relapses and hastening of pancreatic dysfunction. Alcohol cessation may require a team approach incorporating counsellors and psychiatrists for cognitive therapy and behavioural modification.
- The provision of adequate analgesia in chronic pancreatitis is a challenge, with many patients going on to develop chronic pain syndrome. Opioid dependency is a risk. Analgesia should not be withheld during acute episodes. Early referral to a pain management specialist may attenuate/manage opioid dependence. CT-guided coeliac

ganglion blockade provides only temporary relief.
- Malabsorption is treated by a low-fat diet and restoration of pancreatic exocrine function with supplementation of pancreatic enzymes, fat-soluble vitamins and vitamin B12. Diabetes mellitus results from endocrine dysfunction and often requires insulin therapy.
- Relief of mechanical obstruction is achieved by endoscopy or surgical resection or drainage.

CONTROVERSIES

- Many severity scoring systems are available. Although none is perfect, they are superior to clinical judgement in identifying severe pancreatitis.
- The role of adipokines in identification of severe acute pancreatitis.
- The role of haemofiltration in the management of severe acute pancreatitis.
- The role of sphincter of Oddi dysfunction and pancreas divisum in causing acute pancreatitis

7.10 Acute appendicitis

Ashis Banerjee

ESSENTIALS

1 Appendicitis is the commonest cause of acute abdominal pain requiring surgical treatment.

2 The diagnosis is primarily clinical, but the absence of a pathognomonic sign or conclusive first-line diagnostic test can cause diagnostic difficulty.

3 Diagnostic delay is the primary cause of morbidity and mortality and a major source of litigation related to medical negligence in emergency departments.

4 Specialized imaging techniques enhance diagnostic accuracy and reduce the negative laparotomy rate. Computed tomography should be used selectively to reduce exposure to ionizing radiation.

5 Surgical referral is indicated once the diagnosis is confirmed or strongly suspected, but there is an increasingly well-defined role for non-operative management in uncomplicated cases

Introduction

Appendicitis is the commonest cause of acute abdominal pain requiring surgical intervention and is the commonest non-obstetrical surgical emergency complicating pregnancy. A steady decline in incidence in industrialized countries since the late 1940s as measured by appendicectomy rates is accompanied by a rising incidence in newly industrialized countries. The peak incidence is in the second and third decades of life. There is a male preponderance (male:female ratio of 1.4:1), with an overall incidence of around 1.9 per 1000 persons per year and an overall lifetime risk of developing appendicitis of 7%. Diagnostic delay is commoner in infants and young children, women of reproductive age and the elderly. Early diagnosis is essential to avoid the risk of appendiceal perforation leading to intra-abdominal sepsis, abscess formation and/or generalized peritonitis (complicated appendicitis).

Aetiology, pathogenesis and pathology

Bacterial or viral infection of the colon usually precedes mucosal ulceration of the appendix and subsequent secondary bacterial invasion by normal colonic flora. In a minority of cases, luminal obstruction is caused by faecoliths, lymphoid follicle hyperplasia, parasites, strictures, adhesions, foreign bodies, tumour (carcinoid or caecal carcinoma) or Crohn disease. This is followed by increased intraluminal pressure and luminal distension, lymphatic and venous outflow obstruction, arterial inflow occlusion and bacterial overgrowth. Inflammation of the serosa leads to involvement of the parietal peritoneum. Appendiceal perforation may ensue secondary to a high intraluminal pressure.

Clinical features

Appendicitis is a clinical diagnosis, but the clinical presentation may be atypical or equivocal, requiring a period of active observation or recourse to cross-sectional imaging to confirm the suspicion. When any patient with acute abdominal pain is being evaluated in the emergency department (ED), one of the focused questions that must be asked is whether the presentation could be due to appendicitis.

History

The classic presentation of acute appendicitis is with upper midline or periumbilical pain (70%), which represents visceral midgut pain due to appendiceal distension, the afferent fibres being at T10 level. This progresses over a period of 12 to 24 hours to right lower quadrant pain (50%), which represents somatic pain caused by localized irritation of the parietal peritoneum. The migratory pattern of the pain is the most characteristic symptom of appendicitis.

Pain is associated with nausea, anorexia (often a prominent feature) and vomiting. Low-grade fever—typically 37.5°C to 38.0°C—may be present. Once pain localizes in the right lower quadrant, it becomes persistent; it is aggravated by movement, deep inspiration and coughing and tends to progress in severity. Pelvic appendicitis may present with irritative urinary symptoms (frequency of urination and dysuria) or with diarrhoea.

The typical presentation is associated with a retrocaecal or retrocolic position of the appendix. The intraperitoneal position of the appendix depends on the length of the viscus, relationship to the caecum and location of the ascending colon and caecum. Localization of pain may occur in atypical locations, such as the right upper quadrant or right flank with a high retrocaecal appendix (the most common atypical location) or the left lower quadrant with a pelvic appendix or in the presence of situs inversus. Right upper quadrant pain may also result if acute appendicitis complicates pregnancy (on average 1 per 1000 pregnancies).

Examination

Examination findings vary according to the stage of evolution. Vital signs may be normal, but a mild tachycardia is usual along with low-grade fever. There may be some facial flushing, fetor oris and a dry coated tongue.

Typically there is localized tenderness in the right lower quadrant, classically maximal at the McBurney point (two-thirds of the way from the umbilicus to the anterior superior iliac spine). This is accompanied by a reduction in respiratory movement and by involuntary muscle rigidity (guarding). Rigidity may be difficult to elicit in the obese, the elderly, children and in the presence of atypical locations. Active elicitation of rebound tenderness is unpleasant, the same information being provided by aggravation of pain with deep inspiration or forced expiration (drawing in or blowing out the abdominal wall), with coughing, or by percussion of the anterior abdominal wall. Right lower quadrant pain may be provoked by pressure on the left lower quadrant (Rovsing sign) and there may be accompanying hyperaesthesia of the overlying skin (Sherren sign).

Unfortunately the classic constellation of symptoms and signs is seen in only 50% to 70% of patients with acute appendicitis. Ancillary clinical signs may be of value in arriving at a diagnosis in patients with atypical symptoms, usually related to atypical locations of the tip of the appendix.

Psoas muscle irritation, caused by a retrocaecal appendix, may be associated with a flexion deformity of the right hip. A positive psoas sign refers to pain with, and resistance to, passive extension of the right hip with the patient in the left lateral position. This has high specificity but low sensitivity. Irritation of the obturator internus muscle, caused by a pelvic appendix, may be associated with a positive obturator sign (pain on passive internal rotation of the flexed right hip). An abdominal mass may be palpable in 10% to 15% of cases. This represents inflamed omentum and adherent bowel loops in the presence of appendiceal perforation. An appendicectomy scar does not totally exclude the possibility of appendicitis, as recurrent appendicitis in the stump has been reported after both open and laparoscopic appendicectomy.

In most cases rectal examination in patients with suspected appendicitis is of little value and does not alter management. It may be helpful when the diagnosis is in doubt, particularly in the elderly, when tenderness may be elicited in the right lateral wall of the rectum. Rectal examination may also help to diagnose a pelvic abscess in the presence of a ruptured pelvic appendix.

Perforation of the appendix should be suspected in the presence of symptoms of over 24 hours' duration, a temperature higher than 38°C and possibly a white cell count higher than 15,000/mm^3.

Differential diagnosis

Appendicitis can mimic most acute abdominal conditions and should be considered in any patient with acute symptoms referable to the abdomen. There is a wide range of conditions that may resemble appendicitis (Box 7.10.1). On occasion the diagnosis of appendicitis may be confirmed at only surgery or laparoscopy; however, there is a 10% to 20% negative laparotomy rate associated with a preoperative diagnosis of appendicitis. Diagnostic delay can be associated with perforation, progression to abscess formation or generalized peritonitis. These complications can contribute to wound infection, septicaemia and death.

Box 7.10.1 Differential diagnosis of acute appendicitis

- Non-specific abdominal pain
- Female genital tract: pelvic inflammatory disease, ruptured tubal gestation, ovarian cyst accident, ovarian follicle rupture
- Small intestine: Meckel diverticulitis, Crohn disease, ileitis
- Colon: caecal carcinoma, caecal diverticulitis, ileocaecal tuberculosis, *Campylobacter* colitis, epiploic appendagitis
- Renal tract: acute pyelonephritis, ureteric colic
- Lymph nodes: mesenteric lymphadenitis
- Referred testicular pain

Clinical investigations

Urinalysis

A urine dipstick examination should be performed in all patients to exclude urinary tract infection, but pyuria and microscopic haematuria can coexist with appendicitis. Qualitative β-hCG testing should be performed in all women of childbearing age in order to exclude pregnancy and the possibility of ectopic gestation.

Blood tests

The white cell count lacks sufficient sensitivity and specificity for the diagnosis of appendicitis, and undue reliance on this in isolation may lead to delayed treatment. A raised white cell count can also be seen with other causes of an acute surgical abdomen. The white cell response may be blunted or absent in infants and young children with appendicitis as well as in the elderly. Furthermore, leucocytosis can be physiological in pregnancy.

C-reactive protein (CRP) measurements that are within normal limits do not exclude the diagnosis of appendicitis. However, a raised white cell count and CRP in combination add weight to a highly likely diagnosis of appendicitis, and some studies suggest that appendicitis is unlikely if both investigations are normal. CRP level correlates with severity of appendicitis as determined by computed tomography (CT) and could be a useful predictor for appendiceal perforation.

Imaging

Plain abdominal radiography rarely provides helpful information in the workup of clinical appendicitis and is not indicated, having a low sensitivity and specificity as well as being frequently misleading. If an x-ray has been

inadvertently obtained, the presence of a faecolith in the right lower quadrant may favour a diagnosis of appendicitis.

The normal appendix is visualized in less than 50% of cases at ultrasound scanning using a 5 or 7.5 MHz transducer with a graded compression technique to displace mobile small bowel loops. If the appendix is seen, it appears in longitudinal section as an aperistaltic, blind-ended, hypoechoic tubular structure in continuity with the caecum. In transverse section, the appendix appears as a circular target, comprising an anechoic lumen surrounded by hyperechoic mucosa, a hypoechoic muscular layer and echogenic serosa. Its diameter is less than 6 mm when compressed with the examining probe. Visualization of a normal appendix excludes appendicitis. Ultrasound signs of acute appendicitis include a non-compressible appendix more than 6 mm in diameter (measured outer wall to outer wall), wall thickness greater than 2 mm and visualization of an appendicolith, which appears as an echogenic focus with distal acoustic shadowing. Increased vascularity of the appendiceal wall can be visualized on colour Doppler imaging as a 'ring of fire'. With perforation, a loculated peri-caecal fluid collection, a discontinuous wall of the appendix and prominent peri-caecal fat are seen. Ultrasound can also potentially identify other pathologies, especially in female patients. Ultrasound is being recommended as the preferred first option for imaging in children and as preliminary to CT scanning in adults.

CT is useful in equivocal cases, especially in the elderly. CT signs of appendicitis include distension greater than 6 mm, circumferential thickening of the wall greater than 2 mm, periappendiceal inflammation (hazy, streaky linear densities), oedema and mass and visualization of an appendicolith. Contrast enhancement can be achieved by the intravenous, oral or rectal route. Improved diagnostic accuracy with intravenous contrast material has been reported. Sensitivity and specificity of 98% have been reported. The cost of CT scanning can be offset against the cost savings from reduced rates of hospital admission and of negative laparotomy. Compared with ultrasonography, CT has been reported to have superior accuracy for appendicitis in all reported studies. This must be weighed against exposure to ionizing radiation, availability and alternative diagnoses under consideration when the preferred test for an individual patient is being selected.

Magnetic resonance imaging (MRI) has a role in the diagnosis of acute appendicitis in all three trimesters of pregnancy, with one study of 51 patients reporting sensitivity of 100% and specificity of 93.6%. On MRI, acute appendicitis is diagnosed by an enlarged appendix greater than 7 mm in diameter, high-signal-intensity luminal contents caused by fluid, and high-signal-intensity peri-appendiceal fat stranding and fluid on T2-weighted images.

Box 7.10.2 Alvarado score (MANTRELS criteria)

Criterion		*Point(s)*
Symptoms		
M	migration of pain to RLQ	1
A	anorexia	1
N	nausea and vomiting	1
Signs		
T	tenderness in RLQ	2
R	rebound pain	1
E	elevated temperature	1
Laboratory findings		
L	leucocytosis	2
S	shift of WBCs to left	1
Total score		10
Interpretation		
1–4	Appendicitis unlikely	
5–6	Appendicitis possible	
7–8	Probable appendicitis	
9–10	Surgery indicated	

Clinical decision tools

Several tools have been described to assist clinical diagnosis. The best known of these is the 10-point Alvarado score for acute appendicitis, also known as the MANTRELS criteria (Box 7.10.2). These criteria were derived from a retrospective study of hospitalized patients with possible acute appendicitis but have been applied to ED practice. The score was developed as a guide to determine the need for further investigation and laparotomy. Diagnostic accuracy may be improved by combining the score with ultrasonography.

Improving diagnostic accuracy for appendicitis remains a challenge. CT has been shown to reduce negative appendicectomy rates but is not an option for routine diagnostic use.

Treatment

Analgesia, usually small doses of intravenous opioids titrated to the patient's response, should be given as required. There is no evidence that the provision of adequate analgesia is associated with delayed diagnosis, as positive abdominal signs related to peritoneal irritation are not eliminated. Intravenous hydration should also be initiated.

The definitive treatment for appendicitis remains appendicectomy, which may be open or laparoscopic. Laparoscopic appendicectomy allows for combined diagnosis and treatment, as well as the recognition and potential treatment of alternative diagnostic conditions. There is an increase in operative time but a reduction in postoperative analgesia requirements and length of inpatient stay as well as earlier return to work. Broad-spectrum antimicrobial agents given preoperatively or intraoperatively reduce the incidence of post-operative wound infection and intra-abdominal abscess.

Conservative management (intravenous hydration and broad-spectrum antimicrobial therapy) is indicated in the presence of an appendiceal mass (a surgical decision) or in circumstances when surgical help is not readily available, as in remote locations or while at sea. There is an increasing recognition of the potential role of conservative management for uncomplicated appendicitis in high-risk patients with significant co-morbidities and those with increased anaesthetic risk as well as at the extremes of age.

A negative laparotomy rate of around 15% to 20% has been accepted in the past. Negative laparotomy is, however, associated with a longer period of hospitalization, a higher complication rate and mortality.

Acute appendicitis in pregnancy

Acute appendicitis is the commonest non-obstetric reason for laparotomy in the pregnant woman, complicating about 1 in 1000 pregnancies. Symptoms of appendicitis are similar to those in the non-pregnant state but, in late pregnancy, the site of tenderness tends to be higher and more lateral. The incidence of perforation is higher. Foetal loss as a result of appendicitis and laparotomy may be as high as 20%.

Likely developments over the next 5 to 10 years

- Continued validation of diagnostic scoring systems for grading of severity and risk stratification
- Bedside ultrasound for appendix visualization as part of the emergency physician's repertoire, especially in children
- Continued reduction in the negative laparotomy rate, guided by diagnostic scoring systems and additional imaging as appropriate.
- Acceptance of non-operative management or delayed operative management of acute uncomplicated appendicitis

CONTROVERSIES

- The use of first-line diagnostic ultrasound, especially in adults
- The place for conservative management of uncomplicated acute appendicitis
- The role of laparoscopy in diagnosis and treatment

7.11 Inflammatory bowel disease

Kim Yates • Louise Finnel

ESSENTIALS

1 **The two major forms of inflammatory bowel disease (IBD) are Crohn's disease and ulcerative colitis. The principal clinical features are diarrhoea and/or abdominal pain.**

2 **IBD is a chronic and relapsing condition. Patients may present to the emergency department with increased disease activity or with complications of the disease process or treatment.**

3 **Gastrointestinal complications may include dehydration, bleeding, strictures, obstruction, fistulae, sepsis, perforation, neoplasia and toxic megacolon.**

4 **Acute arthropathy and rashes are the most common extraintestinal manifestations of IBD.**

5 **Complications relating to medications may include opportunistic infections in those on corticosteroids, immunomodulators or biological agents.**

6 **Patients with moderate or severe inflammatory bowel disease require admission to hospital and consultation with their specialist service, usually gastroenterology.**

7 **Most patients are managed initially with medical therapy, such as aminosalicylates and/or corticosteroids, but those with intra-abdominal sepsis, perforation, obstruction or toxic megacolon are likely to require emergency surgery.**

Introduction and pathology

Inflammatory bowel disease (IBD) classically refers to Crohn's disease (CD) and ulcerative colitis (UC) but also includes 'IBD Unclassified', which has features of both.[1] All are chronic inflammatory diseases of the gastrointestinal (GI) tract that result from an inappropriate and continuing inflammatory response—where genetic, infectious and other environmental factors interact—leading to dysregulation of intestinal immunity and GI injury. Pathologically, the two major forms of IBD differ. CD is a patchy transmural inflammation that can affect any part of the GI tract, with ileo-colonic disease being most common. It is associated with fistulae, abscesses, strictures and obstruction. In contrast, UC is a continuous, diffuse, colonic mucosal inflammation often associated with bleeding. Clinical features vary depending on the form and anatomic distribution of the disease. When patients who present to emergency department (ED) with known or suspected IBD are being assessed, determining disease activity and identifying potentially serious complications of the disease and its treatment are equally important.[1–4]

Clinical features

History

Bloody diarrhoea is a cardinal symptom of UC and can be associated with colicky abdominal pain, urgency and tenesmus. In CD, abdominal pain and anal complaints—including fissures, diarrhoea without rectal bleeding and weight loss—are more common. Abdominal pain in CD is commonly right-sided and worse with eating. In UC, pain is less frequent and usually crampy, located in the lower abdomen and relieved by passing a motion. If pain is more severe, other GI complications should be considered.[1–7]

A search for symptoms and signs of extraintestinal manifestations and past surgical procedures is helpful. Acute arthropathy and rashes are common extraintestinal manifestations of IBD, but thromboembolic, ocular and hepatobiliary complications can be more serious and require specific therapy. The risk of venous thromboembolism is three to four times higher in patients with IBD, particularly during a flare or when they are being treated with corticosteroids.

A careful drug history is essential, as treatments, such as aminosalicylates, steroids, immunomodulators (such as methotrexate, azathioprine or cyclosporine) and biological agents (such as infliximab, adalimumab or vedolizumab), can cause complications. In patients taking immunomodulators and/or biological agents, symptoms and signs of sepsis and opportunistic infection should be sought. Patients on biological treatments also have an increased risk of hypersensitivity reactions, cancers such as lymphoma, reactivation of tuberculosis or viral infections, demyelinating disease, arthropathies and worsening of congestive cardiac failure.

Enquiry about smoking is particularly important in CD, as smoking increases the risk of relapse.

Examination

Abdominal examination usually reveals a mildly tender abdomen without signs of peritonism. Evidence of dehydration or sepsis should be sought.[1–4,7]

The presence of fever, dehydration, orthostatic hypotension, abdominal tenderness, distension and hypoactive bowel sounds suggests fulminant colitis. Abdominal distension raises the question of fulminant colitis, toxic megacolon or obstruction. Toxic megacolon (colonic dilatation

with severe colitis) is potentially lethal but uncommon. Rectal examination may show anal fissures, abscesses or fistulae (more common in CD).

Investigations

Blood tests

A full blood count to quantify anaemia and determine the need for transfusion is helpful. Leucocytosis may be present in acute disease, but leucopaenia may be seen in patients on immunosuppressants. The erythrocyte sedimentation rate (ESR) and C-reactive protein are frequently used to monitor inflammation. Electrolytes and renal function may be abnormal in dehydration. Iron, folate and vitamin B12 deficiencies and hypoalbuminaemia are common in IBD. Disturbed liver function tests and/or raised amylase/lipase suggest hepatobiliary complications or drug toxicity.[1–4,6–8]

Faecal testing

Faecal calprotectin is a widely used, highly sensitive, non-invasive marker of intestinal inflammation that is used for therapeutic monitoring, early detection of disease relapse and as a surrogate for mucosal healing in IBD. Faecal cultures as well as standard cultures should be tested for *Clostridium difficile* toxin, as *C. difficile* infection has a higher prevalence in patients with IBD and is associated with increased mortality. Cytomegalovirus (CMV) testing should be performed in severe colitis, particularly when patients are on immunosuppressants, as CMV colitis is associated with poor outcome. Both of these conditions would require specific therapy.[1,3,4,6,7]

Imaging studies

On acute presentation, particularly with abdominal pain, abdominal and chest x-rays looking for free gas with perforation, dilated bowel loops and air-fluid levels with obstruction or dilated colon with toxic megacolon (diameter ≥5.5 cm) may be helpful depending on clinical features. A chest x-ray can also be useful in patients on immunomodulators or biological agents when complications such as opportunistic infection or malignancy are being considered.[1,3–7]

Cross-sectional imaging can be used to determine disease extent and severity and to assess for complications. With concerns about cumulative diagnostic radiation exposure, magnetic resonance imaging (MRI) and/or ultrasound are preferred, particularly in younger patients with CD. MRI of the pelvis is the gold standard for assessing perineal fistulae. Computed tomography (CT) is more readily available and plays an important role when acute complications, such as obstruction or sepsis, are suspected. Ultrasound can also be useful with regard to possible extra-intestinal complications of IBD, such as gallstones or kidney stones. Barium studies are now rarely used.

Endoscopy

Endoscopy is still the gold standard for diagnosing IBD, for staging activity and in screening for strictures or cancer. Cautious sigmoidoscopy or colonoscopy may be performed in severe IBD but carries the risk of perforation. Capsule endoscopy (Pill-Cam) does not provide more information than cross-sectional imaging and is rarely used in the acute setting.[1–3,7]

Severity assessment

The Crohn's Disease Activity Index (CDAI) and other indices have been proposed as indicators of CD activity but are not routinely used in clinical practice. The CDAI uses stool frequency, abdominal pain, general well-being, antidiarrhoeal use, presence of complications, abdominal masses, anaemia and weight loss to gauge severity. There are also online tools that can help with calculations, with a score greater than 450 indicating severe disease. For UC, many of the international definitions are based on the criteria of Truelove and Witts, where severe UC is defined as 6 or more bloody stools daily, pulse greater than 90 per minute, fever higher than 37.8°C, anaemia less than 105 g/L and ESR more than 30 mm/h. The sensitivity and specificity of biomarkers such as C-reactive protein and faecal calprotectin are variable, but they are often used to monitor inflammatory burden. There has been debate about expanding severity assessment criteria to include disease effect on the patient, cumulative complications, disability, inflammatory burden and disease course.[3,9,10]

Gastrointestinal complications

Toxic megacolon is a life-threatening complication of severe colitis and is defined as total or segmental non-obstructive dilatation of the colon ≥5.5 cm associated with systemic toxicity. It usually occurs as a complication of severe colitis, and risk factors include hypokalaemia, hypomagnesaemia, and use of bowel preparation or anti-diarrhoeal medications. The mortality of toxic megacolon has decreased with earlier diagnosis, intensive medical management and earlier surgery. Recognition in the ED is important, as patients will need combined medical and surgical care. If intensive medical management fails, then early colectomy will be necessary.[7,8]

Bowel perforation can also occur in patients with IBD, even in the absence of toxic megacolon, and early detection in the ED and referral for surgery is essential.

Strictures and bowel obstruction may be due to acute inflammation and oedema or fibrosis, but in UC colonic strictures suggest malignancy until proved otherwise.

Haemorrhage due to ulceration of the GI tract is more common in UC. Fistulae and abscesses are more common in CD. Fistulae to the urinary tract or vagina are not uncommon and can lead to recurrent urinary tract infections, faecaluria, pneumaturia or gynaecological inflammation. Patients with UC and CD are also prone to superimposed infectious colitis, as with *C. difficile*.

Patients with UC have a significantly increased risk of developing colon cancer, with this risk increasing with extent and duration of disease. CD patients with pancolitis may have the same risk of neoplastic development.

Treatment

General management and disposition

In the ED, the detection and treatment of life-threatening conditions—such as septic or hypovolaemic shock, severe anaemia or dehydration—are the priorities. Thereafter, assessment and treatment focuses on disease activity/severity and the presence of complications. Intravenous fluid therapy, correction of potassium and magnesium deficiencies and/or transfusion may be necessary. For abdominal pain, paracetamol and codeine are safe. Stronger opiates are associated with increased mortality in IBD and should not be routinely used. In severe colitis, non-steroidal anti-inflammatory drugs, opiates, anticholinergics and antidiarrhoeals can lead to toxic megacolon so should be avoided. Smokers with CD should be given cessation advice as cessation reduces relapse rate.[1,2,7,8]

If toxic megacolon is suspected, nasogastric drainage, intravenous steroids and other medical therapy as discussed later should be commenced and gastroenterology and surgical advice sought. Complications requiring surgery—such as bowel obstruction, intra-abdominal sepsis or perforation—should be ruled out early.

Patients presenting to the ED with IBD-related problems usually require discussion with the gastroenterology service, and most with moderate to severe disease require admission for a trial of medical therapy. Some with mild IBD may be discharged with gastroenterology follow-up.

Surgical admission is indicated for perforation, obstruction, intra-abdominal sepsis or toxic megacolon. Treatment for IBD usually involves a stepwise approach depending on the severity of disease and response to treatment, some of which may have to be initiated in the ED.

Medical therapy

Aminosalicylates (sulfasalazine, 5ASA/mesalamine) come in topical/rectal and oral forms and are most effective in maintaining remission in UC but may also be useful in small-bowel CD.[1–3,7,8]

Corticosteroids induce remission of IBD but are not useful as maintenance therapy. There are many different regimens, but a common approach is oral prednisone 40 mg/day for

1 week then weaned over 8 weeks. Oral prednisone is more effective at inducing remission in mild to moderate UC than aminosalicylates alone. Rectal steroids are effective in mild distal UC when used with oral aminosalicylates. Budesonide, which has low bioavailability and fewer systemic side effects, is an alternative to prednisone therapy in milder disease. In the ED, if intravenous steroid is necessary to treat acute severe IBD, hydrocortisone 100 mg or methylprednisolone 60 mg intravenous (IV) can be used until oral therapy is tolerated. Oral or topical steroids can be effective for induction of remission but should not be first-line maintenance therapy in mild or moderate disease. In acute severe UC, which can be difficult to distinguish from infective colitis, commence steroids with antibiotic cover until stool microbiology is available.

Ciprofloxacin and metronidazole are the most common antibiotics used for perianal CD and pouchitis. Infective causes of diarrhoea or colitis will require specific therapy. For *C. difficile* colitis, vancomycin is recommended and, for CMV, colitis antivirals are indicated.

Immunomodulators are used in severe disease, as steroid-sparing agents or in steroid-resistant disease. Thiopurine immunomodulators, such as azathioprine and 6-mercaptopurine, are rarely used in acute flares. They are often preferred to methotrexate, but methotrexate appears effective in CD. Complications of therapy can include bone marrow suppression, hepatitis, pancreatitis and increased risk of infection. Cyclosporine or tacrolimus may be useful in refractory colitis as salvage therapy.

Biological therapies include anti-tumour necrosis factor (anti-TNF) antibodies (e.g. infliximab, adalimumab, or certolizumab), which are used for moderate to severe IBD where standard therapy is insufficient. They are generally well tolerated but are associated with adverse effects such as infection, malignancy and immunogenicity, doubling the risk of opportunistic infections in patients with IBD and increasing the risk of melanoma development.

Newer biological agents include gut-specific vedolizumab, which has fewer side effects but is slower to act, and ustekinumab, which is useful in CD.

Enteral nutrition therapy for the induction of remission in CD is inferior to corticosteroids but may be a useful adjunct or helpful when corticosteroids are contraindicated or declined. In adults with CD, elemental/polymeric diets appear to be less effective than corticosteroids but may be an alternative for some, and nutritional therapy is important supportive care for many.[11]

Surgical therapy

Indications for surgery in IBD include fulminant colitis, toxic megacolon, perforation, severe GI haemorrhage, intractable IBD, stricture with obstruction, abscesses, fistulae or cancer. Intra-abdominal abscesses, more common in CD, may be drained with minimally invasive procedures.[7]

In UC, proctocolectomy is curative; however, subtotal procedures and anastomoses are often performed when disease is limited or when patients wish to avoid a stoma. As CD has a high recurrence rate after segmental resection, surgery is conservative to preserve bowel length and function.

Prognosis

IBD is characterized by exacerbation and remission. With modern medical and surgical management, mortality rates have improved, particularly for UC, where survival rates are now comparable to those of the general population. For patients with CD, mortality rates are 1.3 to 1.5 times higher as a result of complications of the disease.[2]

CONTROVERSIES

- Biological agents and IBD.[1,3,4] Biological agents have been shown to be highly effective in selected patients but it is unclear whether early aggressive therapy or a step-up approach is better, and whether they should be used in combination with immunomodulators. There is data suggesting that introducing biological therapies early in the course of CD may halt progression, but further trials are needed. The number of drugs modulating different pathways is expanding. Tofacitinib, an oral pan-Janus kinase inhibitor appears effective in trials. Etrolizumab and mongersen also appear promising. As the number of biological agents expands, precision medicine to determine drug choice will be needed.
- Faecal microbiota transplantation (FMT).[1,4] Studies of FMT have yielded conflicting results, although studies in the largest trial in UC showed higher rates of remission. It has been used successfully in the management of recurrent *C. difficile* colitis.
- Complementary therapies in IBD.[1] Most are safe but evidence of efficacy and safety is not always available. Turmeric use has been studied and appears to be helpful for inducing and maintaining remission in UC. Enteric-coated peppermint oil capsules in small doses may help with IBD symptoms. Probiotics appear helpful for maintaining remission only in UC. St John's Wort can interact with immunomodulators and should be avoided when taking these. Nutritional therapies may induce remission in CD but appear less effective than corticosteroids.
- Cancer and IBD.[1,7] IBD patients with colitis have increased risk of colorectal cancer. Risk increases with increasing disease duration, earlier age of onset of disease or if there is a family history of colorectal cancer. There is debate about the best surveillance strategies, but more frequent colonoscopy is usually recommended in higher-risk patients.
- Psychological co-morbidities and support.[1] It is well recognized that many IBD patients with relapses suffer anxiety or depression. It is unclear whether psychological support and treatment improve the course of IBD, but they do improve quality of life.
- Timing of surgical management: In older patients with severe disease, surgical teams must carefully determine the timing of surgery and consider that a delay in diagnosis and/or surgery may be life-threatening.

7.12 Acute liver failure

John M. Ryan • John J. Cronin

ESSENTIALS

1 The diagnosis of acute liver failure (ALF) is based on the presence of worsening coagulopathy, hepatic encephalopathy and deepening jaundice.

2 In developing countries, viral causes predominate, with hepatitis E infection recognized as a common cause in many countries.

3 In developed countries, drug-induced liver injury (DILI) predominates, often from paracetamol.

4 Diagnosis of ALF must be considered in anyone presenting with the recent onset of hepatic illness associated with prolonged prothrombin time/international normalized ratio.

5 Early diagnosis is important because of the therapeutic option of using antidotes in the presence of a reversible cause.

6 The general principles of care include standard intensive care with additional specific measures aimed at identification and removal or amelioration of the insult that caused hepatic injury. Organ-system support is used to achieve maximum hepatic regeneration so as to return to premorbid hepatic function while potential complications are anticipated and prevented.

7 Outcomes have been improved by the use of emergency liver transplantation.

8 Public health measures to control patterns of drug use (DILI) and to reduce the incidence of hepatotropic virus infections may significantly reduce the associated morbidity and mortality in the future.

Introduction

Acute liver failure (ALF) remains one of the most challenging medical emergencies. It is a rare condition in which rapid deterioration of liver function results in altered mentation and coagulopathy in previously normal individuals. The overall incidence in developed countries is between one and six cases per million people per year. The most prominent causes include viral hepatitis, drug-induced liver injury (DILI), autoimmune liver disease and shock or hypoperfusion; many cases (≈20%) have no discernible cause. ALF often affects young persons and is associated with high morbidity and mortality. In many countries, it is the most frequent indication for emergency liver transplantation. Prior to the availability of transplantation, mortality due to ALF was extremely high, often exceeding 90%; the most common causes of death were multiorgan failure, haemorrhage, infection and cerebral oedema. Currently, 1-year survival exceeds 80%. Because of its rarity, ALF has been difficult to study in depth and very few controlled therapy trials have been performed. ALF research has been limited to a handful of large units or to collaborative networks, such as the National Institutes of Health (NIH)–sponsored US Acute Liver Failure Study Group (ALFSG).

Aetiology, pathogenesis and pathology

ALF occurs when the rate of hepatocyte death exceeds the rate of hepatocyte regeneration as a result of various insults that lead to a combination of apoptosis or necrosis. Apoptosis is associated with nuclear shrinkage but without cell membrane rupture. Therefore there is no release of intracellular contents and no subsequent secondary inflammation. In contrast, necrosis is associated with ATP depletion, resulting in a swollen cell that eventually lyses with the release of intracellular contents associated with secondary inflammation. Most causes of ALF result in either apoptosis or necrosis; for example, paracetamol toxicity results in apoptosis and ischaemia results in necrosis. The clinical result of the cellular damage is a catastrophic illness that can lead rapidly to coma and death caused by multi-organ failure.

Epidemiology

There is substantial worldwide variation in the cause of ALF. It is relatively uncommon in the United Kingdom, causing fewer than 500 deaths and being responsible for less than 15% of liver transplantations per annum (<100 transplants per year). Meanwhile, ALF affects approximately 2000 people per year in the United States. There, ALF accounts for approximately 7% of all liver transplantations annually; however, it accounts for more than two-thirds of transplantations in the Far East.

Over the past half century, the relative frequency of causes of ALF has evolved, with hepatitis A and B declining in incidence and paracetamol (acetaminophen) overdose increasing in Western Europe and the United States. In parallel to paracetamol overdoses, idiosyncratic DILI is among the most common discernible causes, whereas cases of indeterminate aetiology (cause not discernible after extensive evaluation) continue to constitute a sizable patient group. The differences in aetiology between developing and developed countries are well characterized. Europe and the United States feature a high incidence of paracetamol toxicity leading to ALF, along with DILI due to prescription agents, which is less common but equally important. By contrast, South Asia and Hong Kong have a higher incidence of hepatitis viruses, specifically hepatitis E in Pakistan and hepatitis B in Hong Kong, as well as in Australia, with fewer cases of DILI observed at least in the developing world.

Prevention

Primary prevention of ALF in the West mainly involves strategies to combat increasing rates of paracetamol-induced ALF including legislation to reduce over-the-counter availability of paracetamol, printing specific warnings about overdose in the packets, use of paracetamol/methionine combination analgesics and the promotion of alternative analgesics.

Secondary prevention of ALF involves immunization strategies. Hepatitis A and B vaccination is safe and immunogenic in patients with mild to moderate chronic liver disease (CLD), although vaccination is less effective in those with decompensated liver cirrhosis or after liver transplantation.

Clinical features

History taking should include a careful review of possible exposures to viral infection and drugs or

other toxins. If severe encephalopathy is present, a collateral history may be all that is available or a history may be unavailable. In this setting, limited information is available, particularly regarding possible toxin/drug ingestions.

Physical examination must include careful assessment and documentation of mental status and a search for the stigmata of CLD. Jaundice is often but not invariably seen at presentation. Right upper quadrant tenderness is variably present. Inability to palpate the liver or even to percuss a significant area of dullness over the liver can be indicative of decreased liver volume due to massive hepatocyte loss. Hepatomegaly may be seen early in viral hepatitis or with malignant infiltration, congestive heart failure or acute Budd-Chiari syndrome. History or signs of cirrhosis should be absent, as such features suggest underlying CLD, which may have different management implications.

Differential diagnosis

Common causes of ALF are hepatitis viruses or drugs (Table 7.12.1). In Western countries, drug-induced ALF predominates, comprising 19% to 75% of all cases of ALF. In India, 91% to 100% of ALF cases are due to viruses, with drug-induced cases responsible for 0% to 7.4%.

The developed world is particularly subject to rare ALF due to idiosyncratic DILI because of the large quantity of drugs ingested. Idiosyncratic drug reactions account for 13% of cases of ALF in the United States and 5% of cases in the United Kingdom. Examples of causative drugs include antibiotics (amoxicillin-clavulanic acid, ciprofloxacin, doxycycline, erythromycin, isoniazid, nitrofurantoin, tetracycline, sulphonamides), antivirals (fialuridine), antidepressants (amitriptyline, nortriptyline), oral hypoglycaemic drugs (troglitazone, metformin), anticonvulsants (phenytoin, valproic acid), anaesthetics (halothane, isoflurane), statins (atorvastatin, lovastatin, simvastatin), immunosuppressants (cyclophosphamide, methotrexate, gold), non-steroidal anti-inflammatory drugs (NSAIDs), salicylates (Reye syndrome), antithyroid drugs (propylthiouracil), antiarrhythmics (amiodarone) disulfiram and flutamide. The presentation of DILI is more subacute, with lower aminotransferases and higher bilirubin levels. The likelihood of survival in this setting is less than 30% and such patients more often undergo liver transplantation.

Infectious diseases—such as falciparum malaria, typhoid fever, leptospirosis and dengue fever—may mimic ALF at presentation. Patients can present with fever, jaundice and features of encephalopathy, which should be considered in all patients presenting with ALF, particularly in patients seen in the tropics or in those who have recently travelled in the tropics. Baseline routine clinical and laboratory investigations will provide supportive evidence of an infective cause. After a definitive diagnosis has been reached, specific therapy for the infectious disease in addition to supportive therapy for ALF reduces mortality.

Table 7.12.1 Differential diagnosis of acute liver failure

Viruses	Hepatitis A and B viruses (typical viruses causing viral hepatitis) Hepatitis C virus (rare) Hepatitis D virus Hepatitis E virus (often in pregnant women in endemic areas) Cytomegalovirus Haemorrhagic fever viruses Herpes simplex virus Paramyxovirus Epstein–Barr virus
Drugs	Paracetamol hepatotoxicity Idiosyncratic hypersensitivity reactions (e.g. isoniazid, statins, halothane) Illicit drugs (e.g. Ecstasy, cocaine) Alternative medicines (e.g. chaparral and *Teucrium polium*), traditional Chinese medicine
Toxins	Mushroom poisoning (usually *Amanita phalloides*) *Bacillus cereus* toxin Cyanobacteria toxin Organic solvents (e.g. carbon tetrachloride) Yellow phosphorus
Vasculopathy	Ischaemic hepatitis Hepatic vein thrombosis (Budd-Chiari syndrome) Hepatic veno-occlusive disease Portal vein thrombosis Hepatic arterial thrombosis
Metabolic	Acute fatty liver of pregnancy/haemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome α-1 antitrypsin deficiency Fructose intolerance Galactosaemia Lecithin-cholesterol acyltransferase deficiency Reye syndrome Tyrosinaemia Wilson disease
Autoimmune	Autoimmune hepatitis
Malignancy	Primary liver malignancy (hepatocellular carcinoma or cholangiocarcinoma) Secondary (e.g. extensive hepatic metastases or infiltration of adenocarcinoma)
Miscellaneous	Adult-onset Still disease Heat stroke Primary graft non-function (in liver transplant recipients) Indeterminate aetiology (≈20% of acute liver failure cases)

Clinical investigations

Initial laboratory investigation in the emergency department (ED) is aimed at evaluating both the aetiology and severity of ALF (Table 7.12.2).

Other urgent investigations, mainly aimed at evaluating the aetiology of ALF following hospital admission, include viral hepatitis serologies (anti-HAV IgM, hepatitis B surface antigen [HBSAg], anti-HBc IgM, anti-HEV IgM, anti-HCV IgM), autoimmune markers (antinuclear, anti–smooth muscle antibodies, immunoglobulin levels) and ceruloplasmin level. Plasma ammonia, preferably arterial, may also be helpful. A liver biopsy, most often done via the transjugular route because of coagulopathy, may be indicated when certain conditions (e.g. autoimmune hepatitis, metastatic liver disease, lymphoma or herpes simplex hepatitis) are suspected.

Other investigations may be required as clinically indicated, for example, determination of the HIV status of patients who are candidates for liver transplantation.

Criteria for diagnosis

The diagnosis of ALF must be considered in anyone presenting with the recent onset of hepatic illness where the prothrombin time/international normalized ratio (INR) has become prolonged. The most widely accepted definition of ALF includes impairment of liver function with evidence of coagulation abnormality (usually an INR ≥1.5) and any degree of mental alteration (encephalopathy; Table 7.12.3) in a patient without existing cirrhosis and with an illness of less than 26 weeks' duration. Patients with Wilson disease, vertically acquired HBV or autoimmune hepatitis may be included in spite of the possibility of cirrhosis if their disease has been recognized for less than 26 weeks.

Table 7.12.2 Emergency department investigations for acute liver failure

Haematology	Full blood count Prothrombin time/INR Blood type and screen
Biochemistry	Liver function tests Urea and electrolytes Arterial blood gas Arterial lactate Arterial ammonia Glucose Calcium Magnesium Phosphate Amylase
Toxicology	Paracetamol level Toxicology screen
Urinalysis	hCG (females)
Imaging studies	Chest radiography Liver ultrasonography
Miscellaneous	Electrocardiogram

Table 7.12.3 Grades of hepatic encephalopathy

Grade 1	Drowsy but coherent, mood change
Grade 2	Drowsy, confused at times, inappropriate behaviour
Grade 3	Very drowsy and stuporous but rousable; alternatively restless, screaming
Grade 4	Comatose, barely rousable

A number of other terms have been used, including *fulminant hepatic failure* and *fulminant hepatitis* or *necrosis*. It is intuitively logical that *ALF* would be a better overall term encompassing all durations up to 26 weeks. Terms used signifying length of illness, such as *hyperacute* (<7 days), *acute* (7 to 21 days) and *subacute* (>21 days and <26 weeks), are not particularly helpful since they do not have prognostic significance distinct from the cause of the illness.

Treatment

The backbone of managing ALF patients is good coma care. The most important first step in the treatment of ALF is to identify the cause, since prognosis depends on that. Death in ALF is predominantly related to sepsis, multi-organ failure and intracranial hypertension. The circulatory disturbances in ALF, which contribute to the often-associated renal failure, are characterized by a generalized vasodilatation that results in increased cardiac output and a reduction in both systemic vascular resistance and mean arterial pressure.

Emergency liver transplantation is the only proven therapeutic intervention for ALF. Although treatments for specific aetiologies are also initiated, emergency management requires intensive care support because rapid deterioration can occur. Careful attention must be paid to fluid management, haemodynamics and metabolic parameters as well as surveillance for and treatment of infection. Maintenance of nutrition and prompt recognition and resuscitation of gastrointestinal bleeding are crucial as well. Coagulation parameters, complete blood counts, metabolic panels (including glucose) and arterial blood gas should be checked frequently. Liver function tests (LFTs) are generally measured daily to follow the course of the condition; however, changes in aminotransferase levels correlate poorly with prognosis.

General measures

Fundamental to the management of patients with ALF is the provision of good intensive care support. Aggressive monitoring is required to detect respiratory and haemodynamic complications, neurological changes, infections and gastrointestinal haemorrhage. Airway protection and endotracheal intubation may be required because, as patients with ALF become comatose, their ability to protect the airway from aspiration is reduced. Central venous access and invasive and non-invasive arterial blood pressure monitoring are useful for checking vascular status. All patients should have a urinary catheter placed to monitor urine output. Volume resuscitation should ideally be with colloids and titrated to a pulmonary capillary wedge pressure of 12 to 14 mm Hg. Intravenous noradrenaline (norepinephrine) may be required for systemic hypotension. Metabolic derangements such as hypoglycaemia should be sought and treated aggressively. Hypokalaemia is common and should be managed with intravenous supplements. Intravenous phosphate and magnesium supplements may also be required. Platelets may be required if the count falls below 20,000/mL. H_2-receptor blockers are given for prophylaxis against gastrointestinal bleeding. Nasogastric tube insertion for stomach decompression may be required in comatose patients. Dialysis may be required for deteriorating renal function and worsening acidosis.

The maintenance of adequate cerebral perfusion is paramount, and the patient should be nursed in a quiet environment with 30-degree head-up tilt. Intracranial pressure monitoring may be helpful in some patients for directing therapy to prevent herniation of the brain stem.

Dietary protein withdrawal is commonly recommended to treat acute hepatic encephalopathy, although the traditional use of lactulose for enteral decontamination is now more controversial. Instead, other agents, such as metronidazole and neomycin, have been recommended to treat acute hepatic encephalopathy. Systemic antimicrobial therapy with or without enteral decontamination reduces the infection rate in patients with acute liver failure.

Specific measures

N-acetylcysteine

Several clinical trials support the use of N-acetylcysteine (NAC) in ALF. In late-presenting paracetamol overdose, mortality and progression to grade III and IV encephalopathy is reduced in those receiving NAC.

Penicillin G and silibinin

Penicillin G and silibinin (silymarin or milk thistle) are accepted antidotes for mushroom poisoning (usually *Amanita phalloides*), although there have been no controlled trials proving their efficacy. Some reports have not found penicillin G to be helpful, but enough efficacy has been reported to warrant consideration of the drug (given intravenously in doses of 300,000–1 million units/kg/day) in patients with known or suspected mushroom poisoning. Silibinin has generally been reported to be more successful than penicillin G, although penicillin G has been used more frequently. Silibinin/silymarin is not available as a licensed drug in the United States, although it is widely available in Europe and South America. When used for the treatment of mushroom poisoning, Silymarin has been given in average doses of 30–40 mg/kg/day orally. Silibinin (its purified alkaloid) has been given intravenously as a 5 mg/kg loading dose followed by 20 mg/kg/day as a constant infusion for an average of 3–4 days.

Drug-induced hepatotoxicity

There are no specific antidotes for idiosyncratic drug reactions; corticosteroids are not indicated unless a drug hypersensitivity reaction is suspected. Current recommendations are as follows: (1) obtain details (including onset of ingestion, amount and timing of last dose) concerning all prescription and non-prescription drugs, herbs and dietary supplement taken over the past year; (2) determine the ingredients of non-prescription medications whenever possible; (3) in the setting of ALF, due to possible drug hepatotoxicity, discontinue all but essential medications.

Lamivudine and nucleoside analogues

ALF due to the reactivation of hepatitis B may occur in the setting of chemotherapy or immunosuppression. The nucleoside analogue lamivudine (and possibly adefovir), used widely in the treatment of chronic hepatitis B, may be considered in patients with acute hepatitis B, although these drugs have not been subjected to a controlled trial in acute disease. It is currently recommended that nucleoside analogues be given prior to and

continued for 6 months after completion of chemotherapy in patients with HBSAG positivity to prevent reactivation/acute flare of disease.

Acyclovir

Although herpesvirus infection rarely causes ALF, immunosuppressed patients or pregnant women (usually in the third trimester) are at increased risk. In addition, occurrences of herpesvirus ALF have been reported in previously healthy individuals. Meanwhile, other viruses, such as varicella zoster, have occasionally been implicated in causing hepatic failure. Patients with known or suspected herpesvirus or varicella zoster as the cause of ALF should be treated with acyclovir.

Corticosteroids

Patients with autoimmune hepatitis may have unrecognized pre-existing chronic disease and yet still be considered as having ALF if their illness is of less than 26 weeks' duration. Such patients represent the most severe form of the disease and would generally fall into the category of those recommended for corticosteroid therapy (prednisone 40 to 60 mg/day). Initiation of steroid therapy may constitute a therapeutic trial for some patients, but placement on the transplant list is still indicated. Although some patients with ALF due to autoimmune hepatitis respond to steroid therapy, others require transplantation.

Cardiovascular support

In ALF patients with evidence of ischaemic injury, cardiovascular support is the treatment of choice. In such patients, the ability to manage heart failure or other causes of ischaemia (e.g. significant hypovolaemia) will determine outcome.

Liver transplantation

Orthotopic liver transplantation (OLT) remains the only definitive therapy for patients who are unable to achieve regeneration of sufficient hepatocyte mass to sustain life. Living-related liver transplant (LDLT) is more common in Asia. Urgent liver transplantation is indicated in ALF where prognostic indicators suggest a high likelihood of death. Post-transplant survival rates for ALF have been reported to be as high as 80% to 90%, but accurate long-term outcome data are not yet available.

Patients with ALF secondary to the following causes should be listed for transplantation: mushroom poisoning, Wilson disease, autoimmune hepatitis and hepatic vein thrombosis (provided underlying malignancy is excluded). In such patients initial laboratory investigations should include determination of their HIV status, because this has implications for potential liver transplantation. Early liaison with a liver transplantation unit is mandatory and any contraindications to transplantation should be identified with collateral histories through the family, friends and primary care physicians, if necessary. Planning for transfer to a transplant centre should begin in patients with grade I or II encephalopathy (see Table 7.12.3) because they may worsen rapidly. Early transfer is important, as the risks involved with patient transport may increase or even preclude transfer once stage III or IV encephalopathy develops.

'Bridging options'

The aim of bridging devices is to provide adequate liver function and maintain the patient well enough until recovery of native liver function occurs or a graft is found. In one study, only 29% of patients listed for liver transplantation received a liver graft, whereas 10% of the overall group (one-quarter the number of patients listed for transplantation) died on the waiting list. Other series have reported death rates of those listed for liver transplantation as high as 40% even though most organ donor allocation systems prioritize ALF.

The many and diverse functions of the liver (metabolic, immunological and physiological) make the task of developing bridging devices a major challenge: the effects of the 'toxic liver' itself also require consideration. Bridging devices can be classified into four categories: (1) auxiliary transplant, (2) liver support devices (biological and non-biological), (3) hepatocyte transplantation and (4) innovative/experimental techniques (Table 7.12.4).

The current data regarding the efficacy, cost-effectiveness and safety of liver support devices, both biological and non-biological (artificial) are conflicting and less promising in ALF. Currently available liver support systems are therefore not recommended outside of clinical trials; their future in the management of ALF remains unclear.

Stem cell transplantation (regenerative medicine)

Liver transplantation is limited by the severely limited supply of human donors.

A regenerative medicine approach employing stem cells has recently been proposed to overcome this problem. Experimentation is under way using infusions of hepatic stem cells that are said to be non-immunogenic, but this is currently highly experimental.

Prognosis

The two key factors determining outcome in ALF are aetiology and mental status at admission. In general acetaminophen toxicity, hepatitis A, ischemic hepatitis, and pregnancy have 60% short-term survival, whereas DILI; autoimmune hepatitis and indeterminate cases have only 30% spontaneous survival. Patients with early grades of encephalopathy at presentation have a better prognosis than those presenting with advanced coma.

Given that the only proven beneficial therapeutic intervention in advanced ALF is transplantation, the timing of transplantation and selection of patients is crucial.

Although scoring systems have been proposed, the variety of causes of ALF tends to limit their accuracy. Validating selection criteria is difficult because of poor methodology in several reported series. Furthermore, ALF is rare, therefore most case series involve small numbers and span long periods of time during which important supportive medical therapies may have evolved that could affect prognosis.

Various prognostic evaluation systems have been used to identify candidates for transplantation, but none has the sensitivity and specificity to be usable in clinical practice. Survival after ALF is multifactorial and depends on aetiology, grade of coma on admission, ability to regenerate a healthy liver, and the absence of complications.

Table 7.12.4 'Bridging options' for acute liver failure

Auxilary transplant	Heterotopic auxiliary liver transplantation (HALT) Auxiliary partial orthoptic liver transplantation (APOLT)
Liver support devices	Bioartificial liver (BAL) devices Demetriou's Hepatassist BAL Amsterdam Medical Centre BAL Extracorporeal liver assist device (MELS) Bioartificial liver support system (BLSS) Non-biological liver devices Molecular Adsorbents Recirculating System (MARS) Prometheus system Plasmapheresis and high-volume plasmapheresis
Hepatocyte transplantation	Cryopreserved human hepatocytes via: Intraportal hepatocyte infusions Splenic artery infusion
Innovative/experimental techniques	Total emergency hepatectomy Portal vein arterialization Auxiliary liver organ formation by implantation of spleen-encapsulated hepatocytes

Likely developments over the next 5 to 10 years

- Evidence base for N-acetylcysteine (NAC) in non-paracetamol ALF
- Mild hypothermia to prevent and treat brain oedema in ALF
- Optimal biocomponent for liver support devices in ALF
- Hepatocyte progenitor cells (including foetal liver cells, multipotent hepatic cells and bone marrow derived stem cells) as genuine functional hepatocytes for use in hepatocyte transplantation
- Auxiliary partial orthoptic liver transplantation as a bridge to transplantation or spontaneous recovery in ALF
- Artificial and bioartificial liver (BAL) support systems; filtration and adsorption devices that remove accumulated toxins from the blood

CONTROVERSIES

- Efficacy of penicillin G and silibinin (silymarin or milk thistle) as antidotes for mushroom poisoning
- Selection of patients for transplantation
- Role, selection and efficacy of bridging options for patients awaiting transplantation

7.13 Haematochezia

Francis Chun-Yue Lee

ESSENTIALS

1 Haematochezia is a common presentation in patients aged over 50 years and can result in shock due to large-volume blood loss.

2 The most common cause of lower gastrointestinal bleeding (LGIB) in younger patients (<50 years of age) is anorectal disorders. In elderly patients, diverticular disease is the main cause.

3 Most cases of lower gastrointestinal (GI) haemorrhage are self-limiting and resolve spontaneously.

4 The management of acute LGIB at the emergency department focuses on resuscitation and assessing the risk factors for adverse outcomes.

5 In patients with significant or massive haemorrhage, an oesophagogastroduodenoscopy should be performed to look for haemorrhage from the upper GI tract.

6 Despite improved diagnostic imaging, no source of bleeding will be identified in up to 10% to 20% of patients.

Introduction

Haematochezia is the passage of red blood or clots per rectum. It is commonly associated with lower gastrointestinal bleeding (LGIB), defined as haemorrhage into gastrointestinal (GI) tract distal to the ligament of Trietz. This is in contrast to upper gastrointestinal bleeding (UGIB), which produces melaena, or stools stained black by hematin (oxidized haem released from erythrocytes).

Depending on the aetiology and rapidity of bleeding, the presentation of haematochezia can be mild, moderate or massive; occurring as single, intermittent or recurrent episodes. Some patients have a background of occult bleeding and may have signs of anaemia.

The emergency department management of haematochezia has three key objectives:

- Discovering the aetiology and determination of the severity of bleeding through focused history, examination and investigations

- Resuscitation and optimization of patients' haemodynamic status
- Consultation and coordination with the specialty team for definitive diagnosis and treatment

Aetiology

There are many causes of haematochezia (Box 7.13.1) and the incidence of causes varies with age. Haemorrhoids are the most common cause for haematochezia in patients less than 50 years of age. In a review of the aetiology of LGIB in patients of all ages who presented with significant bleeding and were admitted to hospital or were required to undergo colonoscopy, diverticular disease was the most common aetiology (17% to 40%), followed by angiodysplasia (2% to 30%), inflammatory or ischaemic colitis (9% to 21%) and colonic neoplasia (11% to 14%). Anorectal conditions, such as haemorrhoids or fissures, made up 4% to 10% of cases, but they were more common in patients under 50 years of age. In up to 25% of patients presenting with haematochezia, the source is unidentifiable.

Diverticulosis

A colonic diverticulum is a herniation of the mucosa and submucosa through the muscle layer of the bowel at areas of weakness. It tends to occur alongside the teniae coli, at the entry points of the vasa recta and nerves. *Diverticulosis*, a term for the presence of multiple diverticula, most commonly involves the descending and sigmoid colon. Right-sided diverticulosis is common in the Asian population.

The risk of bleeding in patients with diverticulosis can be as high as 48% and is thought to be caused by the acute rupture of diseased vasa recta. Atherosclerotic disease is an independently risk factor for bleeding, which could explain why the increasing prevalence of this complication with age. Hypertension, smoking, steroid and the use of non-steroidal anti-inflammatory drugs (NSAIDs) are also risk factors.

The presentation is usually an acute painless haematochezia, with spontaneous resolution in 70% to 80% of patients. Of these, 25% to 30% will have recurrence of bleeding.

Box 7.13.1 Causes of lower gastrointestinal bleeding

Diverticulosis
Angiodysplasia
Ischaemic colitis
Infective colitis
Malignancy
Haemorrhoids
Other anorectal conditions: anal fissures, anal fistula
Inflammatory bowel disease
Post-polypectomy
HIV/AIDs–related
Rectal trauma
Aorto-enteric fistula
Radiation-induced colitis
Drug related: NSAIDs, steroids, warfarin
Meckel diverticulum
Rectal varices
Upper gastrointestinal bleeding

HIV, Human immunodeficiency virus; *NSAIDs*, non-steroidal anti-inflammatory drugs

Angiodysplasia

Angiodysplasia is an acquired ectasia of veno-capillary channels in the mucosal and submucosal layers of the GI tract; it is most commonly found in the proximal colon and accounts for up to 3% to 30% of cases of LGIB. Angiodysplastic lesions increase with age and are the second most common cause of bleeding above the age of 65. The bleeding pattern can be acute massive, intermittent or occult. The main contrast to diverticular bleeding is the high rate of self-limiting re-bleeding in patients (80%) with untreated lesions. A small proportion of cases are contributed by angiodysplasia in the small bowel.

Other rarer vascular anomalies—including arteriovenous malformation, haemangioma and telangiectasias—tend to occur in younger patients.

Enterocolitis

Enterocolitis is a collective term for a vast array of pathophysiology involving the inflammation of the small bowel and colon.

By far the most common form of enterocolitis is infectious in origin. In this group, fever, abdominal pain, tenesmus, vomiting and diarrhoea dominate the clinical picture. Haematochezia is often reported as part of the diarrhoea episode rather than frank bleeding. When present, bleeding usually points a bacterial or parasitic cause, although this can be seen in severe forms of haemorrhagic virus infection such as dengue and Ebola. Enterohaemorrhagic *Escherichia coli*, Shiga toxin–producing *E. coli*, *Shigella*, *Salmonella* and *Campylobacter jejuni* are well-known agents producing bloody diarrhoea. The term *dysentery* usually refers to *Shigella*-related diarrheal disease. Ascariasis, necatoriasis, taeniasis and amoebiasis are parasitic causes of chronic intermittent haematochezia, often associated with abdominal pain, loss of appetite and anaemia

Ischaemic colitis is the result of a reduction in mesenteric blood flow causing ischaemia of a segment of colon. This typically occurs in watershed areas, such as the splenic flexure and the rectosigmoid junction. Patients are usually elderly with risk factors for vascular disease such as atherosclerosis, hypertension, diabetes, cardiac arrhythmias and thrombophilia. Chronic constipation and irritable bowel syndrome are independent risk factors. Possible aetiologies in younger patients include vasculitis, drugs (cocaine, methamphetamines), sickle cell anaemia and endurance running. The common presentation is acute abdominal pain followed by haematochezia within 24 hours. There may be paucity of clinical signs, especially in the elderly and immunocompromised, unless bowel infarction and peritonism has occurred.

Radiotherapy or radiation exposure also causes ischaemic enterocolitis. The result is inflammation, sloughing of mucosa and bleeding. Haemorrhagic radiation proctitis is a potential complication of prostate brachytherapy, affecting 4% to 13% of patients.

Inflammatory bowel disease (see Chapter 7.11)

Small to moderate amounts of rectal bleeding occur in up to 50% of patients with ulcerative colitis, often accompanied by other features such as loss of appetite and prolonged diarrhoea. In contrast, haematochezia and diarrhoea are less prominent in Crohn disease.

Neoplasia

Neoplasms of the bowel present as painless occult bleeding but may result in mild recurrent bleeding due to erosion or ulceration of mucosa. They have associated symptoms of weight loss, altered bowel habit, abdominal pain or intestinal obstruction. Colon cancer is the predominant cause of rectal bleeding from neoplastic disease and is more common in patients above 50 years of age. From population studies, the diagnosis of lower GI bleeding is also a predictor of increased risk for non-colorectal GI cancer beyond 1 year of follow-up.

Post-polypectomy bleeding may result in significant blood loss, which is often arterial in nature. This can occur between hours to weeks after polyp removal.

Anorectal disorders (see Chapter 7.14)

Haemorrhoids are the most common cause of haematochezia. Most episodes are self-limiting and respond well to conservative treatment. Rectal varices are porto-systemic anastomoses that develop in almost every patient with portal hypertension, but bleeding from these is rare.

Other causes of haematochezia from anorectal conditions include fissures, fistulae, abscesses, ulcers, foreign-body and rectal trauma. This is usually self-limiting and the treatment is targeted at the primary condition and symptomatic relief.

Clinicians should keep in mind that the detection of anorectal disease on examination does not exclude the possibility of a more proximal source of bleeding.

Aortoenteric fistula

This complication occurs as a rare sequela of endovascular abdominal aortic aneurysm repair (secondary aortoenteric fistulae) and is probably

due to inflammation and prosthetic leak. The site of the fistula is most often the duodenum. The traditional triad of abdominal pain, sepsis and GI bleeding is seen in only 30% of patients. There may be a 'herald bleed' prior to catastrophic exsanguinating haemorrhage. A primary aortoenteric fistula, where an untreated aneurysm exerts pressure and erodes into the GI tract, is even rarer.

Human Immunodeficiency Virus infection

Human immunodeficiency virus (HIV) infection per se rarely causes haematochezia. In such groups of patients, this poses a diagnostic challenge, as the causes related to conditions mentioned earlier are as common as GI diseases unique to HIV infection, such as cytomegalovirus-induced vasculitis, *Cryptosporidium* enteritis, *Chlamydia* proctocolitis, Kaposi sarcoma of the GI tract and lymphoma.

Miscellaneous

NSAIDs and the increasing use of antiplatelet agents, such as aspirin or clopidogrel, may result in drug-induced haematochezia by complicating existing diseases, such as diverticular disease. The same applies to anticoagulation medications, such as warfarin. NSAIDs themselves are also thought to exacerbate underlying inflammatory bowel disease. Inherited or acquired bleeding disorders should also be considered as part of the differential diagnosis.

Clinical features

History

The patient's description of the bleeding is important in helping predict the origins of the haemorrhage. The nature of bleeding should be noted, whether it is spontaneous or occurs with the passage of hard stools. Frank red blood per rectum usually indicates LGIB. Left colonic and anorectal bleeding tends to be bright red, whereas bleeding from the right side of the colon and jejunum (middle GI bleed) tends to produce dark red or maroon coloured stools.

There is a pitfall in using stool colour to distinguish between LGIB and UGIB; the nature of bleeding is a reflection of transit time of blood through the GI tract rather than the actual site of bleeding. This explains the opposing observations of haematochezia in brisk and massive bleeding from the stomach or duodenum and melaena related to caecal bleeding in patients with constipation. Up to 15% of patients with presumed LGIB have an upper GI source.

A history of haematemesis or 'coffee grounds'–like vomitus is useful in directing initial investigation to the upper GI tract (see Chapter 7.6).

Bleeding from a vascular source such as haemorrhoids, diverticula or angiodysplasia tends to be 'painless'—that is, there are few other abdominal symptoms. This is opposed to infection, inflammation or ischaemia of the bowel, where patients often report abdominal pain, tenesmus, diarrhoea or constipation.

Colorectal cancers often produce painless bleeding; a careful history may discover other significant symptoms, such as change in bowel habits and/or loss of both weight and appetite. Symptoms of infection and abdominal or GI trauma should be sought.

With respect to the acuity and severity of bleeding, estimation of the volume of blood loss by the patient is almost always unreliable. Patients who have significant acute blood loss are likely to have symptoms of shock such as giddiness, syncope, palpitations, breathlessness and diaphoresis. Those who have anaemia from chronic bleeding will report fatigue, malaise, breathlessness on exertion and giddiness.

Medical history of pre-existing GI problems—inflammatory bowel disease, diverticular disease, angiodysplasia, colorectal cancers and/or previous colonoscopy—should be noted. Relevant history of co-morbidities would include atherosclerotic disease, diabetes, ischaemic heart disease, HIV infection, liver cirrhosis, coagulopathy and drug therapy (NSAIDs, steroids, aspirin, antiplatelet agents, warfarin or chemotherapy).

Examination

Initial evaluation should begin with an assessment of the haemodynamic consequences of bleeding. Overt signs of haemorrhagic shock include altered mental status, hypotension, tachycardia, pallor, diaphoresis; these point to massive bleeding. Orthostatic hypotension and anaemia are also indicative of significant bleeding.

In patients with significant haematochezia, it is important to quickly determine whether the source is UGIB in origin. Aspiration of blood or coffee-grounds aspirate from the stomach through a nasogastric tube is indicative of UGIB, but this test is not a good negative predictor and should not be performed routinely.

The abdomen should be examined and palpated for tenderness, which may indicate an inflammatory cause for the bleeding. The anorectal region should be inspected and examined via proctoscopy for local disease, such as fistulae, fissures, abscesses or bleeding haemorrhoids. The finding of proctitis together with other clinical features may suggest underlying Crohn disease. A digital rectal examination provides information on the nature of the stools, bleeding and presence of a rectal mass. However, the presence of anorectal disorders does not preclude a more proximal source of bleeding.

Clinical investigations

Blood tests

The laboratory investigation most directly relevant to LGIB is the full blood count. The haemoglobin (Hb) and haematocrit (Hct) values give an indication of the severity of bleeding and the need for blood transfusion.

Blood should also be sent for type and screen in anticipation of blood-product use. Coagulation profile is also indicated in patients with known coagulopathy, on anti-coagulants or those who are critically ill from bleeding.

The renal function test will evaluate acute kidney injury from blood loss. The urea level is also one of the variables in the Glasgow-Blatchford score, the risk-assessment tool for UGIB. A liver function test is of limited use except for serum albumin, which is a component of the NOBLADS score (see later).

Point-of-Care Ultrasonography

In the appropriate clinical context, point-of-care ultrasonography (POCUS) has a role in the diagnosis and management of LGIB. The finding of a high-rupture-risk abdominal aortic aneurysm (>6 cm) may prompt the consideration of aortoenteric fistula as a cause. In dengue infection, the presence of a significant intra-abdominal fluid leak precedes the development of severe dengue and its associated bleeding complications. These findings together GI bleeding symptoms indicate significant morbidity and a high mortality risk. The skilful sonographer can use trans-abdominal ultrasound to detect inflammatory causes of haematochezia, such as ulcerative colitis and ischaemic enterocolitis, in the non-rectal segments of the lower GI tract.

The other uses of ultrasound are in the evaluation of volume status, guidance of fluid replacement and ultrasound-guided venous access.

Risk Assessment

The key focus of LGIB evaluation in the ED is risk assessment for severe bleeding and adverse outcome. Several factors identified for poor outcomes include haemodynamic instability (tachycardia, hypotension, syncope) at presentation, ongoing bleeding, comorbid illness, age above 60 years, a history of diverticulosis or angioectasia, an elevated creatinine and anaemia (initial haematocrit ≤35%).

A study found eight clinical variables as independent risk factors for adverse outcomes: age ≥65 years, use of NSAIDs, no diarrhoea, no abdominal tenderness, blood pressure of 100 mg Hg or lower, use of antiplatelet drugs, albumin level less than 3.0 g/dL, disease scores of 2 or higher and syncope. When all these factors were

combined, a NOBLADS score was derived and validated (Fig. 7.13.1). Patients with a score of less than 2 are deemed low risk and could be managed as outpatients, whereas those with scores of 4 or greater were likely to suffer from severe bleeding and required transfusions or haemostatic interventions.

Management

The approach to patients with haematochezia will differ depending on their risk profiles. The priorities are haemodynamic stabilization, localization of the bleeding site and the formulation of an interventional plan (Fig. 7.13.1).

High risk

Patients who have signs of significant blood loss or are in haemorrhagic shock should be placed on close continuous cardiac and haemodynamic monitoring at the ED. The focus is on airway, breathing and circulation with optimization of oxygen delivery. Crystalloids or colloids are the initial fluids for volume replacement, administered as an initial fluid challenge of 500 mL over 30 minutes. Subsequent fluid resuscitation is tailored to the patient's parameters and clinical status. In non-responders to fluid challenge, blood products should be given as 'the fluid of choice'. Patients who receive massive blood transfusion should be given platelets and fresh frozen plasma as well. Immediate reversal of any acquired coagulopathic state (vitamin K, fresh frozen plasma or prothrombin complex) should be carried out.

For patients on anticoagulant agents, the need for reversal should be weighed against the risk of thromboembolic events. This decision requires consultation with the respective disciplines involved in the patient's care. The goal of resuscitation is the normalization of blood pressure and heart rate before endoscopic procedures.

Moderate risk

Patients with moderate bleeding at presentation or non-massive persistent bleeding require admission and close observation. These patients would generally require colonoscopy, ideally performed within 24 hours. Measures should be taken to reduce the risk of re-bleeding, such as avoidance of NSAIDs or a review of the need for reversal of anticoagulation therapy.

Low risk

Most patients who present with mild intermittent bleeding usually have anorectal conditions. Those with risk factors for re-bleeding (i.e. age 60 and above, especially with co-morbidities, history of diverticulosis or angiodysplasia, recent admission or colonoscopy for LGIB) should preferably be observed and receive a surgical consult. The rest can be discharged home and arrangements made for outpatient care with either a surgical or a gastroenterology service. On follow-up, colonoscopic examination for patients above 50 years of age is expected.

Definitive Investigations and Management of Lower Gastrointestinal Bleeding

Colonoscopy

Colonoscopy is the procedure of choice for the management of LGIB. Urgent colonoscopy (within 8 hours) is more likely to identify a definite source of bleeding (in 74% to 82% of patients) compared with delayed colonoscopy (within 48 hours). It also offers the ability to establish tissue diagnosis by biopsy and to perform therapeutic interventions (adrenaline injection, bipolar coagulation or haemo-clipping). These have high success rates, particularly in active diverticular bleeding (70% to 100% success) or post-polypectomy bleeding (95% to 100% success). Adequate bowel preparation

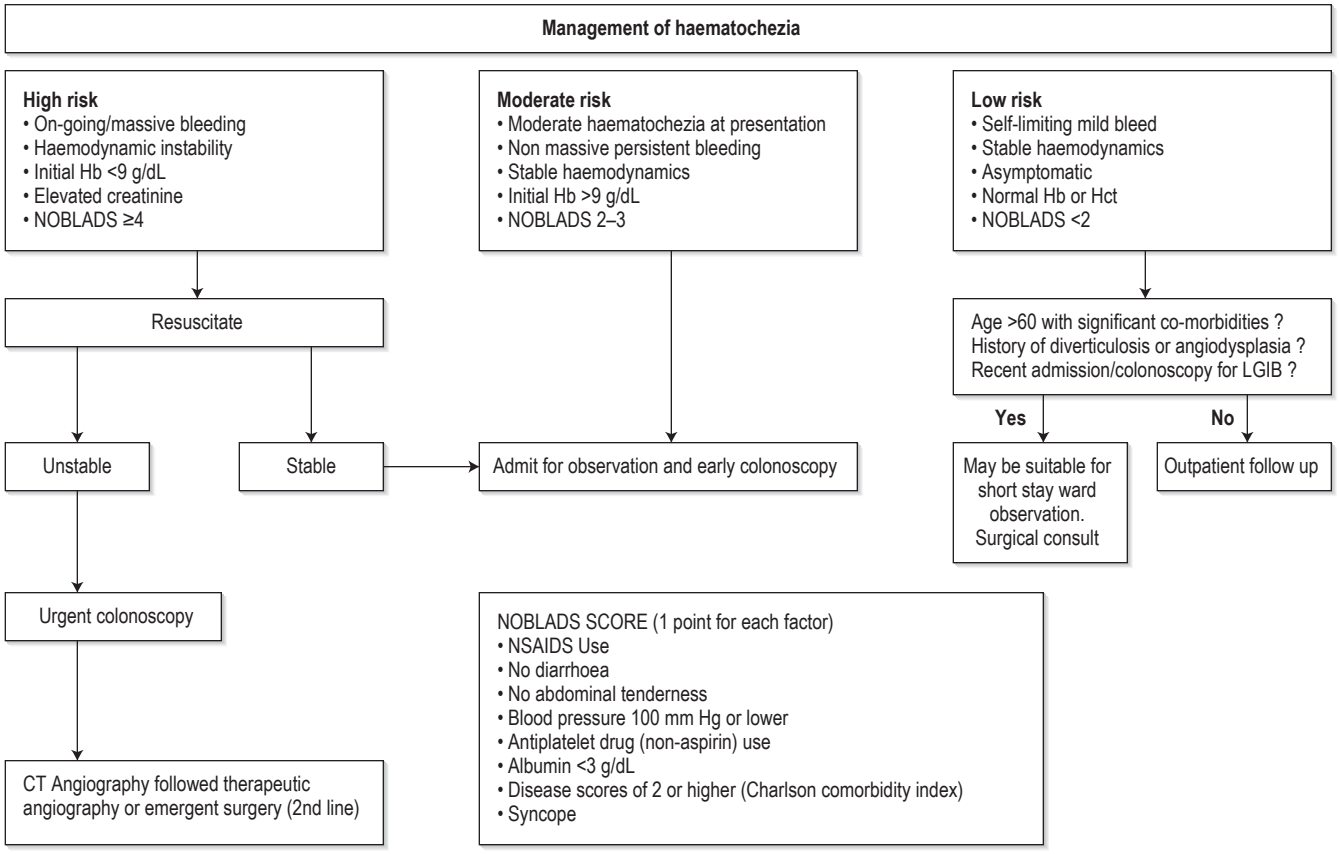

FIG. 7.13.1 Management of haematochezia. *CT*, Computed tomography; *Hb,* haemoglobin; *Hct,* haematocrit; *LGIB,* lower gastrointestinal bleeding.

is necessary for colonoscopic procedures to be successful.

Oesophagogastroduodenoscopy

Consideration should be given as to whether an oesophagogastroduodenoscopy should be done prior or at the same time as the colonoscopy. There is evidence that in patients with severe haematochezia, 11% to 15% had upper GI tract lesions, so some authors recommend endoscopy of the upper GI tract as the initial examination in this group.

Multi-detector computed tomography angiography

Computed tomography angiography (CTA) is a modality for localizing GI bleeding sites in patients who are haemodynamically unstable or cannot tolerate bowel preparations for colonoscopy. The sensitivity for the localization of bleeding sites varies according to severity; highest (91% to 92%) for active bleeding, dropping to 45% to 47% when the bleeding is intermittent.

Angiography

Selective mesenteric angiography has traditionally been the investigation of choice for localization of bleeding where it may be difficult to perform colonoscopy or following colonoscopy where the bleeding site was not identified. It is performed by an interventional radiologist injecting contrast into the superior mesenteric artery, inferior mesenteric artery and coeliac trunk in sequential order. A positive study is where there is extravasation of contrast seen during fluoroscopy. Sensitivity varies widely (27% to 86%), but it is reported to detect bleeding when the rate is more than 0.5 mL/min.

During angiography, superselective embolization via a microcatheter can stop bleeding with a success rate of 80% to 100%. Selective vasopressin infusion is used as a second line when embolization procedure is not feasible.

Technetium-labelled red blood cell scans

There is considerable debate regarding the utility of tagged red blood cell (^{99m}Tc RBC) scintigraphy to localize GI bleeding prior to angiography. Tagged RBC scintigraphy study may increase the diagnostic yield of angiography and enables targeted contrast injection. If tagged RBC scintigraphy is positive, angiography should be performed immediately following to maximize the chance of a positive test. The ability of tagged RBC scintigraphy to accurately localize a bleeding source is suboptimal (65% to 80%) and bleeding location should be confirmed prior to surgical resection particularly if the tagged RBC scintigraphy is positive only on delayed images. One advantage of tagged RBC scintigraphy is the ability to perform repeated scans after the initial injection of tagged cells. This makes RBC scintigraphy most suitable for the evaluation of intermittent, obscure-overt GI bleeding.

Other imaging modalities

Magnetic resonance imaging (MRI) is a useful modality for the investigation of rectal cancer and provides good visualization of important local prognostic factors. Endoscopic ultrasound is the modality of choice for small superficial tumours. Given its current promise of offering high sensitivity, specificity and accuracy, the indications for positron emission tomography (PET) may well expand in the future, but its final role is yet to be determined.

Wireless capsule endoscopy (WCE) is the modality of choice for visualization of small bowel bleeding. WCE is indicated where the bleeding source is not identified by the above methods or after a negative oesophagogastroduodenoscopy and colonoscopy or scintigraphy.

Surgery

Surgery for acute LGIB should be considered only after other therapeutic options have failed and should take into consideration extent and success of prior bleeding control measures, severity and source of bleeding, and level of co-morbid disease. It is important to very carefully localize the source of bleeding whenever possible prior to surgical resection to avoid continued or re-bleeding from an un-resected culprit lesion.

CONTROVERSIES

The decision to use antiplatelet and anticoagulant medications after an episode of LGIB requires a multidisciplinary approach that takes into consideration the risk of bleeding as well as the risk of thromboembolic events. During the first 30 days following coronary stenting, the risk of death and myocardial infarction is doubled in patients who have discontinued clopidogrel. The risk associated with discontinuation is also high in the first 90 days following an acute coronary syndrome. However, discontinuation for up to 7 days in patients with more distant coronary stenting or coronary syndrome appears to be safe as long as aspirin therapy is continued.

7.14 Perianal conditions

Michael R. Augello

ESSENTIALS

1 **Anal pain, bleeding and masses are common symptoms in many different types of anorectal pathology. A careful history and anorectal examination are important in making the correct diagnosis.**

2 **Increasing fibre intake and reducing constipation are effective initial treatments for mild, uncomplicated haemorrhoidal disease and perianal fissures.**

3 **Anorectal abscesses require incision and drainage. In some cases, this can be done safely in the emergency department, but all supralevator, intersphincteric and ischiorectal abscesses require formal surgical exploration and drainage in theatre.**

4 **Incision and drainage of cutaneous abscesses is not associated with bacteraemia in immunocompetent, afebrile adults, so routine antibiotic cover is not required.**

5 **Irreducible haemorrhoids require urgent reduction and surgery.**

Anorectal abscesses and fistulae

Introduction

Anorectal abscesses and fistulae are the acute and chronic phases of the same disease. An infection in the anal gland caused by occlusion of the crypt is the usual source. Anorectal abscesses are twice as common in men as in women and are most common between 20 and 40 years of age.[1] Associated factors may include inflammatory bowel disease, infection, trauma, surgery, malignancy, radiation and immunosuppression. Fistula formation following the first presentation of an anorectal abscess occurs overall in about 20% of cases, with higher rates in patients with Crohn disease.[2] Fistulous tracts may be multiple and be intimately related to the sphincters essential for continence. Treatment of anorectal fistulae is complex and the domain of colorectal surgeons.

Perianal pain is the most common symptom. Swelling and fever may also be present. Examination reveals a tender, erythematous, fluctuant mass in the anorectal region.

One commonly used classification system (Fig. 7.14.1) is according to the four potential anorectal spaces they may occupy.

Perianal abscess

Perianal abscess presents as a painful lump around the anal verge, usually lateral and posterior to the anus. It may result from an infected anal gland or, more rarely, is a presentation of Crohn disease. Systemic symptoms are uncommon. On examination, most will be pointing, with an indurated red area that may be fluctuant. Such abscesses may be suitable for incision and drainage in the emergency department (ED).

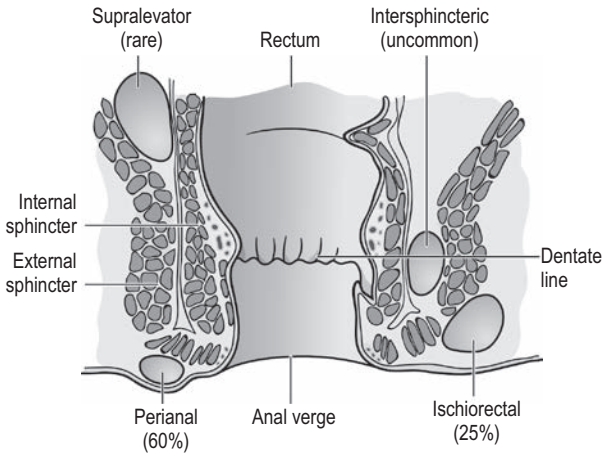

FIG 7.14.1 Anatomic locations of anorectal abscesses. (Reproduced with permission from Pfenninger J & Fowler G 2011 Pfenninger & Fowler's Procedures for Primary Care. Saunders)

Ischiorectal abscess

Ischiorectal (or perirectal) abscesses tend to be larger yet may present with less dramatic cutaneous findings because of the compressibility of ischiorectal fat. Patients may be febrile and systemically unwell. The area of induration is likely to be large and more lateral than a simple perianal abscess. Pointing may not occur until late and the initial assessment may seem more like buttock cellulitis.

Intersphincteric abscess

Intersphincteric or submucous abscesses are within the anal canal, between the internal and external sphincter. These abscesses may be associated with severe pain and with urinary symptoms although no external swelling may be visible. They point within the anal canal and may rupture spontaneously.

Supralevator abscess

Supralevator abscesses arise above the levator ani. They can be considered to be pelvic abscesses and are often secondary to intra-abdominal conditions such as diverticular disease or Crohn disease. A supralevator abscess may present as pyrexia of unknown origin. The patient may present with pain on defecation and altered bowel habit. Inspection of the perineum may be normal but rectal examination will reveal a firm, spongy, tender mass.

Treatment

The treatment of all anorectal abscesses is incision and drainage. There is no role for antibiotic treatment alone. Small perianal abscesses can be considered for drainage in the ED using local anaesthesia. Radial, curvilinear and/or a cruciate incision may be used, although each has different risks and benefits in regard to further fistula surgery and anal sphincter damage.[3] All other larger and more complicated anorectal abscesses are best treated under general anaesthesia by a surgeon with colorectal expertise in order to minimize the risk of complications including

fistula formation and damage to the anal sphincter. Diagnosis of fistulous disease is suspected on a history of recurrent perianal suppuration and is confirmed by the delineation of fistulous tracks during surgery under anaesthesia. In carefully selected patients, immediate management of the fistula may decrease recurrence or persistence of abscess without an increase in incontinence.[4] The drained wound should be kept open long enough for the abscess to heal from below and may require placement of a formal drain. Aggressive probing of the cavity should be avoided, as it can lead to iatrogenic fistulae. Regular sitz baths, review and dressing changes should continue until healing is confirmed. Antibiotics are ineffective and are indicated only as an adjunct in patients with valvular or rheumatic heart disease, diabetes, immunosuppression, extensive cellulitis or a prosthetic device.[5]

Pilonidal disease

Introduction

Pilonidal disease is an acquired recurrent disease of young adults, affecting men more commonly than women. It is a separate entity to anorectal abscess. The pathogenesis is the migration of loose hair ends into the natal cleft, where they become embedded, causing irritation and inflammation. A pilonidal sinus or abscess may then form around these loose hairs. The clinical spectrum of pilonidal disease includes acute abscess, formation of sinus tracts and complex disease with chronic or recurrent abscesses and extensive, branching sinus tracts. Risk factors include hirsutism, obesity, sedentary occupation and local irritation.[6]

Patients usually describe a painful lump in the sacrococcygeal area, with or without seropurulent discharge. Systemic symptoms are uncommon. Examination commonly reveals pain, swelling and discharge in the natal cleft. There may also be one or more midline draining pits or sinuses. Occasionally hair is seen protruding from a pit.

Treatment

Initial treatment for an acute pilonidal abscess should be incision, preferably off midline, over the area where the abscess is pointing, with drainage and evacuation of pus and hair. This may take place under local or general anaesthesia and, in up to 58% of patients, no further treatment is required. Healing may take up to 10 weeks, so additional surgery should not be considered early but may be required in up to 63% for treatment failure or late recurrence.[7] Laser hair depilation may have some benefit in preventing recurrence, although shaving is associated with a higher recurrence rate. Failure of initial treatment and delayed recurrence are not uncommon. More complex surgical procedures—including various forms of open and closed excision, marsupialization of sinus tracts and the use of fibrin glue—is reserved for complex disease that fails more simple procedures as the healing time and hospital stays a—re more prolonged.[8]

Haemorrhoids

Introduction

Haemorrhoidal cushions are normal anatomical structures located in the anal canal; they play a role in differentiating between liquids, solids and gas and maintaining anal continence. Haemorrhoids are composed of cushions of submucosal vascular tissue, usually located in the 3, 7 and 11 o'clock positions as viewed through an anoscope with the patient in the lithotomy position. Haemorrhoidal disease occurs when there are symptoms such as bleeding, prolapse, pain, thrombosis, a mass, discharge or pruritus. Straining, inadequate fibre intake, prolonged sitting on the toilet, constipation, diarrhoea, pregnancy and other conditions with elevated intra-abdominal pressure have been suspected to contribute to the development of the disease.

The dentate line divides haemorrhoidal tissue into internal and external haemorrhoids. Internal haemorrhoids are classically painless and are divided into four grades, depending on the degree of prolapse (Table 7.14.1).

Clinical features and differential diagnosis

Painless, bright red bleeding during defecation is the most common symptom, with the blood not mixed in stool but streaked on pain or on toilet paper. Bleeding between bowel actions or blood mixed with the stool should raise suspicion of other pathologies, such as diverticular disease or neoplasia, and requires further investigation. Other symptoms include pruritus, a sensation of inadequate cleaning, or a tender lump. Severe pain is uncommon and should raise suspicion of alternate pathologies.

Table 7.14.1 Grades of internal haemorrhoid and clinical features

Grade of internal haemorrhoid	*Clinical features*
Grade 1	Cause painless bleeding; do not prolapse
Grade 2	Prolapse, usually after straining at stool, but reduce spontaneously
Grade 3	Prolapse and require digital reduction
Grade 4	Prolapsed and irreducible

Examination involves observing the perineum with the patient straining. Redundant skin tags may be present. Grape-like structures may be seen to bulge around the classic 3, 7 and 11 o'clock positions. Anoscopy may reveal one or more internal haemorrhoids.

Differential diagnoses to consider include colorectal malignancy, inflammatory bowel disease, anal warts and other anorectal conditions. Patients with any suspicious findings on history or examination, iron-deficiency anaemia, positive faecal occult blood tests, those aged over 40 years with a positive family history of neoplasia and those aged over 50 years with no recent colonoscopy should be evaluated further with colonoscopy to exclude more serious disease.[9]

Treatment

Conservative treatment aimed at reducing constipation is often successful, especially in less severe disease. Increasing the intake of dietary fibre decreases overall haemorrhoidal symptoms by over 50%, especially bleeding.[10] Stool softeners to reduce straining and constipation, as well as sitz baths, are recommended to assist with symptom control. Topical agents (e.g. 0.2% glyceryl trinitrate [GTN] paste, such as Rectogesic) have shown a reduction in overall haemorrhoidal symptoms as well as bleeding.[11] GTN paste works by relaxing the muscles around the anus. Relaxing the muscles increases the flow of blood to the area, which eases pain. Ice applied topically may assist in the control of acute symptoms.

Many other popular over-the-counter medications are available. These include suppositories, creams, ointments and pads that contain various cocktails of local anaesthetics, steroids, vasoconstrictors, antiseptics, keratolytics, protectants (such as mineral oils and cocoa butter) and astringents. There is no evidence to show that these agents have any benefit in the prevention or long-term treatment of haemorrhoidal disease. There is also no evidence that spicy food worsens haemorrhoidal symptoms.[12] Haemorrhoidal conditions that may benefit from specific timely treatment include prolapsed irreducible haemorrhoids and thrombosed external haemorrhoids.

Prolapsed irreducible haemorrhoids

Prolapsed irreducible haemorrhoids may become gangrenous and usually cause severe pain. Reduction can sometimes be achieved using adequate analgesia, a foot-up tilted trolley, ice, local anaesthesia and firm slow pressure applied digitally. If these measures are successful, the requirement for surgery may change from emergency to urgent elective.

Thrombosed external haemorrhoids

A thrombosed external haemorrhoid presents as a painful tender mass in the anus, often following an episode of constipation or diarrhoea. Examination reveals a bluish, exquisitely tender skin-covered lump sited lateral to the anus. Pain peaks at 48 hours before gradually easing. If the patient presents in severe pain within 48 hours of onset, surgical excision may result in earlier pain relief and reduced rates of recurrence at 1 year as compared with incision alone or conservative treatment. Conservative treatment will also ultimately result in the resolution of symptoms.[13]

Procedural treatment options

Procedural options for haemorrhoidal disease are reserved for mild disease that has failed conservative procedures, grade 3 or 4 haemorrhoids, as well as strangulated and/or thrombosed haemorrhoidal disease. Procedural options include rubber-band ligation, sclerosant injection, infrared photocoagulation (for haemorrhoids above the dentate line), progressing to more invasive surgical procedures including haemorrhoidectomy and stapled haemorrhoidopexy. All surgical techniques may be associated with a significant amount of postoperative pain and bleeding.[14]

Anal fissure

Introduction

Anal fissure is a painful linear ulcer situated in the anal canal. It has a similar incidence in both males and females and is found in the posterior midline in 90% of cases. The anterior midline accounts for almost all other cases. When an anal fissure is not found in the midline, secondary causes such as Crohn disease or malignancy require exclusion. Although hard stool is most commonly implicated as the initiating trauma, loose stools may also be associated. Anal spasm and decreased blood flow to the posterior midline anal canal maintains the ulcer. Most acute anal fissures heal with conservative treatment. Some go on to become chronic and develop secondary changes, forming a fibrous skin tag, often referred to as a sentinel pile, as well as hypertrophied anal papillae and relative anal stenosis due to scarring.

Clinical features

The history is often strongly suggestive of the condition. Typically patients describe severe, knife-like, intense anal pain initiated during the passage of stool, described as a feeling of being 'split open'. The pain may persist for hours, with a tight throbbing quality and is usually accompanied by a small amount of bright red rectal blood, often as a smear on the toilet paper.

Inspection of the perineum may reveal tightening of the corrugator cutis ani, an almost diagnostic sign of anospasm that is usually secondary to a fissure. If a small midline 'sentinel' pile is seen, the diagnosis is confirmed. Gentle retraction of the perianal skin usually allows one to visualize the fissure directly. Rectal examination and anoscopy should be deferred until the acute pain has subsided. Anal fissure is sometimes complicated by abscess formation in the sentinel pile. This is suggested by a very swollen oedematous tag and requires surgical drainage.

Treatment

In acute fissures, conservative treatment is effective in up to 50% of cases. Warm baths may help to relieve sphincter spasm. Stool softeners (such as docusate), bulk-forming laxatives (such as bran) and high-fibre food are the mainstays of medical treatment. Acute relief of pain and spasm can be achieved with local anaesthetic gel.

Avoidance of constipation is probably the single most important non-operative treatment. Recurrence of symptoms after initial success with conservative treatment can occur, but conservative treatment still has a good success rate in preventing recurrent episodes.

Pharmacological agents that reduce internal sphincter tone and improve anodermal blood flow can also be used. GTN is marginally more successful than placebo. Topical treatments direct to the anus or by transdermal patch placed elsewhere have been shown to be equivalent, but headache may cause 1 in 5 patients to abandon treatment. Calcium channel blockers and injection with botulinum toxin (Botox) are alternatives, with no treatment showing clear superiority. Topical calcium channel blocker creams are not available in Australia. Botox causes a temporary 'chemical' sphincterotomy that enables healing of a chronic anal fissure, but there may still be recurrences.

Chronic anal fissures suffer from the relatively poor success rates of all medical therapies.[15] Failed medical therapy in acute and all chronic fissures warrants surgical referral. Modern surgical practice achieves long-term cures in about 90% of cases, with the most serious surgical complication of anal incontinence occurring in up to 20% of this population.[16] Lateral internal sphincterotomy is safer than controlled anal dilatation.[17]

Pruritus ani

Pruritus ani is a dermatological condition characterized by an unpleasant itchy or burning sensation in the perianal region. Although it may be due to a definable perianal dermatological condition—including psoriasis, eczema and lichen sclerosis—most cases are idiopathic. Fungal, bacterial or parasitic infections such as pinworm and pediculosis are rare causes (except in children). Contributing factors may include excessive attempts at hygiene causing local irritation, loose stools, prolapsing haemorrhoids and the frequent use of anorectal creams and ointments, which may lead to perianal wetness with maceration of the skin and contact dermatitis. An itch-and-scratch cycle that can be very difficult to break results in chronic skin changes including lichenification. It is important to consider rare neoplasms, such as Bowen disease, lymphoma and Kaposi sarcoma, all of which may cause pruritus.

Persistent itchiness in the anal region can be a difficult condition to treat. Potential identified causes should be treated appropriately. Idiopathic cases may benefit from reassurance, discontinuation of previously tried anorectal medications and avoidance of irritants, such as bar soap and vigorous scrubbing. Avoiding foods identified as exacerbating symptoms may be tried, as well as air-drying the area after sitz baths. A short course of topical hydrocortisone or Sorbolene cream may provide relief and a break in the itch-and-scratch cycle.[18]

Proctalgia fugax

Proctalgia fugax is episodic, sudden and unpredictable onset of shearing or knife-like pain in the anus and rectum. It is usually of very short duration and is most common in males. Apart from reassurance, no specific therapy is usually required. When pain is more long-standing and no overt cause is found clinically and on investigation, it is managed as part of the spectrum of functional anorectal pain disorders.[19]

Injuries and foreign bodies in the perianal region

History is paramount and sexual violence needs consideration. Examination should focus on the function of the sphincter and be alert to the possibility of intra-abdominal extension of penetrating injuries causing perforation. Plain films may assess position of any foreign body as well as the presence of free intra-abdominal gas, raising the suspicion for perforation. If perforation is not present and the object is low-lying, most foreign bodies will be successfully removed transanally.[20,21] Except for extremely low-lying objects within easy reach, foreign bodies should be removed in theatre.

Other anorectal conditions

Other important local conditions not covered in this chapter but to be considered in the differential diagnosis of most anorectal conditions include proctitis, rectal prolapse, Fournier gangrene, faecal impaction, condylomata acuminata (warts associated with human papillomavirus), condylomata lata (flat white lesions associated with secondary syphilis) and carcinoma. A complete anorectal examination reduces the risk that such conditions will be missed or misdiagnosed.

CONTROVERSIES

- If some anorectal abscesses can be drained in the ED under local anaesthesia, how do we select the appropriate cases?
- Are thrombosed external haemorrhoids better managed by early excision or conservative management?
- What is the optimal long-term treatment strategy for pilonidal disease?
- Is botulinum toxin any more effective than GTN ointment and topical calcium channel blockers in the treatment of acute anal fissure?
- What role, if any, do antibiotics play in perianal suppurative diseases?
- How do you select foreign bodies to be considered for attempted removal in ED?

SECTION 8

NEUROLOGY EMERGENCIES

Edited by *Conor Deasy*

8.1 Headache

Anne-Maree Kelly

ESSENTIALS

1 **The pathophysiological basis of headache is understood to be traction or inflammation of extracranial structures, the basal dura or the large intracranial arteries and veins, dilatation/distension of cranial vascular structures or activation/sensitization of perivascular nerves.**

2 **Severity of headache is not a reliable indicator of the underlying pathology.**

3 **History is of paramount importance in the assessment of headache.**

4 **A normal physical examination does not rule out serious pathology.**

5 **Sudden, severe headache and chronic, unremitting headache are more likely to have a serious cause and should be investigated accordingly.**

6 **Non-steroidal anti-inflammatory drugs (NSAIDs) and paracetamol are effective in treating tension headache.**

7 **As most patients have tried oral medications prior to attending the emergency department, parenterally administered agents are usually indicated for the treatment of migraine.**

8 **Based on current evidence, the most effective agents for treating migraine are phenothiazines and triptans. Pethidine is not indicated because it is less effective than other agents, has a high rebound headache rate and carries the potential for the development of dependence.**

9 **Carbamazepine is the agent of choice for treatment of trigeminal neuralgia.**

Introduction

Headache is a common condition that is often due to a combination of physical and psychological factors. The vast majority of headaches are benign and self-limiting and are managed by patients in the community. Only a very small proportion of patients experiencing headache attend emergency departments (ED) for treatment. The challenges are to distinguish potentially life-threatening causes from the more benign and to effectively manage the pain of headache.

Aetiology, pathophysiology and pathology

The structures in the head capable of producing headache are limited. They include the following:

- Extracranial structures, including skin and mucosae, blood vessels, nerves, muscles and fascial planes
- The main arteries at the base of the skull (as arteries branch they progressively lose the ability to produce painful stimuli)
- The great venous sinuses and their branches
- The basal dura and dural arteries, but to a lesser extent than the other structures.

The bulk of the intracranial contents—including the parenchyma of the brain, the subarachnoid and pia mater and most of the dura mater—are incapable of producing painful stimuli.

The pathological processes that may cause headache are as follows:

- Tension. This usually refers to contraction of muscles of the head and/or neck and is thought to be the major factor in 'tension headache'.
- Traction. Traction is caused by the stretching of intracranial structures due to a mass effect, as with a space-occupying lesion. Pain caused by this mechanism is characteristically constant but may vary in severity.
- Vascular processes. These include dilatation or distension of vascular structures and often result in pain that is throbbing in nature.
- Inflammation. This may involve the dura at the base of the skull or the nerves or soft tis-

Table 8.1.1 A pathophysiological classification of headache

	Extracranial	*Intracranial*
Tension/traction	Muscular headache, 'tension headache'	Intracranial tumour Cerebral abscess Intracranial haematoma
Vascular	Migraine	Severe hypertension
Inflammatory	Temporal arteritis	Meningitis
	Sinusitis	Subarachnoid haemorrhage
	Otitis media	
	Mastoiditis	
	Tooth abscess	
	Neuralgia	

sues of the head and neck. This mechanism is responsible for the initial pain of subarachnoid haemorrhage and meningitis as well as for the pain of sinusitis.

The pathophysiological causes of headache are summarized in Table 8.1.1.

Clinical features

In the assessment of a patient with headache, history is of prime importance. Specific information should be sought about the timing of the headache (in terms of both overall duration and speed of onset), the site and quality of the pain, aggravating and relieving factors, the presence of associated features—such as nausea and vomiting, photophobia and alteration in mental state—medical and occupational history and drug use.

Intensity of the pain is important from the viewpoint of management but is not a reliable indicator of the nature of underlying pathology. This said, sudden, severe headache and chronic, unremitting or progressive headache are more likely to have a serious cause.

Physical examination should include temperature, pulse rate and blood pressure measurements, assessment of conscious state and neck stiffness and a neurological examination. Other physical examination should be guided by the clinical presentation. Abnormal physical signs are uncommon, but the presence of neurological findings makes a serious cause probable. In addition, a search should be made for sinus, ear, mouth and neck pathology and muscular or superficial temporal artery tenderness.

Headache patterns

Some headaches have 'classic' clinical features: these are listed in Table 8.1.2. It must be remembered that, as with all diseases, there is a spectrum of presenting features, and the absence of the classic features does not rule out a particular diagnosis. Patients should be assessed on their merits and, if symptoms persist without reasonable explanation, further investigation is indicated.

Clinical investigations

For the majority of patients with headache, no investigation is required. The investigation of suspected subarachnoid haemorrhage and meningitis is discussed elsewhere in this book. If tumour is suspected, the investigations of choice are magnetic resonance imaging (MRI) or a contrast-enhanced computed tomography (CT) scan. An elevated erythrocyte sedimentation rate (ESR) may provide supporting evidence for a diagnosis of temporal arteritis. With respect to sinusitis, facial x-rays are of very limited value.

Tension headache

The pathological basis of tension headaches remains unclear, but increased tension of the neck or cranial muscles is a prominent feature. A family history of headache is common, and there is an association with injury in childhood or adolescence. The most common precipitants are stress and alteration in sleep patterns.

Multilevel treatment—including analgesia, physiotherapy, acupuncture, behavioural therapy and in some cases botulinum toxin—is often required for patients who suffer recurrent tension headache. In the ED, non-steroidal anti-inflammatory agents (NSAIDs) and paracetamol (acetaminophen) have been shown to be effective in the treatment of tension headaches, with success rates between 50% and 70%. Ibuprofen 400 mg or ketoprofen 25 to 50 mg appears to be the most effective, followed by aspirin 600 to 1000 mg and paracetamol 1000 mg.

Migraine

Migraine can be a disabling condition. Most migraine headaches are successfully managed in the community, but a small number fail to respond to usual therapy or become 'fixed', and sufferers may present for treatment at the ED. As most patients (up to 80% in some studies) have tried oral medications prior to presenting, parenterally administered agents are usually indicated for ED treatment.

Migraine is a clinical diagnosis and, in the ED setting, a diagnosis of exclusion. Other causes of severe headache, such as subarachnoid haemorrhage and meningitis, should be ruled out before this diagnosis is made. Of particular note, the response of a headache to anti-migraine therapy should not be used to assume that the cause was migraine. There have been reports that the headaches associated with subarachnoid haemorrhage and meningitis have sometimes responded to these agents.

Pathophysiology

A detailed discussion of the pathophysiology of migraine is beyond the scope of this chapter, and knowledge in this regard is continually evolving. Current evidence supports the concept of migraine as a primarily neuronal disorder, whereas vascular changes represent an epiphenomenon. Migraine pain is mediated by the trigeminal nerve, resulting in the release of neuropeptides and trigeminal-mediated meningeal and brain stem events.[1]

Classification and clinical features

Migraine is defined as an idiopathic recurring headache disorder with attacks that last 4 to 72 hours. Typical characteristics are unilateral location, pulsating quality, moderate or severe intensity and aggravation by routine physical activity. There is also usually nausea, photophobia and phonophobia.

In some patients, migraine is preceded by an 'aura' of neurological symptoms localizable to the cerebral cortex or brain stem, such as visual disturbance, paraesthesia, diplopia or limb weakness. These develop gradually over 5 to 20 minutes and usually last less than 60 minutes. Headache, nausea and/or photophobia typically follow after an interval of less than an hour.

Several variant forms of migraine have been defined, including ophthalmoplegic, abdominal, hemiplegic and retinal migraine, but all are uncommon. In ophthalmoplegic migraine, the headache is associated with paralysis of one or more of the nerves supplying the ocular muscles. Horner syndrome may also occur. Abdominal migraine manifests as recurrent episodes of abdominal pain for which no other cause is found. Retinal migraine, which is fortunately

very rare, involves recurrent attacks of retinal ischaemia, which may lead to bilateral optic atrophy. Hemiplegic migraine is a stroke mimic.

Treatment

A wide variety of pharmacological agents and combinations of agents have been tried for the treatment of migraine, with varying results. Interpreting the evidence is challenging, as the majority of the studies have small sample sizes, compare different agents or combinations of agents, are conducted in settings other than EDs and the outcome measure or measures tested vary widely. For mild to moderate migraine headache in patients who have not taken other medication, aspirin 900 mg combined with metoclopramide 10 mg orally is recommended by Australian guidelines and is often effective.[2] Most ED patients, however, have either tried their usual medication or have significant nausea or vomiting, making oral therapy inappropriate.

The most effective agents appear to be the phenothiazines (chlorpromazine and prochlorperazine) and the triptans, each of which has achieved better than 70% efficacy in a number of studies.[3–6] Note that triptans are contraindicated in patients with a history of ischaemic heart disease, uncontrolled hypertension or with the concomitant use of ergot preparations. Dosing and administration are summarized in Table 8.1.3.

Although highly effective, intravenous phenothiazines can be accompanied by extrapyramidal symptoms, most commonly akathisia, a distressing syndrome of restlessness and agitation. Akathisia is usually short-lived, but patients find it unpleasant. A slower rate of medication administration is associated with less frequent akathisia. Once it develops, akathisia can be treated with benzodiazepines. Anticholinergic medications (e.g. benztropine) are often helpful when other extrapyramidal features are present.

Pethidine (meperidine) is not indicated for the treatment of migraine. Its reported effectiveness is only about 56%, it has a high rate of rebound headache and it carries a risk of dependence.[7] The data on dihydroergotamine are difficult to interpret because it is often used in combination with other agents (e.g. metoclopramide); however, it has also been shown to be less effective than chlorpromazine and sumatriptan in acute treatment and to have a high rate of unpleasant side effects. Sodium valproate and haloperidol have also shown moderate effectiveness in small studies, but there are insufficient data to draw robust conclusions regarding their efficacy relative to the agents above.

Rebound or recurrent headache is common in ED patients treated for migraine (approximately 30%). There is evidence that oral or intravenous dexamethasone, in addition to standard migraine therapy for selected patients, reduces

Table 8.1.2 Classic clinical complexes and causes of headache

Preceded by an aura Throbbing unilateral headache, nausea Family history	Migraine
Sudden onset Severe occipital headache; 'like a blow' Worst headache ever	Subarachnoid haemorrhage
Throbbing/constant frontal headache Worse with cough, leaning forward Recent URTI Pain on percussion of sinuses	Sinusitis
Paroxysmal fleeting pain Distribution of a nerve Trigger manoeuvres cause pain Hyperalgesia of nerve distribution	Neuralgia
Unilateral with superimposed stabbing Claudication on chewing Associated malaise, myalgia Tender artery with reduced pulsation	Temporal arteritis
Persistent deep-seated headache Increasing duration and intensity Worse in morning Aching in character	Tumour, primary or secondary
Acute generalized headache Fever, nausea and vomiting Altered level of consciousness Neck stiffness ± rash	Meningitis
Unilateral, aching, related to eye Nausea and vomiting Raised intraocular pressure	Glaucoma
Aching, facial region Worse at night Tooth sensitive to heat, pressure	Dental cause

URTI, Upper respiratory tract infection.

Table 8.1.3 Drug dosing and administration

Agent	*Drug dosing/ administration*	*Common adverse effects*	*Precautions*
Chlorpromazine (IV)	12.5 mg IV, repeated q 20 min as needed to a maximum dose of 37.5 mg, accompanied by 1 L normal saline over 1 h to avoid hypotension OR 25 mg in 1 L normal saline over 1 h, repeated if necessary	Akathisia, drowsiness, postural dizziness if not administered IV fluids	
Prochlorperazine (IM or IV)	10/12.5 mg (depending on packaging)	Akathisia, drowsiness	
Sumatriptan (SC, IN)	6 mg SC, 20 mg IN	Flushing, dizziness, palpitations, drowsiness, injection site reactions	Use cautiously in patients with cardiovascular risk factors or who have already received triptans within 24 h.
Metoclopramide (IV)	10–20 mg	Akathisia, drowsiness, dizziness, feeling weak	
Ketorolac (IM or IV)	30 mg IV, 60 mg IM	Usually well tolerated	
Tramadol (IM)	100 mg	Drowsiness, feeling weak, dry mouth	

IV, intravenous; *IM*, intramuscular; *SC*, subcutanous; *IN*, intranasal.

the proportion of patients who experience early recurrence (so-called rebound headache). A meta-analysis of published papers reports a 26% reduction in the relative risk of headache recurrence within 72 hours. Doses used were 10–24 mg IV or 8 mg orally.[8]

Trigeminal neuralgia

Trigeminal neuralgia is a debilitating condition in which patients describe pain that is like 'lightning' or a 'hot poker' that is severe and follows the distribution of the trigeminal nerve. Individual episodes of pain last only seconds, but may recur repeatedly within a short period and can be triggered by minor stimuli, such as light touch, eating or drinking, shaving or a passing gust of wind. It is most common in patients who are middle-aged or older.

Aetiology and pathophysiology

Evidence suggests that the pathological basis of trigeminal neuralgia is the demyelination of sensory fibres of the trigeminal nerve in the proximal (central nervous system) portion of the nerve root or, rarely, in the brain stem, most commonly due to compression of the nerve root by an overlying artery or vein. A minority of cases are symptomatic of multiple sclerosis or nerve compression by tumour.

Trigeminal neuralgia is classified as classic trigeminal neuralgia (no cause identified) and symptomatic trigeminal neuralgia (secondary to another condition). Characteristics associated with symptomatic trigeminal neuralgia are trigeminal sensory deficits and bilateral involvement.

Clinical investigations

In approximately 15% of cases, there is a structural cause for trigeminal neuralgia. For this reason there is some support for routine neuroimaging (CT, MRI) in these patients. Electrophysiological assessment of trigeminal reflexes can also be helpful in distinguishing classic from symptomatic trigeminal neuralgia. The choice between the two approaches will depend on availability, expertise, cost and patient and the treating clinician's preference.

Treatment

Trigeminal neuralgia is most commonly treated with carbamazepine, the mainstay of therapy. The usual starting dose is 200 to 400 mg/day in divided doses, increased by 200 mg/day until relief up to a maximum of 1200 mg/day. The average dose required is 800 mg/day. If the patient responds well, a controlled-release preparation can be substituted and the dose can gradually be reduced. For patients who fail first-line therapy a range of options have been proposed including baclofen, gabapentin, lamotrigine, oxcarbazepine, phenytoin and pimozide. There is little evidence to guide choice among these agents. Referral for consideration of surgery is appropriate in patients who are refractory to medical therapy.[9,10]

Temporal (giant cell) arteritis

Giant cell arteritis is the most common form of vasculitis in patients aged over 50 years. It affects large and middle-sided blood vessels with a predisposition for the cranial arteries arising from the carotid arteries. Clinical features include headache, painless vision loss, jaw claudication, fatigue, fever, anorexia and temporal artery tenderness. Loss of vision is the most common severe complication. Involvement of extracranial arteries including the aorta is more frequent than previously assumed. Inflammation markers in blood are usually elevated, but specific laboratory tests for the diagnosis of giant cell arteritis are not available. Imaging using ultrasonography, MRI and positron emission tomography can be useful to confirm, localize and assess the extent of vascular involvement. Temporal artery biopsy is the gold standard for diagnosis. Glucocorticoids are the standard therapy (50 to 100 mg/day). Patients with acute visual changes secondary to giant cell arteritis should receive parenteral corticosteroid therapy and be admitted until their condition stabilizes.

CONTROVERSIES

- Choice of drug therapy for migraine.
- Role and timing of investigations in atypical migraine. CT or MRI may be indicated acutely to rule out other intracranial pathology.
- The role of corticosteroids in prevention of recurrent/rebound migraine.
- Role and timing of investigations, in particular neuroimaging, for persistent or atypical headache.
- Second-line treatment for trigeminal neuralgia.

8.2 Stroke and transient ischaemic attacks

Philip Aplin • Mark Morphett

ESSENTIALS

1 **Ischaemic strokes and transient ischaemic attacks (TIAs) are most commonly due to atherosclerotic thromboembolism of the cerebral vasculature or emboli from the heart. Other causes should be considered in younger patients, those presenting with atypical features or when evaluation is negative for the more common aetiologies.**

2 **Haemorrhagic and ischaemic strokes cannot be reliably differentiated on clinical grounds alone; therefore further imaging, most commonly computed tomography (CT) scanning, is required prior to the commencement of antiplatelet, thrombolytic or interventional therapies.**

3 **The risk of a completed stroke following a TIA can be high—up to 15% in the first week. Clinical scoring systems, such as the ABCD² score, along with the results of brain and carotid vessel imaging, provide assessment tools for estimating stroke risk following TIA. Patients with TIA identified as at low risk for progression to stroke (e.g. ABCD² <4, minimal large vessel disease on imaging) can be safely managed through integrated rapid-access TIA assessment clinics in an outpatient setting, with admission reserved for those at higher risk.**

4 **Differentiating strokes from other acute neurological presentations may be difficult in the emergency department. This issue has implications for the use of high-risk therapies such as thrombolysis.**

5 **The early phase of stroke management concentrates on airway and breathing, rapid neurological assessment of consciousness level, pupillary size, lateralizing signs and blood sugar measurements. Hyperglycaemia may worsen neurological outcome in stroke; therefore glucose should not be given in likely stroke patients unless a low blood sugar level is objectively demonstrated.**

6 **Outcomes in stroke patients are improved when they are admitted to a dedicated stroke unit. This involves a multidisciplinary approach to all aspects of stroke management.**

7 **Treating doctors should be fully aware of the risks/benefits and indications/contraindications of thrombolytic therapy in treating acute strokes. Currently, thrombolytic therapy should be considered for use in selected acute ischaemic strokes when administered within 4.5 hours of symptom onset, but controversies remain.**

8 **More complex imaging modalities, such as CT perfusion and diffusion/perfusion magnetic resonance imaging , continue to be evaluated in acute stroke workup in an attempt to better define the patient group that will benefit from aggressive vessel-opening strategies.**

9 **In the setting of acute large cerebral vessel occlusion, intra-arterial therapies such as clot retrieval devices continue to be evaluated and improved. The place of these interventions in acute stroke therapy is the subject of ongoing research. Recent trials suggest that clot retrieval may be safe in selected patients up to 24 hours after the onset of stroke symptoms.**

Introduction

Cerebrovascular disease is the third most frequent cause of death in developed countries, after heart disease and cancer. A stroke is an acute neurological injury secondary to cerebrovascular disease, either by infarction (80%) or by haemorrhage (20%). The incidence of stroke is steady and, although mortality is decreasing, it is still a leading cause of long-term disability. Transient ischaemic attacks (TIAs) are defined as transient episodes of neurological dysfunction caused by focal brain, spinal cord or retinal ischaemia without acute infarction. Causes are similar to those of ischaemic stroke, particularly atherosclerotic thromboembolism related to the cerebral circulation and cardioembolism. Diagnosis of the cause of TIAs with appropriate management is important in order to prevent a potentially devastating stroke.

Pathophysiology

Brain tissue is very sensitive to the effects of oxygen deprivation. Following cerebral vascular occlusion, a series of metabolic consequences may ensue, depending on the extent, duration and vessels involved, which can lead to cell death. Reperfusion of occluded vessels may also occur, either spontaneously or via therapeutic intervention, with the potential for reperfusion injury. An area of threatened but possibly salvageable brain may surround an area of infarction. The identification of this so-called ischaemic penumbra and therapeutic efforts to ameliorate the extent of irreversible neuronal damage have been the subject of ongoing research efforts.

Large anterior circulation ischaemic strokes can be associated with increasing mass effect and intracranial pressure (ICP) in the hours to days following onset. Secondary haemorrhage into an infarct may also occur, either spontaneously or related to therapy. Clinical deterioration often follows.

Ischaemic strokes

These are the results of several pathological processes (Box 8.2.1):

- Ischaemic strokes are most commonly due to thromboembolism originating from the cerebral vasculature, the heart or, occasionally, the aorta. Thrombosis usually occurs at the site of an atherosclerotic plaque secondary to a combination of shear-induced injury of the vessel wall, turbulence and flow obstruction. Vessel wall lesions may also be the site of emboli that dislodge and subsequently occlude more distal parts of the cerebral circulation. Atherosclerotic plaque develops at the sites of vessel bifurcation. Lesions affecting the origin of the internal carotid artery (ICA) are the most important source of thromboembolic events. The more distal intracerebral branches of the ICA, the aorta and the vertebrobasilar system are also significant sites. Acute plaque change is likely to be the precipitant of symptomatic cerebrovascular

Box 8.2.1 Causes of stroke

Ischaemic stroke
Arterial thromboembolism
- Carotid and vertebral artery atheroma
- Intracranial vessel atheroma
- Small vessel disease—lacunar infarction
- Haematological disorders—hypercoagulable states

Cardioembolism
- Aortic and mitral valve disease
- Atrial fibrillation
- Mural thrombus
- Atrial myxoma
- Paradoxical emboli
- Hypoperfusion

Severe vascular stenosis or a combination of these factors
- Hypotension
- Vasoconstriction—drug-induced, post-SAH, pre-eclampsia

Other vascular disorders
- Arterial dissection
- Gas embolism syndromes
- Moyamoya disease
- Arteritis

Intracerebral haemorrhage
Hypertensive vascular disease
Lipohyalinosis and microaneurysms
Aneurysms
- Saccular
- Mycotic

Arteriovenous malformations
Amyloid angiopathy
Bleeding diathesis
- Anti-coagulation
- Thrombolytics
- Thrombocytopenia/disseminated intravascular coagulation
- Haemophilia

Secondary haemorrhage into a lesion—tumour or infarction

SAH, Subarachnoid haemorrhage.

disease, particularly in patients with carotid stenosis. Hence the most effective therapies will probably not only target the consequences of acute plaque change, such as thrombosis and embolism, but also aim for plaque stabilization using such agents as antiplatelet drugs, statins and antihypertensive drugs along the lines used in the management of acute coronary syndromes.

- Approximately 20% of cerebrovascular events are due to emboli originating from the heart. Rarely, emboli may arise from the peripheral venous circulation, the embolus being carried to the cerebral circulation via a patent foramen ovale.
- Lipohyalinosis of small arteries is a degenerative process associated with diabetes and hypertension, which mainly affects the penetrating vessels that supply areas such as the subcortical white matter and is the postulated cause of lacunar infarcts.
- Dissection of the carotid or vertebral arteries may cause TIAs and stroke. This may occur spontaneously or following trauma to the head and neck region, particularly in young people not thought to be at risk of stroke. Distal embolization from the area of vascular injury is the main pathological process involved.
- Haemodynamic reduction in cerebral flow may occur as a result of systemic hypotension or severe carotid stenosis. In these cases, cerebral infarction typically occurs in a vascular watershed area.
- Cerebral vasoconstriction may occur in association with subarachnoid haemorrhage (SAH), migraine and pre-eclampsia and with drugs such as sympathomimetics and cocaine, which may precipitate stroke.
- Less common vascular disorders—such as arteritis, venous sinus thrombosis, sickle cell disease and moyamoya disease—may be causes of stroke.
- Venous sinus thrombosis may occur spontaneously or in relation to an underlying risk factor, such as an acquired or congenital prothrombotic disorder, dehydration or meningitis. The consequences depend on the extent and localization of the thrombosis. Stroke secondary to venous thrombosis is due to venous stasis, increased hydrostatic pressures and associated haemorrhage.

Haemorrhagic stroke

Haemorrhagic stroke is the result of vessel rupture into the surrounding intracerebral tissue or subarachnoid space. SAH is the subject of a separate chapter in this book (see Chapter 8.3).

The neurological defect associated with an intracerebral haemorrhage (ICH) is the consequence of direct brain injury, secondary occlusion of nearby vessels, reduced cerebral perfusion caused by associated raised ICP and cerebral herniation. The causes of ICH include the following:

- Aneurysmal vessel dilatation. Vascular dilatation occurs at a site of weakness in the arterial wall, resulting in an aneurysm that expands until it ruptures into the subarachnoid space and in some cases the brain tissue as well.
- Arteriovenous malformation (AVM). A collection of weakened vessels exists as a result of abnormal development of the arteriovenous connections. AVMs may rupture to cause haemorrhagic stroke or, more rarely, cerebral ischaemia from a 'steal' phenomenon.
- Hypertensive vascular disease. Lipohyalinosis, mentioned earlier as a cause of microatheromatous infarcts, is also responsible for rupture of small penetrating vessels causing haemorrhage in characteristic locations, typically the putamen, thalamus, upper brain stem and cerebellum.
- Amyloid angiopathy. Post-mortem pathological examination has found these changes, particularly in elderly patients with lobar haemorrhages.
- Haemorrhage into an underlying lesion (e.g. tumour or infarction).
- Drug toxicity from sympathomimetics and cocaine.
- Anticoagulation and bleeding diatheses.

Risk factors for transient ischaemic attack/stroke and prevention

This particularly applies to cerebral ischaemic events, both TIAs and strokes. Non-modifiable risk factors for ischaemic stroke include the following:

- Increasing age: the stroke rate more than doubles for each 10 years above age 55 years.
- Gender: stroke is slightly more common in males than in females.
- Family history.

In terms of primary prevention, hypertension is the most important modifiable risk factor. The benefit of antihypertensive treatment in stroke prevention has been well shown. The other major risk factors for atherosclerosis and its complications—diabetes, smoking and hypercholesterolaemia—often contribute to increased stroke risk. These should be managed according to standard guidelines.

The most important cardiac risk factor for TIA and stroke is atrial fibrillation (AF), both chronic and paroxysmal. Anticoagulation is recommended to prevent cardioembolism where the risk:benefit ratio of anticoagulation (target international normalized ratio [INR] 2.0 to 3.0) favours this. Prediction tools, such as the $CHADS_2$ (Congestive heart failure, Hypertension, Age >74, Diabetes and previous stroke / TIA) and CHA_2DS_2-VASc (Congestive heart failure, age, hypertension, sex, stroke / TIA history, vascular disease, diabetes) scores, have been developed to standardize the approach to primary stroke prevention in patients with non-valvular AF. The choice of appropriate anticoagulation should be tailored to each patient in consultation with his or her usual treating doctor and follow counselling and assessment of the risk:benefit ratio. The non vitamin K antagonist oral anticoagulants - or NOACs (apixaban, rivaroxaban or dabigatran) have been shown to be non-inferior to warfarin for the prevention of stroke in patients with non-valvular AF. Patients with valvular disease and AF should be commenced on warfarin unless there

are contraindications to this therapy. Patients with contraindications to warfarin or very low stroke risk should initially receive aspirin.

A carotid bruit or carotid stenosis found in an otherwise asymptomatic patient is associated with an increased stroke risk. However, the role of carotid endarterectomy in these patients is controversial. Although early trials suggested some minor benefit, more recent studies have refuted this, and it is increasingly clear that intensive medical therapy in patients with asymptomatic carotid stenosis reduces stroke risk well below the reduction achieved with either endarterectomy or carotid stenting.

Other major cardiac conditions associated with increased TIA/stroke risk include endocarditis, mitral stenosis, prosthetic heart valves, recent myocardial infarction and left ventricular aneurysm. Less common ones include atrial myxoma, a patent foramen ovale and cardiomyopathies.

Secondary prevention involves detection and modification, if possible, of conditions that may have caused a TIA or stroke in order to prevent further events that could result in worse clinical outcomes. As well as the risk factors already mentioned, many other uncommon conditions, such as arterial dissection and prothrombotic states, may cause TIA and stroke. These are discussed later in the chapter.

Ischaemic stroke syndromes

The symptoms and signs of stroke or TIA correspond to the area of the brain affected by ischaemia or haemorrhage (Table 8.2.1).

In ischaemic brain injury, the history and pattern of physical signs may correspond to a characteristic clinical syndrome according to the underlying cause and the vessel occluded. This has a bearing on the direction of further investigation and treatment decisions. Differentiating between anterior and posterior circulation ischaemia/infarction is important in this respect but is not always possible on clinical grounds alone.

Determining the cause of the event is the next step. Once again, clues such as a carotid bruit or AF may be present on clinical evaluation. For accurate delineation of the site of the brain lesion, exclusion of haemorrhage and assessment of the underlying cause, it is usually necessary to undertake imaging studies.

Anterior circulation ischaemia

The anterior circulation supplies blood to 80% of the brain and consists of the ICA and its branches, principally the ophthalmic, middle cerebral and anterior cerebral arteries. This system supplies the optic nerve, retina, frontoparietal lobes and most of the temporal lobes. Ischaemic injury involving the anterior cerebral circulation commonly has its origins in atherothrombotic disease

Table 8.2.1 Location of transient ischaemic attack

	Arterial territory		
Symptom	*Carotid*	*Either*	*Vertebrobasilar*
Dysphasia	+		
Monocular visual loss	+		
Unilateral weakness[a]		+	
Unilateral sensory disturbance[a]		+	
Dysarthria[b]		+	
Homonymous hemianopia		+	
Dysphagia[b]		+	
Diplopia[b]			+
Vertigo[b]			+
Bilateral simultaneous visual loss			+
Bilateral simultaneous weakness			+
Bilateral simultaneous sensory disturbance			+
Crossed sensory/motor loss			+

[a]Usually regarded as carotid distribution.
[b]Not necessarily a transient ischaemic attack if an isolated symptom.
(Reproduced with permission from Hankey GJ. Management of first time transient ischaemic attack. *Emerg Med.* 2001;13:70–81.)

of the ICA. Atherosclerosis of this artery usually affects the proximal 2 cm, just distal to the division of the common carotid artery. Advanced lesions may be the source of embolism to other parts of the anterior circulation or cause severe stenosis with resultant hypoperfusion distally if there is inadequate collateral supply via the circle of Willis. This is usually manifest by signs and symptoms in the middle cerebral artery (MCA) territory (Box 8.2.2). Less commonly, lesions of the intracranial ICA and MCA may cause similar clinical features.

Embolism to the ophthalmic artery or its branches causes monocular visual symptoms of blurring, loss of vision and field defects. When transient, this is referred to as amaurosis fugax or transient monocular blindness.

The territory of the anterior cerebral artery is the least commonly affected by ischaemia because of the collateral supply via the anterior communicating artery. If occlusion occurs distally

Box 8.2.2 Signs of middle cerebral artery occlusion

Homonymous hemianopia
Contralateral hemiplegia affecting face and arm more than leg
Contralateral hemisensory loss
Dysphasias with dominant hemispheric involvement (usually left)
Spatial neglect and dressing apraxia with non-dominant hemispheric involvement

or the collateral supply is inadequate, then ischaemia may occur. This manifests as sensorimotor changes in the leg more than in the arm. More subtle changes of personality may occur with frontal lobe lesions, as may disturbances of micturition and conjugate gaze.

Major alterations of consciousness, with Glasgow Coma Scale scores below 8, imply bilateral hemispheric or brain stem dysfunction. The brain stem may be primarily involved by a brain stem stroke or secondarily affected by an ischaemic or haemorrhagic lesion elsewhere in the brain owing to a mass effect and/or increased ICP.

Posterior circulation ischaemia

Ischaemic injury in the posterior circulation involves the vertebra-basilar arteries and their major branches, which supply the cerebellum, brain stem, thalamus, medial temporal and occipital lobes. Posterior cerebral artery occlusion is manifested by visual changes of homonymous hemianopia (typically with macular sparing if the MCA supplies this part of the occipital cortex). Cortical blindness, of which the patient may be unaware, occurs with bilateral posterior cerebral artery infarction.

Depending on the area and extent of involvement, brain stem and cerebellar stroke manifest as a combination of motor and sensory abnormalities that may be uni- or bilateral; cerebellar features of vertigo, nystagmus and ataxia; and cranial nerve signs, such as diplopia/ophthalmoplegia, facial weakness and dysarthria. Consciousness may also be affected.

Examples of cerebellar and brain stem stroke patterns include the following (this list is by no means exhaustive):

- Ipsilateral cranial nerve with crossed corticospinal motor signs.
- Lateral medullary syndrome: clinical features include sudden onset of vertigo, nystagmus, ataxia, ipsilateral loss of facial pain and temperature sensation (V) with contralateral loss of pain and temperature sensation of the limbs (anterior spinothalamic), ipsilateral Horner syndrome and dysarthria and dysphagia (IX and X).
- Internuclear ophthalmoplegia manifesting as diplopia and a horizontal gaze palsy due

to involvement of the medial longitudinal fasciculus (MLF).
- 'Locked-in' syndrome: this is caused by bilateral infarction of a ventral pons with or without medullary involvement. The patient is conscious due to an intact brain stem reticular formation but cannot speak and is paralysed. Patients can move their eyes owing to sparing of the third and fourth cranial nerves in the midbrain.
- Acute vertigo. Cerebellar and small strokes involving the cerebellum's connections with the brain stem may present as acute ataxia and vertigo without other neurological signs. Signs that point to a central cause of vertigo include severe ataxia, inco-ordination and features outlined in the HINTS exam: maintained fixation on Head Impulse test, multidirectional Nystagmus and positive Test of Skew.
- Acute deterioration of conscious state may be the presentation of acute basilar artery occlusion and should be in the differential diagnosis of coma for investigation.

Lacunar infarcts

Lacunar infarcts are associated primarily with hypertension and diabetes. They occur in the small penetrating arteries supplying the internal capsule, thalamus and upper brain stem. Isolated motor or sensory deficits are most commonly seen.

Clinical features

History

This includes the circumstances, time of onset, associated symptoms such as headache, and any resolution/progression of signs and symptoms. It may be necessary to take a history from a relative or friend, particularly in the presence of dysphasia or reduced conscious state. The history of a stroke is usually that of the acute onset of a neurological deficit over minutes; occasionally, however, there may be a more gradual or stuttering presentation over a period of hours. A past history of similar events suggestive of a TIA should be carefully sought. The presence of severe headache with the onset of symptoms may indicate ICH or SAH. However, headache may also occur with ischaemic strokes. Acute neck pain in association with neurological symptoms should raise the concern of arterial dissection or SAH.

A declining level of consciousness may indicate increasing ICP due to an ICH or a large anterior circulation infarct—so-called malignant MCA infarction. It may also be caused by pressure on the brain stem by an infratentorial lesion, such as a cerebellar haemorrhage.

The possibility of trauma or drug abuse should be remembered along with the past medical and medication history, particularly anticoagulant/antiplatelet therapy. Risk factors for vascular disease, cardiac embolism, venous embolism and increased bleeding should be sought.

In young patients with an acute neurological deficit, the possibility of paradoxical embolization should be considered as well as dissection of the carotid or vertebral artery. Arterial dissection is often associated with neck pain and headaches/facial pain with or without a history of neck trauma. Trauma, if present, may be minor, such as a twisting or hyperextension/flexion injury sustained in a motor vehicle accident, in playing sports or caused by neck manipulation.

Cardioembolism tends to produce ischaemic injury in different parts of the brain, resulting in non-stereotypical recurrent TIAs of longer duration (hours), whereas atherothrombotic disease of the cerebral vessels tends to cause recurrent TIAs of a similar nature with a shorter duration (minutes), particularly in stenosing lesions of the internal carotid or vertebrobasilar arteries.

Examination

Central nervous system This includes assessing the level of consciousness, pupillary size and reactivity, extent of neurological deficit, presence of neck stiffness and fundoscopy for signs of papilloedema and retinal haemorrhage. Quantifying the neurological deficit using a stroke scale, such as the 42-point National Institute of Health Stroke Scale (NIHSS), is useful in the initial assessment and also for monitoring progress in a more objective way than clinical description alone. Strokes with a NIHSS score greater than 22 are classified as severe.

In the case of TIA, all clinical signs may have resolved. The average TIA lasts less than 15 minutes.

Cardiovascular This includes carotid auscultation and is directed toward findings associated with a cardioembolic source. The absence of a carotid bruit does not exclude significant carotid artery disease as the cause of a TIA or stroke. Major risk factors for cardioembolism that can be identified in the emergency department (ED) include AF, mitral stenosis, prosthetic heart valves, infective endocarditis, recent myocardial infarction, left ventricular aneurysm and cardiomyopathies.

Differential diagnosis

The acute onset of stroke and TIA is characteristic; however, misdiagnoses (the so-called stroke mimics) can occur. The most common stroke mimics are seizures (particularly when there is associated Todd paresis), hypoglycaemia, systemic infection, brain tumour and toxic/metabolic disorders. Others include subdural haematoma, hypertensive encephalopathy, encephalitis, multiple sclerosis, migraine and conversion disorder. (Box 8.2.3) This has implications when more aggressive stroke interventions, such as thrombolysis, are being considered.

Box 8.2.3 Differential diagnosis of stroke

Intracranial space-occupying lesion
Subdural haematoma
Brain tumour
Brain abscess
Postictal neurological deficit—Todd paresis
Head injury
Encephalitis
Metabolic or drug-induced encephalopathy
Hypoglycaemia, hyponatraemia, etc.
Wernicke-Korsakoff syndrome
Drug toxicity
Hypertensive encephalopathy
Multiple sclerosis
Migraine
Peripheral nerve lesions
Functional

Complications

Central Nervous System complications of stroke include the following:
- Cerebral oedema and raised ICP. This is an uncommon problem in the first 24 hours following ischaemic stroke, but it may occur with large anterior circulation infarcts. It is more commonly seen with ICH, where acutely raised ICP may lead to herniation and brain stem compression in the first few hours.
- Haemorrhagic transformation of ischaemic strokes may occur either spontaneously or associated with treatment.
- Seizures can occur and should be treated in the standard way. Seizure prophylaxis is not generally recommended.
- Non-CNS complications include aspiration pneumonia, hypoventilation, deep venous thrombosis and pulmonary embolism, urinary tract infections and pressure ulcers. In the ED, it is particularly important to be aware of the risk of aspiration.

Clinical investigations

The investigations of TIA and stroke often overlap, but the priorities and implications for management may differ significantly.

General investigations

Standard investigations that may identify contributing factors to stroke/TIA or guide therapy include a complete blood picture, blood glucose, coagulation profile, electrolytes, liver function tests, fasting lipids and, in selected cases, C-reactive protein (CRP). An electrocardiogram (ECG) should be performed to identify arrhythmias and signs of pre-existing cardiac disease. A

prothrombotic screen may be indicated, particularly in younger patients. Further investigations depend on the nature of the neurological deficit and other risk factors for stroke identified on evaluation but that usually involve a combination of brain, vascular and cardiac imaging.

Imaging in transient ischaemic attacks

Prompt diagnosis and management of patients presenting with TIAs and non-disabling strokes has been shown to reduce the risk of subsequent stroke by up to 80%. Risk stratification for patients presenting with TIAs can guide the urgency of investigations required to determine the underlying cause of the TIA; this is discussed more fully later.

Brain imaging A head computed tomography (CT) or magnetic resonance imaging (MRI) scan is indicated in all patients with TIA in order to exclude lesions that occasionally mimic TIA, such as subdural haematomas and brain tumours. CT and, more particularly MRI, may show areas of infarction matching the symptoms of an ischaemic event that, on clinical grounds, has completely resolved. CT is less sensitive than MRI in detecting posterior territory ischaemic lesions, particularly in the brain stem. In TIAs due to AF or another known cardiac source, brain imaging to exclude ICH is necessary prior to commencing anticoagulation. The exception is in cases of emboli from endocarditis, in which anticoagulation is contraindicated owing to the increased risk of secondary ICH.

Imaging vessels *Ultrasound:* Carotid ultrasound has classically been the most commonly used initial study to investigate the presence and degree of a carotid stenosis. More recently, many centres have moved to the use of CT angiography (CTA) for assessment of carotid patency.

CTA: CTA is increasingly being used to image vessels in cases of TIA, commonly in conjunction with contrast studies examining cerebral perfusion. Advantages include ease of access and avoidance of further delay waiting for second-modality imaging. Disadvantages include exposure to contrast dye and ionizing radiation.

MRI and magnetic resonance angiography (MRA): this provides non-invasive imaging of the brain and major cerebral vasculature. MRA can show lesions suggestive of a vascular aetiology for TIAs, such as a stenosis due to atheromatous disease and dissection. MRA is more prone to artefact than CTA, hence CTA is generally the preferred modality. MRI/MRA is not routine in TIA workup but may be indicated in more prolonged TIAs, in patients in whom an uncommon cause is suspected or in younger patients and in those where CTA is contraindicated.

Angiography: The use of formal angiography has declined in recent years, with greater use of both CT angiography and MRA studies as confirmatory tests where atheroma is found on carotid ultrasound.

Cardiac imaging If the clinical evaluation indicates that a cardioembolic source is a likely cause of a TIA, echocardiography is a priority. However, if there is no evidence of cardiac disease on clinical evaluation and the ECG is normal, then the yield of echocardiography is relatively low. A transthoracic echocardiogram (TTE) is the first-line investigation in cardiac imaging. A transoesophageal echocardiogram (TOE) is more sensitive than TTE in detecting potential cardiac sources of emboli, such as mitral valve vegetations, atrial/mural thrombi and atrial myxoma. TOE should be considered in patients with inconclusive or normal TTE with ongoing clinical concern of a cardioembolic source or patent foramen ovale. This particularly applies to younger patients with unexplained TIAs/non-disabling stroke.

Imaging in stroke

Brain imaging *Computed tomography:* in the setting of completed stroke, the usual first-line investigation is a non-contrast CT scan. The main value of CT is its sensitivity in the detection of ICH and its ready availability. However, CT scans are often normal in the first hours following ischaemic stroke. In only about half of cases will there be changes detected 24 hours after the onset of symptoms.

The early signs of ischaemic stroke include loss of the cortical grey/white matter distinction and hypoattenuation in the affected arterial distribution (e.g. the insular ribbon sign and obscuration of the lenticulostriate territory in MCA infarcts). Occasionally, a hyperdense clot sign will be seen in the region of the MCA. As well as the presence of haemorrhage, the degree of acute ischaemic change—typically change affecting greater than a third of the MCA territory—has been used to exclude patients from some thrombolytic trials due to possible lack of therapeutic benefit and increased haemorrhage risk. The degree of acute ischaemic change involving the anterior circulation on plain CT can be more reliably quantified by using the ASPECTS (Alberta stroke program early CT score), a stroke scoring system based on the extent of brain involvement evident on CT.

A CT scan should be performed as soon as possible following stroke onset. Urgent CT scanning is indicated in patients with a reduced level of consciousness, deteriorating clinical state, symptoms suggestive of ICH, associated seizures prior to thrombolytic therapy, in younger patients, in patients who are on warfarin and in cases of diagnostic doubt. A CT scan should also be performed to exclude haemorrhage prior to the commencement of antiplatelet therapies. It should, however, be noted that ICH may be subtle and difficult to diagnose, even for radiologists.

CT perfusion/CT angiography: Following plain CT, CT perfusion studies are the primary imaging modality employed in stroke centres and in cases where reperfusion therapies may be planned. Following intravenous contrast injection, an area of the brain is imaged and analysed using computer software with respect to the cerebral blood volume (CBV), cerebral blood flow (CBF) and mean transit time (MTT). Using predetermined cut-offs of these values, the areas of likely irreversibly infarcted brain (infarct core) and at-risk ischaemic brain (ischaemic penumbra) can be demonstrated (e-Fig. 8.2.1). A CT angiogram that includes the carotid vessels is also performed to determine if there is a site of large vessel occlusion. This technology is seen as offering an alternative to diffusion/perfusion MRI and MRA, as it is more readily available, generally quicker and less subject to artefact.

CTA: CTA is the imaging modality of choice in the evaluation of primary ICH to identify the underlying cause, such as an aneurysm or AVM. CTA should be performed in cases of stroke due to suspected arterial dissection and basilar artery thrombosis.

Formal angiography may be performed if intra-arterial therapy, such as embolectomy, is being considered in specialized centres.

MRI: there are many magnetic resonance modalities available for imaging the brain in acute stroke. Even standard MRI is superior to CT in showing early signs of infarction, with 90% showing changes at 24 hours on T2-weighted images. Multimodal MRI typically involves additional modes, such as gradient recalled echo (GRE) and fluid-attenuated inversion recovery (FLAIR) sequences for the detection of acute and chronic haemorrhage and diffusion-weighted imaging (DWI) for the detection of early ischaemia or infarction. MR DWI images show areas of reduced water diffusion in the parts of the brain that are ischaemic and likely to be irreversibly injured. This occurs rapidly after vessel occlusion (less than an hour after stroke onset) and manifests as an area of abnormal high signal in the area of core ischaemia. Hence it is much more sensitive in detecting early ischaemia/infarction than standard T2-weighted MRI modalities or CT. Perfusion-weighted MRI scans (PWI) reveal areas of reduced or delayed CBF following MRI contrast injection. This area of the brain is likely to become infarcted if flow is not restored. The DWI and PWI lesions can then be compared. A PWI lesion significantly larger than a DWI lesion is a marker of potentially salvageable brain: the ischaemic penumbra. It is postulated that acute ischaemic stroke patients with this pattern are

most likely to benefit from vessel opening strategies, such as thrombolysis. Large areas of diffusion abnormality may also be a marker for increased risk of ICH with thrombolysis. An MRA can be performed at the same time to identify a major vessel occlusion. DWI/PWI imaging is generally considered to be easier to interpret and more reliable than CT perfusion studies. However, MRI may not be as available or feasible. A significant number of patients are unsuitable for MRI, and the multimodal imaging takes longer than CT, which increases the risk of motion artefact and potential delay of treatment. Radiation and iodinated contrast exposure are absent in MRI.

The place of advanced imaging modalities, such as CT perfusion and DWI/PWI MRI, in acute stroke workup continues to evolve. For over a decade now it has been hoped that the information provided by these studies will help to better select patients who will benefit from aggressive stroke therapies such as thrombolysis and extend the current time window for such treatment on the basis of the existence of a significant ischaemic penumbra. They are now a common feature of acute stroke imaging workup protocols if thrombolysis is being considered. However, there remains no convincing evidence supporting the use of these modalities in patients undergoing thrombolysis up to 4.5 hours after symptom onset. Some positive studies of the use of clot retrieval after thrombolysis up to 6 hours beyond symptom onset in large-vessel occlusion (LVO) did employ selection criteria based on the results of perfusion studies, but others have not. Recently the DAWN and Defuse 3 studies have been published; they studied the use of clot retrieval devices from 6 to 24 and 6 to 16 hours, respectively, after the onset of symptoms (including wake-up strokes). Both these trials, which revealed benefit, used selection criteria based on the presence of a significant penumbra/small-core infarct pattern on CT perfusion or DWI/PWI MRI as well as the presence of LVO on angiography. Decisions around the use and implications for therapy of using these perfusion-based imaging modalities remain best made by stroke specialists and neuroradiologists.

MRI is indicated in strokes involving the brain stem and posterior fossa, where CT has poor accuracy. MRA/MRV is particularly useful in the evaluation of unusual causes of stroke, such as arterial dissection, venous sinus thrombosis and arteritis. Basilar artery thrombosis causes a brain stem stroke with an associated high mortality. If the diagnosis is suspected, urgent specialist consultation should be obtained. If MRA or CTA confirms the diagnosis, then aggressive therapies such as thrombolysis and clot retrieval may improve outcome.

Other investigations

Other investigations may be indicated, particularly in young people, in whom the cause of stroke/TIA may be obscure. These include tests to detect prothrombotic states and uncommon vascular disorders. The list of tests is potentially long and includes a thrombophilia screen, vasculitic and luetic screens, echocardiography and angiography.

Treatment

The treatment of cerebrovascular events must be individualized. It is determined by the nature and site of the neurological lesion and its underlying cause. The benefits and risks of any treatment strategy can then be considered and informed decisions made by the patient or his or her surrogate. This is particularly the case with the use of more aggressive therapies, such as anticoagulation, thrombolysis, clot retrieval and surgery.

Pre-hospital care

The pre-hospital care of the possible stroke patient involves the usual attention to the ABCs of resuscitation and early blood sugar measurement. It is unusual for interventions to be required.

Of potentially greater significance is the development of stroke systems (along the lines of trauma systems) in which the sudden onset of neurological signs and symptoms, identified in the pre-hospital evaluation as being consistent with acute stroke, is used to direct patients to stroke centres with the facilities and expertise to manage them, particularly with regard to the delivery of thrombolytic agents and/or clot retrieval. Closer hospitals without these capabilities may be bypassed.

Pre-hospital evaluation and early hospital triage tools that have been developed for the rapid identification of stroke include the Cincinnati Prehospital Stroke Scale or FAST (F, facial movements; A, arm movements; S, speech and T, test) and the Rosier score. Using these simple scales, pre-hospital personnel who identify patients with acute onset of neurological deficits consistent with stroke can potentially be directed to stroke centres and in-hospital acute stroke responses can be activated so as to expedite assessment and imaging, particularly if thrombolysis is being considered. The specificity of these scoring systems in identifying stroke is affected by the fact that both involve relatively imprecise elements such as speech disturbance, which may be caused by many non-stroke pathologies.

General measures

The ED management of a TIA and stroke requires reassessment of the ABCDs and repeated blood glucose testing. Airway intervention may be necessary in the setting of a severely depressed level of consciousness, neurological deterioration or signs of raised ICP and cerebral herniation.

Hypotension is very uncommon in stroke patients except in the terminal phase of brain stem failure. Hypertension is much more likely to be associated with stroke because of the associated pain, vomiting and raised ICP and/or pre-existing hypertension, but it rarely requires treatment and usually settles spontaneously. It may be a physiological response to maintain cerebral perfusion pressure in the face of cerebral hypoxia and raised ICP. The use of antihypertensives in this situation may aggravate the neurological deficit. Current guidelines in ischaemic stroke recommend that only systolic BP greater than 220 mm Hg be lowered by no more than 20% in the first 24 hours. Patients otherwise eligible for thrombolytic therapy should have their blood pressure reduced to less than 185/110 mm Hg prior to commencing treatment and be maintained below this level for 24 hours. Local guidelines should be followed.

An elevated temperature can occur in stroke and should be controlled. It should also raise the suspicion of other possible causes for the neurological findings or an associated infective focus. Hyperglycaemia should be treated appropriately; however, intensive euglycaemic therapy is not indicated.

Transient ischaemic attacks

Risk stratification As already stated, the main aim in therapy in TIAs and minor strokes is to prevent a major subsequent cerebrovascular event through initiation of secondary prevention measures. Not all patients presenting after a TIA require admission to hospital for inpatient workup. Risk-stratification tools exist to help identify higher-risk patients for inpatient workup as well as lower-risk patients who may be suitable for early outpatient follow-up in rapid-access 'TIA clinics'.

The classical tool for risk stratification in this population is the ABCD^2 score. The ABCD^2 stroke risk score for TIA has been developed and validated to evaluate the very early risk of a stroke following a TIA. The scoring system is shown in Table 8.2.2. In patients with an ABCD^2 score less than 4, there is minimal short-term risk of stroke. With scores of 4 to 5 and 6 to 7, the 2-day risk is 4.1%, and 8.1%, respectively. The use of the ABCD^2 score is not universally accepted, however, as ongoing validation studies have had mixed results. More recently, the ABCD^2 score has been modified to include a history of two or more TIAs within the preceding week as well as the results of DWI MRI and carotid imaging to form the ABCD3-I score, which has shown superior performance as a risk-stratification tool. These changes underscore a move to imaging based risk stratification and on the observation

that patients with established areas of infarction on brain imaging, and imaging evidence (ultrasound [US] or CTA) of significant (>50%) carotid stenosis in a distribution consistent with their TIA symptoms are at highest risk for early recurrent cerebrovascular events. Other patient groups are at increased risk of stroke independent of the classical risk stratification systems. These include patients with multiple TIAs within a short period ('crescendo TIAs') and those with a probable or proven cardioembolic source.

Antiplatelet therapy Following CT scanning that excludes ICH, aspirin should be commenced at a dose of 300 mg and maintained at 75 to 150 mg/day in patients with TIAs or minor ischaemic strokes. It has been shown to be effective in preventing further ischaemic events. The ESPRIT trial showed a modest additional benefit from a combination of dipyridamole with aspirin over aspirin alone. There was no increased risk of bleeding complications but a significantly increased rate of withdrawal of patients from the combination arm owing to side effects from dipyridamole, principally headache. Clopidogrel or ticagrelor may be substituted for aspirin if the patient is intolerant of aspirin or aspirin is contraindicated. There is some evidence that ticagrelor may be more effective than aspirin in the prevention of recurrent cerebrovascular events in patients with carotid atherosclerosis; however, further work is needed to confirm this. The combination of aspirin and clopidogrel is not recommended, as it does not appear to provide any greater therapeutic benefits in the longer term and there is increased bleeding risk. Anticoagulation with heparin and warfarin has not been shown to be superior to aspirin except in cases of TIA/minor stroke due to cardioembolism (excluding endocarditis).

Anticoagulant therapy Patients with a cardioembolic source of TIA should be considered for full anticoagulation following neurological consultation and normal brain imaging with the exception of those with endocarditis, in whom the risk of haemorrhagic complications is increased.

Surgery Trials have demonstrated a beneficial outcome of urgent surgery for symptomatic carotid stenosis in patients with anterior circulation TIAs and minor stroke with a demonstrated carotid stenosis of between 70% and 99%. The benefit of surgery may extend to lesser grades of stenosis down to 50% in selected patients. The patient's baseline neurological state, co-morbidities and operative mortality and morbidity rate also need to be assessed when surgery is being considered. The recent CREST trial compared carotid artery stenting (CAS) with endarterectomy (CEA). It revealed slightly superior stroke prevention for CEA in symptomatic patients. In patients with significant co-morbidities, CAS remains an option.

Other medical therapies Risk factors for stroke and TIAs should be identified and treated. Statins should be considered regardless of cholesterol levels. The benefit of lowering low-density lipoprotein (LDL) cholesterol levels using atorvastatin in preventing further cerebro- and cardiovascular events following an initial episode of cerebral ischaemia was demonstrated in the SPARCL trial.

Ischaemic stroke

A more active approach to the acute management of ischaemic stroke is seen as having the potential to improve neurological outcomes. The ED is the place where these important treatment decisions will largely be made. Most patients with stroke will require hospital admission for further evaluation and treatment as well as for observation and rehabilitation. Studies of stroke units show that patients benefit from being under the care of physicians with expertise in stroke and a multidisciplinary team that can manage all aspects of stroke care.

Antiplatelet therapy In two large trials, aspirin administered within 48 hours of the onset of stroke was found to improve the outcomes of early death or recurrent stroke compared with placebo. A CT or MRI scan should be performed to exclude ICH prior to commencing aspirin. Aspirin should be withheld for at least 24 hours in patients treated with thrombolytics.

Thrombolysis As a critical factor in ischaemic stroke outcome is occluded vessel reopening, thrombolytic agents and more recently clot retrieval devices are seen as having an important place in the management of acute ischaemic stroke. The critical starting points are a significant neurological deficit, a non contrast CT (NCCT) showing no evidence of haemorrhage and ascertaining the time of onset or when the patient was last seen well. Many studies have been performed since the pivotal National Institute of Neurological Disorders and Stroke (NINDS) study of intravenous alteplase in 1996. The current state of these therapies in treating acute ischaemic stroke is summarized here.

IV alteplase (0.9 mg/kg with a maximal dose of 90 mg over 60 minutes and 10% of the total dose given as a bolus) is recommended for eligible patients who can be treated within 3 hours of onset of symptoms. The number needed to treat (NNT) to achieve a good neurological outcome is approximately 10. The number needed to harm (NNH), primarily due to increased spontaneous intracranial haemorrhage rates is approximately 40. An ACEM statement on intravenous thrombolysis for acute ischaemic stroke supported this therapy. Current indications and contraindications for intravenous alteplase are published in the most recent 2018 American Heart Association (AHA) guidelines for the management of ischaemic stroke. Specific clinical presentations where thrombolysis is contraindicated are ischaemic stroke known or likely to have been caused by infective endocarditis and aortic arch dissection.

Extending the use of alteplase to 4.5 hours is recommended in guidelines published by the Stroke Foundation of Australia and the AHA, although the likelihood of benefit is reduced and significant risk of SICH remains. This recommendation is principally based on the ECASS 3 study and registry data. The ECASS 3 study had additional exclusion criteria of age above 80 years, NIHSS score above 25, acute ischaemia score of greater than one-third of the MCA territory on CT, any anti-coagulation therapy or previous history if diabetes or stroke. The AHA guidelines acknowledge that these factors should be taken into account in deciding on thrombolysis therapy in this time window. Alteplase is not approved by the US Food and Drug Administration for use in this time window.

Every effort should be made to reduce the door-to-needle time with thrombolysis, as current evidence indicates that time to administration strongly influences outcome within the 0- to 4.5-hour time window. Prehospital notification and 'code stroke' teams to streamline this process are now commonplace. Pre-hospital CT scanners are also being introduced in some cities to image patients en route to the ED.

Explanation of the potential risks of thrombolysis, particularly SICH, is an important and sometimes overlooked aspect of the consent process before commencing this treatment.

Clot retrieval A number of similar studies (MR Clean, ESCAPE, SWIFT PRIME, EXTEND 1A and REVASCAT) have shown that in patients with large vessel occlusion typically involving the intracranial internal carotid, proximal MCA and basilar artery, endovascular interventions using the latest clot retrieval devices can improve neurological outcomes up to 6 hours after the onset of symptoms. Inclusion criteria included adults with pre-existing good neurological status, ongoing significant neurological deficit, limited early ischaemic change on NCCT and clot retrieval skin puncture time achieved within 6 hours. In these studies all eligible patients received thrombolysis prior to being randomized into the clot retrieval or standard therapy arms. As stated previously, only some of these studies used advanced imaging criteria showing a significant penumbra/small infarct pattern as part of the selection criteria. Delays to clot retrieval in potentially suitable patients should be minimized, and such patients may have to be transferred

Table 8.2.2 The ABCD² transient ischaemic attack risk score

ABCD²	*Risk factor*	*Score*
Age	Below 60	0
	Above 60	1
Blood pressure	BP above systolic 140 mm Hg and/or diastolic 90 mm Hg on first assessment after TIA	1
Clinical	Unilateral weakness of face, arm, hand or leg	2
	Speech disturbance without weakness	1
Duration	Symptoms lasted >60 min	2
	Symptoms lasted 10–60 min	1
	Symptoms lasted <10 min	0
Diabetes	Presence of diabetes	1

to centres with necessary neuro-interventional expertise with ongoing thrombolysis infusions. Waiting for a possible response to thrombolysis before activating the pathway to potential clot retrieval in suitable patients is not advised.

Clot retrieval within 6 hours of onset can also be considered in patients with ischaemic stroke due to LVO and contraindications to thrombolysis or who present beyond the 4.5-hour thrombolysis window if the skin puncture can be achieved within 6 hours of onset.

Delayed clot retrieval The DAWN and DEFUSE 3 trials have shown that in a small number of highly selected patients, extending the time window for clot retrieval up to 24 hours after symptom onset, including wake-up strokes, can improve outcomes. Other inclusion criteria were internal carotid or M1 MCA occlusion on CTA or MRA and 'penumbral selection' (based on advanced imaging modalities) indicating a small infarct core and persisting significant neuroogical deficit. Patients who had failed thrombolysis were still eligible. A total of approximately 400 patients were enrolled. In the DAWN study (6 to 24 hours), the rate of functional independence (modified Rankin Score, mRS 0 to 2) was a highly significant 49% in the intervention group, compared with 13% in the control group. Similar results were found in the DEFUSE 3 study (6 to 16 hours). There were no significant differences in mortality or complication rates.

The implication of these two studies for stroke care is now a topic of intense discussion, but it is likely that it will result in more stroke patients with significant ongoing neurological disability being transferred to stroke centres.

Overall, the rise in neuro-intervention as a treatment in selected strokes will mean that the presence and utilization of advanced imaging modalities, tele-radiology and assessment of stroke patients in 'primary' stroke centres in order to select appropriate patients for transfer to 'comprehensive' neuro-interventional centres is likely to be increasingly incorporated into stroke care systems.

Anticoagulation Therapeutic anticoagulation with heparin or clexane is associated with increased risk of haemorrhagic transformation in acute ischaemic stroke. Stroke due to endocarditis poses a particularly high risk for this complication. Anticoagulation following acute ischaemic stroke should not be commenced in the ED. In cases of stroke due to cardioembolism, the timing and manner of anticoagulation should be determined by stroke physicians.

Neuroprotection A range of neuroprotective agents has been trialled in the setting of acute stroke in the hope that modulation of the ischaemic cascade of metabolic changes that follows vascular occlusion may result in improved neurological outcomes. At this stage, however, none of these therapies is recommended for use in the treatment of acute stroke.

Surgery As for TIAs, patients with non-disabling stroke should be considered for investigation with a vascular imaging modality to detect a significant carotid artery stenosis that may be appropriate for urgent surgery or, in some selected cases, stenting.

Large infarcts of the anterior circulation have a significant risk of developing cerebral oedema and raised ICP with associated clinical deterioration, particularly manifest by a declining conscious state with or without progression of other signs. These are termed *malignant MCA infarcts*. Along with standard measures for managing raised ICP, there may be a place for early decompressive craniotomy in carefully selected cases. Studies in young patients (<61 years) have shown improved survival, but with rates of significant residual disability (mRS >3) approaching 50%.

Intracerebral haemorrhage

Primary ICH is most commonly caused by long-standing hypertension-induced small vessel disease. Hypertensive haemorrhage tends to occur in characteristic locations, such as the basal ganglia, thalamus and cerebellum. Berry aneurysms most commonly arise around the circle of Willis, hence ICH due to aneurysmal rupture is often located around this area. Secondary ICH may occur into an underlying lesion, such as a tumour or infarct, and clinical deterioration may result—so-called symptomatic ICH—but this is not always the case.

The clinical presentation of primary ICH is typical of sudden onset of a neurological deficit with associated headache, collapse/transient loss of consciousness, hypertension and vomiting. However, clinical features alone cannot serve to differentiate ICH from infarction; hence the requirement for brain imaging to confirm the diagnosis. Both CT and MRI (using gradient echo sequences) are equivalent in the detection of ICH.

Medical Treatment

Primary ICH is a medical emergency with a high mortality (between 35% and 50%), with half of these deaths occurring in the first 2 days. There is also a very high risk of dependency. Haematomas can expand rapidly, and there is a significant risk of early neurological deterioration and increasing ICP. General measures, as for TIAs and ischaemic stroke, should be initiated, in particular with attention to airway and ventilatory support. Treatment of raised ICP in a setting of ICH involves a range of modalities similar to those used in head trauma. These include elevation of the head of the bed, analgesia, sedation, an osmotic diuretic such as mannitol and hypertonic saline, hyperventilation, drainage of cerebrospinal fluid (CSF) via ventricular catheter and neuromuscular paralysis.

The INTERACT 2 trial showed that acute reduction of blood pressure to an end point aim of 140 mm Hg systolic was safe and may improve neurological outcomes. Treatment should be individualized and take place in consultation with stroke/neurosurgery/intensive care specialists. Hypotension should be avoided.

Use of recombinant factor VIIa is not recommended. Steroids are also not indicated in ICH. Anticonvulsant prophylaxis is common practice.

Management of ICH associated with anticoagulation or thrombolysis is a matter of urgency and should be done in consultation with a haematologist and a neurosurgeon. Depending on the clinical situation, agents such as protamine sulphate, vitamin K, prothrombin complex concentrate and fresh frozen plasma (FFP) may be indicated. Patients on direct oral anticoagulants should receive a specific antidote where available. Otherwise consultation with a haematologist is recommended.

Surgery

Surgical management of ICH depends on the location, cause, neurological deficit and patient's overall clinical state. Early neurosurgical consultation should be obtained. High-level evidence for improved outcomes following drainage of large supratentorial haematomas by craniotomy is lacking. The procedure may be lifesaving in selected patients, but consideration of the likely level of long-term disability is required.

The presence of a large cerebellar haematoma is a particular indication for surgery, with the potential for a good neurological recovery.

External ventricular drainage devices (EVDs) may be indicated if hydrocephalus develops in the setting of ICH.

CONTROVERSIES

- Thrombolysis beyond 3 hours.
- Delayed neuro-interventional therapies up to 6 hours post onset and beyond.
- Advances in neuroimaging, particularly diffusion/perfusion MRI and perfusion CT/CTA, show promise for improved selection of patients likely to benefit from vessel opening strategies.
- The place of interventional therapies in acute ischaemic stroke is the subject of intense research. These approaches have the potential to improve outcome by prolonging the treatment window, increasing recanalization rates in LVOs and reducing haemorrhagic complications. A number of clot retrieval devices are being evaluated, as is intra-arterial thrombolysis.
- The place of DOACs in AF/stroke prevention. Although uptake in the community has been rapid, more time is needed to see whether industry-sponsored trials of efficacy translate into real-world benefits.
- The follow-up investigation and management of patients presenting to EDs with TIA is moving increasingly to an outpatient model of care. The optimum method of risk stratification and patient selection for this approach has yet to be conclusively determined.
- Neuroprotective therapies continue to be evaluated; however, at this stage they cannot be recommended outside of a clinical trial.

8.3 Subarachnoid haemorrhage

Íomhar O'Sullivan

ESSENTIALS

1 **The diagnosis of subarachnoid haemorrhage (SAH) requires a high index of suspicion.**

2 **Up to a third of patients with SAH experience a warning leak—the sentinel haemorrhage—in the hours to days prior to the major bleed.**

3 **Risk of re-bleeding is maximal in first 2 to 12 hours and is associated with a poor prognosis and high mortality.**

4 **Severe sudden headache is the primary clinical feature.**

5 **A computed tomography (CT) scan of the brain without contrast is the initial investigation of choice.**

6 **A negative CT scan for SAH should be followed by lumbar puncture and examination of the cerebrospinal fluid.**

7 **Patients with SAH require urgent neurosurgical referral and management.**

8 **Early definitive isolation and occlusion of the aneurysm reduces early complications and improves outcome.**

9 **Endovascular treatment is the treatment of choice in most cases.**

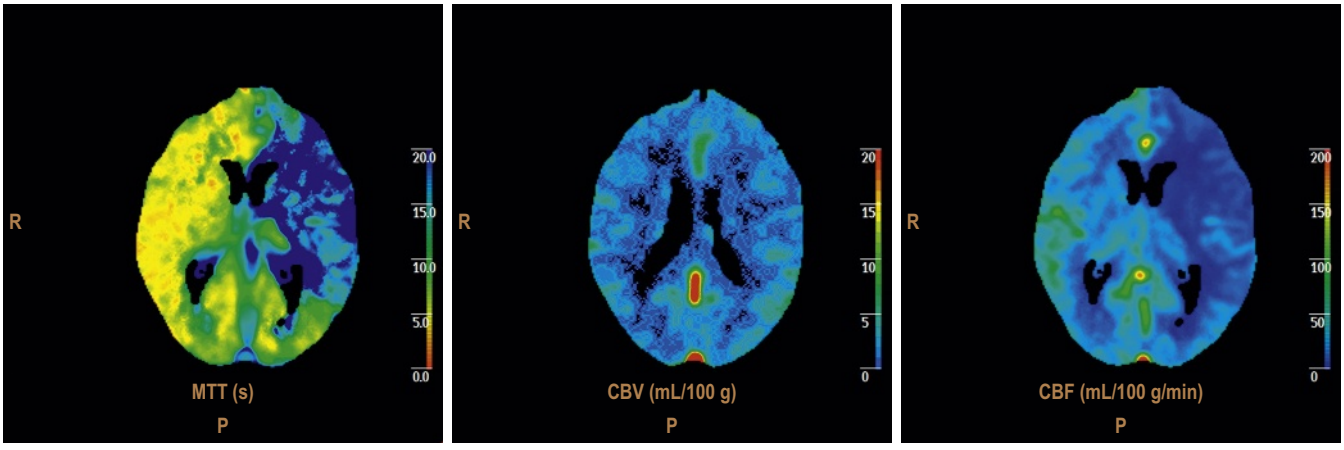
Introduction

Patients with headache account for approximately 1% of all emergency department (ED) visits; of these, 1% to 5% have a final diagnosis of subarachnoid haemorrhage (SAH). Early accurate diagnosis of aneurysmal SAH is imperative, as early occlusion of the aneurysm has been shown to reduce early complications of re-bleeding and vasospasm and to improve outcome.

Epidemiology and pathology

SAH is the presence of extravasated blood within the subarachnoid space. The incidence in Australia is approximately 10 cases per 100,000 patient-years, but, for reasons that are unclear, it is significantly higher (around 20 per 100,000) in Japan and Finland. Although incidence increases with age, about half of those affected are aged under 55.

The most common cause of SAH is head trauma, which is dealt with elsewhere in this book. Non-traumatic or spontaneous SAH



A B C

E-FIG. 8.2.1 Computed tomography perfusion study of a left middle cerebral artery stroke. (A) mean transit time; (B) cerebral blood volume; (C) cerebral blood flow.

results from rupture of a cerebral aneurysm in approximately 85% of cases, non-aneurysmal perimesencephalic haemorrhage in 10% and the remaining 5% from other rare causes including rupture of mycotic aneurysms, intracranial arterial dissection, arteriovenous malformations, vasculitis, central venous thrombosis, bleeding diatheses, tumours and drugs, such as cocaine, amphetamines and anticoagulants.

Aneurysms

Intracranial aneurysms are not congenital. Rather, they develop during the course of life. An estimate of the frequency for an adult without risk factors is 2.3%, with the proportion increasing with age. Most aneurysms will never rupture, but the risk increases with size. Paradoxically, because the vast majority of aneurysms are small, most aneurysms that rupture are small. An aneurysm of the posterior circulation is more likely to rupture than one of comparable size in the anterior circulation.

Risk factors can be divided into those that are modifiable and those that are not. Modifiable risk factors include cigarette smoking, hypertension, the use of sympathomimetic drugs (e.g. cocaine) and excessive alcohol intake. Non-modifiable factors include history of previous aneurysmal SAH, a family history of first-degree relatives with SAH, inherited connective tissue disorders (particularly polycystic kidney disease, Marfan syndrome, Ehlers-Dahnlos syndrome and neurofibromatosis), coarctation of the aorta, sickle cell disease and α_1-antitrypsin deficiency.

Non-aneurysmal peri-mesencephalic haemorrhage

This type of SAH is defined by the characteristic distribution of blood in the cisterns around the midbrain in combination with normal angiographic studies. It usually carries a relatively benign prognosis. A small proportion of patients with this distribution of blood may have a ruptured aneurysm of a vertebral or basilar artery.

Clinical features

History

The history is critical to the diagnosis of SAH.

- Headache is the principal presenting symptom, being present in up to 95% of patients with SAH and being the solitary symptom in up to 40% of patients. It is typically occipital, severe ('worst'), of sudden onset, almost instantaneously reaching peak intensity and often being the worst headache ever experienced. Approximately 25% of patients presenting with sudden severe headache will have SAH. The pain differs from any other headache the patient might have had ('first').
- One-third of patients experience a warning leak (sentinel haemorrhage) in the hours to weeks before the major bleed. This headache may be mild, generalized or localized and of variable duration; it may resolve spontaneously within minutes to hours or last several days and usually responds to analgesic therapy. It does, however, tend to develop abruptly and to differ in quality from other headaches that the patient may previously have experienced. Hence a patient's worst or first headache is suggestive of SAH.
- Upper neck pain or stiffness (and then meningism) is common.
- About half of patients will develop SAH during strenuous exercise (e.g. bending or lifting).
- Nausea and vomiting are present in 75% of patients.
- Brief or continuing loss of consciousness may occur, the headache typically occurring just prior to loss of consciousness.
- Seizures occur in circa 10%. When associated with headache, they are a strong indicator of SAH, even if the patient is neurologically normal when assessed.
- Prodromal symptoms—particularly involving the third cranial nerve with pupillary dilatation and sixth cranial nerve palsies—are uncommon but may suggest the presence and location of a progressively enlarging unruptured aneurysm.
- No clinical feature can reliably identify SAH.

Table 8.3.1 Clinical grading schemes for patients with subarachnoid haemorrhage

		Grading scheme of WFNS	
Grade	*Grading scheme of Hunt and Hess*	*GCS*	*Motor deficit*
1	No symptoms or minimal headache, slight nuchal rigidity	15	No
2	Moderate to severe headache, no neurological deficit other than cranial nerve palsy	13–14	No
3	Drowsy, confused, mild focal deficit	13–14	Yes
4	Stupor, moderate to severe hemiparesis, vegetative posturing	7–12	Yes or no
5	Deep coma, decerebration, moribund	3–6	Yes or no

GCS, Glasgow Coma Scale score; *SAH*, subarachnoid haemorrhage; *WFNS*, World Federation of Neurosurgeons

Examination

There is a wide spectrum of clinical presentations, the level of consciousness and clinical signs being dependent on the site and extent of the haemorrhage, as follows:

- On ED presentation, two-thirds of patients have an impaired level of consciousness, 50% with coma. Consciousness may improve or deteriorate. An acute confusional state can occur, which may be mistaken for a psychological problem.
- Signs of meningism, photophobia and neck stiffness are present in 75% of patients but may take several hours to develop and may be absent (particularly with more severe bleeds). Absence of neck stiffness does not exclude SAH. Photophobia is neither sensitive nor specific for SAH. Fever may be present.
- Focal neurological signs are present in up to 25% of patients and are secondary to associated intracranial haemorrhage, cerebral vasospasm, local compression of a cranial nerve by the aneurysm (e.g. oculomotor nerve palsy by posterior communicating aneurysm or bilateral lower limb weakness due to anterior communicating aneurysm) or raised intracranial pressure (sixth-nerve palsy).
- Ophthalmological examination may reveal papilloedema (40%), retinal haemorrhages (25%) or, rarely, subhyaloid haemorrhages (see Entezari et al., 2009).
- Systemic features associated with SAH include hypertension, hypoxia and acute electrocardiographic (ECG) changes that may mimic acute myocardial infarction.
- Neurogenic pulmonary oedema is more common in obtunded SAH patients.
- A small proportion of patients present in cardiac arrest. Resuscitation attempts are vital, as half of the survivors regain independent function.

Patients are categorized into clinical grades from I to V, according to their conscious state and neurological deficit. Two grading schemes, that of Hunt and Hess and that of the World Federation of Neurosurgeons, which is preferred, are depicted in Table 8.3.1. The higher the score, the worse the prognosis.

Differential diagnosis

Important differential diagnoses include benign thunderclap headache (40%), migraine, cluster headache, headache associated with sexual exertion, vascular headaches of stroke, intracranial

FIG. 8.3.1 Non-contrast computed tomography scan of the head demonstrating widespread subarachnoid and intraventricular blood.

haemorrhage, venous thrombosis and arterial dissection, meningitis, encephalitis, acute hydrocephalus, intracranial tumour and intracranial hypotension.

Clinical investigations

Imaging

Computed tomography

Non-contrast CT of the brain is the initial investigation of choice. In the first 24 hours after haemorrhage it can demonstrate the presence of subarachnoid blood in more than 95% of cases (Fig. 8.3.1). Some (Perry, 2011) report a sensitivity of 100% if completed within 6 hours of symptom onset. Others, including patients with atypical presentations and interpretation by non-neuroradiologists, claim a sensitivity closer to 95%. The sensitivity of CT in detecting acute haemorrhage decreases with time owing to the rapid clearance of iron (haemoglobin) with only 80% of scans being positive at 3 days and 50% positive at 1 week. CT will also demonstrate the site and extent of the haemorrhage, indicate the possible location of the aneurysm and demonstrate the presence of hydrocephalus and other pathological changes.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) has little role in the diagnosis of acute SAH. It is less sensitive than CT (with or without lumbar puncture) but may assist in identifying the location of the 'guilty' aneurysm when CT is positive and the patient has multiple aneurysms on angiography. Availability and logistical considerations, including longer procedure time, make MRI impractical for use in the initial diagnostic workup of SAH, but it may be considered in patients who present late.

Computed tomography angiography

CT angiography (CTA) is the preferred angiographic technique once SAH has been identified. Compared with catheter angiography, it has a sensitivity of 98% for cerebral aneurysms, is readily available and has a lower complication rate. It should be performed as soon as the diagnosis is made. Where diagnosis has been made by CT, CTA should preferably be performed while the patient is still in the scanner. CTA is usually of sufficient quality to allow the planning of endovascular or neurosurgical interventions. It is important to note that small aneurysms (<3 mm in diameter) may not be detected reliably on CTA; therefore further investigations may be warranted in CTA-negative SAH.

A CT/CTA approach has been suggested as an alternate diagnostic strategy to CT/lumbar puncture (LP) in the diagnosis of SAH. However, this approach focuses on identifying an aneurysm rather than on the presence of intracranial haemorrhage. The consequence of this strategy may be that the aneurysm detected is an incidental finding, as aneurysms are known to occur in about 2.5% of the normal population. This would then result in unnecessary investigation and treatment of an asymptomatic aneurysm and is therefore not currently supported.

Cerebral angiography

Cerebral angiography is the gold standard for confirming the presence of an aneurysm, its location and the presence of vasospasm; it was previously the preferred angiographic test. It is not, however, without risk. Neurological complications occur in ≈1.8% of cases, with re-rupture of an aneurysm reported in 2% to 3%. It is also less available than CTA. These factors have seen it become less favoured, so that it is used in selected cases only.

Magnetic resonance angiography

Magnetic resonance angiography (MRA) is currently useful as a screening tool for the diagnosis of intracranial aneurysms in patients at increased risk.

Further imaging when no cause for subarachnoid haemorrhage is found

In patients where SAH is present and no cause is found, the distribution of extravasated blood on the CT scan should be reviewed. If this conforms to the peri-mesencephalic distribution of non-aneurysmal haemorrhage, then no further investigations may be warranted. If, however, an aneurysmal pattern of haemorrhage is present, then a second CTA is recommended, as occasionally an aneurysm may have gone undetected on the original test.

Lumbar puncture

Lumbar puncture is necessary when there is clinical suspicion of SAH; the CT scan is negative, equivocal or technically inadequate; and no mass lesion or signs of raised intracranial pressure are found. In about 3% to 5% of patients with SAH, the CT scan will be normal. Although it has been suggested that a negative CT scan performed in the first 6 hours following headache onset is sufficient to exclude a diagnosis of SAH, evidence is inadequate to support this practice; therefore it cannot be recommended to replace a CT/LP strategy.

The diagnosis of SAH, then, is dependent on the finding of red blood cells not due to traumatic tap or red blood cell breakdown products within the CSF. Lumbar puncture should be delayed for at least 6 and preferably 12 hours after symptom onset to allow bilirubin to be formed from cell breakdown in SAH. Detection of bilirubin and xanthochromia is the only reliable method of distinguishing SAH from a traumatic tap. Proceeding to angiographic studies in every patient with bloodstained CSF would be expected to identify an incidental finding of a small unruptured aneurysm in about 2%.

It is important to measure the opening pressure when performing a lumbar puncture, as CSF pressure may be elevated in SAH or in other conditions, such as intracranial venous thrombosis or pseudotumour cerebri, or low in spontaneous intracranial hypotension.

Xanthochromia, the yellow discoloration of CSF caused by the haemoglobin degradation products oxyhaemoglobin and bilirubin due to lysis of red blood cells, is generally agreed to be the primary criterion for diagnosis of SAH and differentiates SAH from traumatic tap. It is usually present within 6 hours of SAH and has been demonstrated in all patients with SAH between 12 hours and 2 weeks following the haemorrhage. Spectrophotometric analysis of CSF for bilirubin is considered to be the most sensitive means of detecting xanthochromia.

Controversy exists as to the optimal timing of lumbar puncture. Early lumbar puncture within 12 hours may have negative or equivocal CSF findings, whereas delayed lumbar puncture may result in an increased risk of early rebleeding as well as having practical implications for the ED. In general at least 6 to 12 hours should have elapsed between the onset of headache and lumbar puncture. Although the detection of xanthochromia is indicative of SAH, it does not entirely rule out traumatic lumbar puncture and can occur in extremely bloody taps (>12,000 red blood cells per millilitre) or where the lumbar puncture has been repeated after an initial traumatic tap.

Other studies of the CSF—such as three tube-cell counts, D-dimer assay and the detection of erythrophages—have been found to be inconsistent in differentiating SAH from traumatic tap.

General investigations

General investigations to be performed include full blood examination, erythrocyte sedimentation rate, urea, electrolytes including magnesium, blood glucose, coagulation screen, chest x-ray and 12-lead ECG. ECG changes are frequently present and include ST- and T-wave changes, which may mimic ischaemia, QRS and QT prolongation and arrhythmias. Cardiac biomarkers, including troponin, may also be elevated.

Complications

Early complications

- Re-bleeding occurring in up to 15% of patients within hours of the initial haemorrhage. Overall, 40% of patients re-bleed within the first 4 weeks if there is no intervention. Re-bleeding is associated with 60% mortality and half of the survivors remain disabled.
- Subdural haematoma or a large intracerebral haematoma can be life threatening and requires immediate drainage. Similarly, a large intracerebral haematoma may be contributing to the patient's poor clinical condition and warrants drainage along with simultaneous treatment of the aneurysm.
- Global cerebral ischaemia. Irreversible brain damage resulting from haemorrhage at the time of aneurysmal rupture is probably secondary to a marked rise in intracranial pressure, resulting in inadequate cerebral perfusion.
- Cerebral vasospasm. Clinically significant vasospasm occurs in approximately 20% of patients with SAH and is a major cause of death and morbidity. It tends to occur between days 3 and 15 after SAH, with a peak incidence at days 6 to 8. Vasospasm causes ischaemia or infarction and should be suspected in any patient who suffers a deterioration in neurological status or develops neurological deficits. The best predictor of vasospasm is the amount of blood seen on the initial CT scan.
- Hydrocephalus occurs in approximately 20% of patients with SAH. It can occur within 24 hours of haemorrhage and should be suspected in any patient who suffers a deterioration in mentation or conscious state, particularly if associated with slowed pupillary responses.
- Seizures.
- Fluid and electrolyte disturbances. Patients with SAH may develop hyponatraemia and hypovolaemia secondary to excessive natriuresis (cerebral salt wasting) or, alternatively, such patients may develop a syndrome of inappropriate antidiuretic hormone (SIADH).
- Hyperglycaemia and hyperthermia, both being associated with a poor outcome.
- Medical complications include cardiogenic or neurogenic pulmonary oedema (23%), cardiac arrhythmias (35%), sepsis, venous thromboembolism and respiratory failure.

Late complications

- Late re-bleeding, from a new aneurysm or regrowth of the treated aneurysm is estimated at ≈1.3% in 4 years for coiling and ≈2% to 3% in 10 years for surgical clipping.
- Anosmia: up to 30%.
- Epilepsy: 5% to 7%.
- Cognitive deficits and psychosocial dysfunction are common even in those who make a good recovery; 60% of patients report personality change.

Treatment

The management of SAH requires general supportive measures, particularly airway protection and blood pressure control, as well as specific management of the ruptured aneurysm and the complications of aneurysmal haemorrhage.

General measures

- Stabilization of the unconscious patient, with particular attention to the airway. Endotracheal intubation with oxygenation and ventilation will be required in patients with higher-grade (4 to 5) SAH.
- Close observation of the Glasgow Coma Scale (GCS) score and vital signs.
- In all patients, oxygenation and circulation must be maintained to ensure adequate (euvolaemic) blood volume.
- Analgesia, using reversible narcotic analgesic agents, sedation and antiemetics as required. Bed rest with minimal stimulation is to be ensured; aspirin and non-steroidal analgesic agents (NSAIDs) are to be avoided.
- Blood pressure control. Blood pressure levels are often of the order of 150/90 mm Hg immediately following SAH and, in most patients, can be adequately controlled by analgesia. Normotensive levels extending to mild to moderately hypertensive levels, especially in patients with pre-existing hypertension, are acceptable. Antihypertensive therapy should be reserved for patients with severe (mean arterial pressure >130 mm Hg) hypertension or who have evidence of progressive end-organ dysfunction; short-acting antihypertensive agents (e.g. esmolol) and intensive haemodynamic monitoring should be employed.
- Fever should be regulated to maintain normothermia, which is associated with improved functional outcome.
- Seizures should be treated as they occur. The routine use of prophylactic phenytoin is controversial.
- Electrolyte imbalances must be corrected. Hyponatraemia due to excessive natriuresis must be differentiated from that of SIADH. Hypovolaemia is to be avoided.
- There is no convincing evidence for the use of steroids.
- Effective glucose control, importantly avoiding hyper- and hypoglycaemia.
- Venous thromboembolism prophylaxis, initially with compressive devices and later with subcutaneous heparin following treatment of the aneurysm.
- Treatment of hydrocephalus by ventricular drainage may be required.

Specific treatment

Prevention of re-bleeding

Obliteration of the ruptured aneurysm by endovascular coiling or surgical clipping should be performed as early as possible to prevent re-bleeding, remove clot, reduce the incidence of early complications and improve outcomes.

Endovascular occlusion, achieved by placing detachable coils in aneurysms under radiological guidance (coiling), has largely replaced surgical occlusion as the method of choice for the prevention of re-bleeding in suitable cases. The method of treatment, however, depends on anatomical considerations, as aneurysms are not equally amenable to this option. In aneurysms that are suitable to treatment by either modality, the 4-year outcome has been demonstrated to be better with coiling, although there are higher aneurysmal recurrence and re-bleeding rates.

Surgical clipping is now a second-line option for most patients. It is usually done early—within 3 days and preferably within 24 hours.

Antifibrinolytic agents may reduce the incidence of early re-bleeding, but current evidence does not support their routine use in SAH (Baharoglu et al., 2013).

Prevention of delayed cerebral ischaemia

Cerebral ischaemia is often gradual in onset and involves the territory of more than one cerebral artery. Peak frequency is at 5 to 14 days after SAH. Nimodipine, a calcium channel antagonist, improves clinical outcome in SAH, with a relative risk reduction of 18% and an absolute risk reduction of 5.1%. The current standard regimen is nimodipine 60 mg orally every 4 hours for 3 weeks. It should be commenced within 48 hours of haemorrhage. Nimodipine is indicated irrespective of whether a ruptured aneurysm has been coiled or not.

There is insufficient evidence to support medically induced hypertension, hypervolaemia and haemodilution in the management of vasospasm (Loan et al., 2018).

Other treatments—including magnesium sulphate, the statins and antiplatelet agents—have not been demonstrated to improve clinical outcomes.

There are no definitive treatments for delayed cerebral ischaemia, although improving cerebral perfusion by the maintenance of euvolaemia and induced hypertension is recommended where blood pressure and cardiac status permit. In vasospasm unresponsive to medical management and where focal vessel narrowing is demonstrated, emergency cerebral angiography with intra-arterial vasodilator infusion or transluminal balloon angioplasty may be considered.

Prognosis

SAH has a 40% to 60% mortality rate from the initial haemorrhage, with up to one-third of survivors having a significant neurological deficit. The most important prognostic factor is the patient's clinical condition at the time of presentation, with coma and major neurological deficits generally being associated with a poor prognosis. Survival rates have been reported at 70% for grade I, 60% for grade II, 50% for grade III, 40% for grade IV and 10% for grade V SAH.

It is worth noting, however, that survival without brain damage is possible even after respiratory arrest. Even patients who make a good recovery may suffer cognitive and psychosocial dysfunction.

Aneurysm screening in patients who have survived aneurysmal SAH is advocated, as these patients are at increased risk of new or recurrent aneurysmal bleeds.

Incidental unruptured aneurysms

If an unruptured aneurysm is found incidentally, it raises the dilemma of the risk-benefit rationale between intervention and conservative management. Factors taken into account include the patient's age, aneurysmal size and location, gender, country, co-morbidity and family history. Such patients should be referred to a neurosurgical service for advice and counseling.

Conclusion

Clinical suspicion of the diagnosis of SAH gained from a history of sudden, severe or atypical headache demands a full investigation, including a CT scan of the brain and, if necessary, lumbar puncture. Once SAH has been diagnosed, urgent neurosurgical referral and management are required.

CONTROVERSIES

- The timing of lumbar puncture (LP) following a negative CT scan for SAH.
- Non-contrast CT without LP within first 6 hours of headache and CT/CTA as diagnostic strategies for SAH.
- Vascular imaging for patients with a negative CT scan and negative CSF is indicated in those with ambiguous test results, those at high risk for SAH and patients presenting more than 2 weeks after the event.
- Prophylactic anticonvulsant therapy for patients with SAH.
- Follow-up for patients after coiling.

8.4 Altered conscious state

Ruth Hew

ESSENTIALS

1 **For clinical purposes, the ability of the individual to respond appropriately to environmental stimuli provides a quantifiable definition of consciousness.**

2 **The causes of altered conscious state can be divided pathophysiologically into structural and metabolic insults.**

3 **A thorough history and examination is the key to guiding investigation choice and identifying the cause of the primary insult. Management is directed towards resuscitation, specific correction of the primary pathology and minimization of secondary injury.**

4 **Bedside blood glucose measurement is essential and may be lifesaving.**

Introduction

Consciousness is variously termed *lucidity, orientation, awakeness* and *mentation* in the context of emergency department (ED) patients. None of these terms comprehensively defines consciousness. The Glasgow Coma Scale (GCS) (Box 8.4.1), developed for head-injured patients in a time when computed tomography (CT) scanning was unavailable, is routinely used but not specifically suited to measuring conscious state. Ultimately, consciousness is an amalgam of alertness, orientation and clarity of cognition. Of

Box 8.4.1 The Glasgow Coma Scale

The GCS scores range between 3 and 15, 3 being the worst and 15 the best. This scale is composed of three parameters: best eye response, best verbal response, best motor response, as given below:

Best eye response (score out of 4)
1—No eye opening
2—Eye opening to pain
3—Eye opening to verbal command
4—Eyes open spontaneously

Best verbal response (score out of 5)
1—No verbal response
2—Incomprehensible sounds
3—Inappropriate words
4—Confused
5—Orientated

Best motor response (score out of 6)
1—No motor response
2—Extension to pain
3—Flexion to pain
4—Withdrawal from pain
5—Localizing pain
6—Obeys commands

note, isolated absence or derangement of cognition and mentation (e.g. caused by dementia or psychiatric illness or both, considered elsewhere) does not result in the clinical entity of altered conscious state. In the same way, simple lack of orientation does not constitute a clinical alteration in conscious state.

In the clinical context, an alteration in conscious state requires a drop in alertness and 'awakeness'. This drop may result in a corresponding loss of orientation and/or a clouding of cognition, thereby altering a patient's response to environmental stimuli or provocation. The reverse, an increase in alertness, could also be considered an alteration in conscious state but, in practice, is most often due to pharmacological agents or a mood-elevating psychiatric illness, both of which are beyond the scope of the present discussion.

Pathophysiology

The level of consciousness describes the rousability of the individual, whereas the content of consciousness may be assessed in terms of the appropriateness of the individual's response. Broadly speaking, the first is a brain stem function and the second is an attribute of the forebrain.

The physical portions of the brain involved in consciousness consist of the ascending arousal system, which begins with monoaminergic cell groups in the brain stem and culminates in extensive diffuse cortical projections throughout the cerebrum. En route there is input and modulation from both thalamic and hypothalamic nuclei as well as basal forebrain cell groups.

Integration of the brain stem and the forebrain is illustrated by individuals who have an isolated pontine injury. They remain aware, but the intact forebrain is unable to interact with the external world, hence the aptly named 'locked-in syndrome'. At the other end of the spectrum are individuals with unresponsive wakefulness syndrome (persistent vegetative state) who, in spite of extensive forebrain impairment, appear awake but totally lack the content of consciousness. These clinical extremes emphasize the important role of the brain stem in modulating motor and sensory systems through its descending pathways and regulating the wakefulness of the forebrain through its ascending pathways.

Differential diagnosis

Given the pathophysiology, the causes of an altered conscious state are myriad and include any cause of insult or injury either directly or indirectly to the brain (Box 8.4.2). Direct injury resulting in structural insults may be traumatic or non-traumatic (e.g. subdural haemorrhage, stroke). Indirect injury may encompass any change in the metabolic and chemical milieu of the brain, resulting in a depression of neuronal function (e.g. sepsis, hyper- or hypoglycaemia, drug ingestion).

Structural insults, commonly focal intracranial lesions that exert direct or indirect pressure on the brain stem and the more caudal portions of the ascending arousal system, tend to produce lateralizing neurological signs that help to pinpoint the level of the lesion. As there is little space in and around the brain stem, any extrinsic or intrinsic compression will rapidly progress through coma to death unless the pressure on the brain stem is relieved surgically or pharmacologically.

Metabolic insults, commonly due to systemic pathology that affects primarily the forebrain (although direct depression of the brain stem may also occur) seldom result in lateralizing signs. The appropriate treatment is correction of the underlying metabolic impairment. Naturally, as in all clinical practice, there are no absolute distinctions. Uncorrected, any of the metabolic causes can eventually cause cerebral oedema and herniation, leading thence to brain stem compression with lateralizing signs, coma and death.

Clinical assessment

In approaching a patient with an altered conscious state, the initial imperatives are to ensure the safety of the airway, breathing and

circulation and to determine the cause for the alteration with a view to correcting the rapidly reversible causes and offering supportive care while working through the remainder. To this end, assessment and management must proceed concurrently. As in other time-critical situations, the primary and secondary survey approach is useful, seeking to identify and correct the primary insult whilst preventing or minimizing secondary injury, such as hypoxia, acidosis and raised intracranial pressure.

Primary survey and resuscitation

Immediate, easily reversible causes that can be identified and corrected include hypoxia and hypoglycaemia. These should be prioritized.

Thereafter an assessment of the airway, breathing and circulation of the patient is urgently required to ensure that lifesaving measures, such as airway and ventilation support, can be instituted. Initially, supplemental oxygen and non-invasive monitoring should be applied and attention paid to the absolute value and trends in the GCS score and vital signs. Normotension should be the goal of blood pressure monitoring, and this may require inotropic or antihypertensive support.

Early endotracheal intubation may be required if the GCS score is less than 8 or the patient's ventilatory effort is inadequate. Mechanical ventilation to maintain normocarbia, a pCO_2 of 35 to 40 mm Hg may assist in correcting underlying acidosis and reducing intracranial pressure; over-correction may be detrimental. Accurate end-tidal CO_2 monitoring correlated with arterial pCO_2 is required. In the setting of trauma, spinal precautions should be maintained until any possibility of trauma is excluded or clearance of the spine can be obtained.

In certain patient populations, pinpoint pupils and a depressed respiratory response may suggest a diagnosis of opiate toxicity and the administration of naloxone as a diagnostic and therapeutic tool. Often this has already been assayed in the prehospital arena, where intranasal naloxone has significantly reduced the risk of needlestick injuries. Although the adverse reactions to naloxone in initial doses is small, the greater risk is in the unmasking of the proconvulsant or proarrhythmic effects of other co-ingestants. Thus naloxone should not be given unless clinically indicated. There is also the potential of introducing diagnostic bias, as a percentage of non-opioid ingestants also appear to respond clinically to naloxone.

Secondary survey

Following initial assessment and resuscitation, it is important to complete the assessment by obtaining a full history, conducting a full examination and performing adjunctive investigations. This will help to identify the cause of the condition and to plan further management.

History

This is often difficult with an obtunded or confused patient and may have to rely heavily on ancillary sources, such as first responders, caregivers, primary-care physicians, medical records and patient alert identification.

It is crucial to establish the events leading up to the presentation with specific questioning about prodromal events (e.g. ingestions; intravenous drug usage; trauma; underlying illness, particularly infective prodromes; medications, allergies), associated seizures and abnormal movements. For example, a sudden-onset headache may signal subarachnoid haemorrhage and a history of head injury with loss of consciousness would increase the likelihood of an extra-axial intracranial collection. Patients on anticoagulants also have an increased risk of intracranial haemorrhage with minimal trauma. Patients with a history of hepatic failure may require specific treatment for hepatic encephalopathy. The recent delineation of the complex symptomology of anti–N-methyl-D-aspartate (NMDA) receptor encephalitis highlights the importance of a detailed history and examination.

In the elderly, dementia, itself a progressive illness, may be exacerbated by delirium caused by an acute illness. Then only a careful corroborated history from caregivers and the passage of time will allow the two to be distinguished. Often the most helpful portion of the history lies in ascertaining the patient's usual pattern of behaviour and the degree and time course of any changes that have occurred. In these patients, it is important to remember that dementia as a cause of altered conscious state is a diagnosis of exclusion.

Examination

A general physical examination, bearing in mind the various differential diagnoses, is very important. In the absence of adequate history, a thorough physical examination may offer the only pointers to initial treatment. Vital signs (e.g. tachycardia, hypotension, temperature) may suggest sepsis or other causes of shock. If infection is suspected, a search for possible sources should be pursued, the common culprits being chest and urine; but more occult infections such as endocarditis, meningitis and encephalitis should not be overlooked. As a rule, in the presence of sepsis, presumptive antibiotic administration should not be delayed for the sake of identifying a specific infective source. A keen sense of smell might detect fetor hepaticus or the sweet breath of ketosis. A bitter-almond scent is pathognomonic of cyanide poisoning. Of note, alteration of consciousness can be attributed to alcoholic intoxication only by the process of exclusion. Thus the characteristic odour of alcoholic liquor is indicative but cannot be presumed to be diagnostic. A bedside blood glucose determination is mandatory, as deficits are easily correctable.

Neurological examination must be as comprehensive as possible. There are several obstacles to this. Initial resuscitation measures, such as endotracheal intubation, will reduce the ability of the patient to cooperate with the examination, and language difficulties will be accentuated, as the neurological examination is strongly language orientated. Thus patients who do not share a common language with clinicians and those with dysphasia may be disadvantaged. Also, sensory modalities are difficult to assess in patients with impaired mentation, although these deficits are often paralleled by deficits in the motor system.

The aim of the neurological examination is first to differentiate structural and non-structural causes; second, to identify groups of signs that may indicate specific diagnoses, such as meningitis; and finally, to pinpoint the location of any structural lesion. Therefore emphasis must be placed on signs of trauma, tone, reflexes, pupillary responses and eye signs as well as serial calculation of the GCS score. Circumstances permitting, as much as possible of the neurological examination should be performed before the patient receives neuromuscular paralysing agents.

Signs of trauma must be documented and spinal precautions maintained as indicated. Palpation of the soft tissues and bones of the skull may detect deformity or bruising, and a haemotympanum may herald a fracture of the base of the skull.

Hypotonia is common in acute neurological deficits. Specific examination of anal sphincter tone will uncover spinal cord compromise and is crucial in trauma patients who have a depressed level of consciousness. An upgoing Babinski response is indicative of pyramidal pathology, and asymmetry of the peripheral limb reflexes may help to localize a unilateral lesion. Heightened tone in the neck muscles may indicate meningitis or subarachnoid haemorrhage.

Pupillary responses and eye signs may be useful to differentiate metabolic and structural insults and, more importantly, to detect incipient uncal herniation. Intact oculocephalic reflexes and preservation of the 'doll's eyes' response indicates an intact medial longitudinal fasciculus and, by default, an intact brain stem, suggesting a metabolic cause for coma. Four pairs of nuclei spread between the midbrain and the pons govern ocular movements. Patterns of their dysfunction can be used to pinpoint the site of a brain stem lesion (Table 8.4.1). Likewise, specific testing of the oculovestibular reflex and the cranial

Table 8.4.1 Ocular responses to cold caloric testing of the oculovestibular reflex

Response	*Cerebrum*	*Medial longitudinal fasciculus*	*Brain stem*
Bilateral nystagmus	Intact	Intact	Intact
Bilateral conjugate deviation towards the stimulus	Metabolic dysfunction	Intact	Intact
No response			Structural or metabolic dysfunction
Ipsilateral dysconjugate deviation			Structural dysfunction

Table 8.4.2 Patterns of dysfunction in various parameters determined by the site of the structural or metabolic insult

	Respiratory pattern	*Motor response*	*Pupillary light response*	*Eye movements*
Forebrain	Cheyne-Stokes waxing and waning	Localizing to pain	Symmetrical, small, reactive Pretectal • symmetrical, large, fixed	
Midbrain	Hyperventilation	Decorticate	Fixed	Upper midbrain CN III palsy Lower midbrain • CN IV deficit • Loss of ipsilateral adduction
Pons	Apneusis • Halts briefly in full inspiration	Decerebrate	Symmetrical, pinpoint, reactive Uncal—ipsilateral, fixed, dilated	CN VI deficit; loss of ipsilateral abduction
Medulla	Ataxic irregular rate and uneven depth Apnoeic Bilateral ventrolateral medulla lesions			

nerve examination can be used to locate a brain stem lesion precisely, but this is of limited use in the emergency setting except as a predictor of herniation (Tables 8.4.1 and 8.4.2). However, with increasing access to CT scanning, the most commonly utilized eye sign is the unilateral or bilateral fixed or dilated pupil, potential signs of early or late herniation and incipient brain and metabolic death.

More generally, skin examination may reveal needle tracks suggestive of drug use, envenomation bite marks or a meningococcal rash. Mucosal changes, such as cyanosis or the cherry-red glow of carbon monoxide poisoning, can be diagnostic. Cardiac monitoring and cardiovascular examination should identify rhythm disturbances, the murmurs of endocarditis and valvular disease or evidence of shock from myocardial ischaemia or infarction. Respiratory patterns may aid in identifying the site of the lesion (see Table 8.4.2). Abdominal examination may detect organomegaly, ascites, bruits or pulsatile masses.

Toxidromes (e.g. anticholinergic or serotoninergic) should be sought, as these are not uncommon causes of alterations in conscious state, with or without psychiatric symptoms. Further information on toxidromes can be found in the relevant chapters of this text.

A mental state examination may also serve to differentiate between psychiatric and organic disease, stable dementia and acute delirium.

Clinical investigations

Given the breadth of differential diagnoses, clinical investigations must be guided by the preceding history and examination and their timing dictated by the resuscitation imperatives. The following is an extensive list of possible investigations, but there is no suggestion that they should all be performed in every patient with an altered conscious state without due consideration of the patient's context and condition. A comprehensive history and thorough examination are crucial to direct investigation choices.

Haematology

A full blood examination may reveal anaemia, immunocompromise, thrombocytopaenia, inflammation or infection but is rarely diagnostically specific. In the setting of trauma, a bedside haemoglobin determination can direct immediate blood-product replacement. C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are non-specific acute-phase reactants and single determinants are not initially useful, although they may later be followed to monitor resolution of the illness or response to therapy. Coagulation profiles are particularly useful in haematological and liver disease or if patients are taking anticoagulants such as warfarin, usage of which should lower the threshold for radiological imaging of the brain.

Biochemistry

Serum electrolyte levels aid in the differentiation of the various hypo- and hyper-elemental causes of coma. Electrolyte imbalances may also be secondary to the causative insult and may not need specific correction. In hypotensive patients, a high to normal sodium and low potassium may suggest primary or secondary addisonian crisis.

Cardiac markers as well as liver, renal and thyroid function tests may confirm focal organ dysfunction. The last may not always be immediately available, but hypothyroidism should be considered in the hypothermic patient and hyperthyroidism in the presence of tremor and tachyarrhythmias.

Serum glucose provides confirmation of bedside testing. Serum lactate determinations may reveal a metabolic acidosis and reflect the degree of tissue hypoxia; this, again, may be primary or secondary. Creatinine kinase and myoglobinuria are useful to determine the presence and extent of rhabdomyolysis and to predict the likelihood that the patient will require dialysis. Serum and urine osmolarity may be useful in toxic ingestions, such as ethylene glycol, and in other hyperosmolar states.

Blood gas analysis may give important information regarding acid-base balance, a useful marker of severity of disease; along with the anion gap and the serum electrolytes, it can help to distinguish between the various types and causes of acidosis and alkalosis. Knowledge of the partial pressures of oxygen and carbon dioxide is vital to resuscitative efforts.

Microbiology

Sepsis is a major metabolic cause of alteration in conscious state and may present with no localizing symptoms or signs, especially in the elderly. In this case, blood cultures—preferably multiple sets obtained before antibiotic therapy—may be the only means of isolating the causative organism. Naturally, system-specific specimens—such

as sputum, urine and cerebrospinal fluid—should be collected when clinically indicated. A bedside dipstick of the urine sample can provide valuable information to guide initial treatment. Although as a rule specimens should be obtained prior to therapy, the administration of antibiotics or antiviral agents in suspected meningitis or encephalitis should not be delayed while a lumbar puncture (LP)/CT scan is performed.

Specific laboratory testing

Based on information from the history and examination, specific drug assays and urine screens may be indicated. These may include over-the-counter or prescribed medications (e.g. paracetamol, antiepileptics, lithium or theophylline) or drugs of addiction (e.g. amphetamine or opiates). Routine urine drug screens are of very limited overall value and of no help to emergency management.

Venom detection kits can be used in specific clinical situations, and screening for systemic envenomation should include coagulation profiles and creatinine kinase.

Imaging

Intracranial imaging is best achieved with a plain CT of the head, which, if normal and concern regarding intracranial pathology persists, may be followed by a contrast-enhanced scan or magnetic resonance imaging (MRI). The latter has a higher sensitivity for encephalitis and cerebral vasculitis, although it may not always be easily accessible from the ED. Also, the technical constraints of MRI require a 'stable' patient. Emergency CT angiography has a role in the delineation of cerebral aneurysms, and interventional angiography can provide therapeutic options, particularly in a patient who is progressing towards herniation. A normal CT scan does not completely exclude treatable intracranial infection or subarachnoid haemorrhage. Therefore, depending on the patient's conscious state and the level of clinical suspicion, an LP may further assist with diagnosis. However, it must be emphasized that in suspected intracranial infection, an obtunded patient should be treated empirically with appropriate antiviral agents and antibiotics and the LP deferred till the risk of herniation is minimized.

A chest x-ray may reveal primary infection or malignancy. In a patient with an altered conscious state and any suspicion of head trauma, imaging of the cervical spine must be considered and spinal precautions maintained until resuscitation imperative are satisfied. Imaging of the rest of the spine and other trauma imaging should be guided by clinical assessment.

Other tests

The 12-lead ECG can highlight rate and rhythm disturbances. Specific changes—such as the U wave of hypokalaemia, the J wave of hypothermia and focal infarction and ischaemic patterns—serve to confirm and offer pointers to the cause of the conscious state alteration. It is worth noting that intracranial bleeding, such as subarachnoid haemorrhage, can be associated with an ischaemic-looking ECG. Care is required in cases of depressed level of consciousness with ECG changes, as the use of thrombolysis or anticoagulation based on the ECG in the presence of intracranial bleeding may well be fatal.

Treatment

Management, by necessity, is governed by assessment findings, projected differential diagnoses and the patient's response to initial management. The algorithm in Fig. 8.4.1 is aimed at correcting immediate life-threatening pathology and then identifying and treating reversible structural and metabolic causes. Treatment of specific causes is addressed elsewhere in this text.

In the Australian and New Zealand context, the common causes of alteration in conscious state include infection and sepsis, intracranial pathology, metabolic derangement (e.g. hypo-/hyperglycaemia, hyponatraemia and complications of drugs including prescription medication).

General measures

The priorities of ED management include avoiding of hypoxia, hypotension, hyperthermia and hypoglycaemia; maintaining normovolaemia and cerebral and renal perfusion; and minimizing any increase in intracranial pressure.

To optimize haemodynamics and ventilation, the monitoring of arterial blood pressure and central venous pressure is often required, particularly if the patient is intubated or on inotropic support. The choice of inotropes should be dictated by the underlying pathology. Strict attention to fluid replacement and the need to monitor end-organ perfusion necessitate a urinary catheter. This can also be used to maintain normothermia.

With regard to drugs required to manage the airway and ventilation, propofol is a powerful, fast-acting, short-duration sedative that provides potentially neuroprotective effects through decreases in peripheral vascular tension. However, reviews of multiple small trials and datasets do not suggest any overall long-term mortality benefits of propofol over the opiate class in the management of sedation and ventilation of the traumatic brain-injured patient. It is important to provide analgesia and sedation, as their absence will result in physiological stimulation and increase intracranial pressure. Optimization of ventilation is useful to reduce hypoxia; neuromuscular paralytic agents may assist to this end.

Management of intracranial pressure

There are no class I studies comparing the efficacy of either mannitol (0.5 g/kg) or hypertonic saline (5 mL/kg of 3% saline) with placebo for intracranial pressure reduction. Osmotic diuretics for the reduction of intracranial pressure should be used only in consultation with the receiving neurosurgical team due to their potential for additional haemodynamic compromise and secondary neurological embarrassment.

Disposition

Patients with continuing altered consciousness should be admitted to a hospital with the range of services and clinical disciplines to manage the primary diagnosis. This may require stabilization prior to transfer and transport, sometimes over long distances. The exigencies of transfer may also dictate some of the initial management choices. The level of care required will depend on the state of the patient on presentation and his or her subsequent response to treatment. Patient wishes, premorbid status and prognosis may also temper treatment choices and pathways.

Prognosis

Discussion of prognosis is difficult, as it depends on the cause and patient-specific factors. Effective cerebral resuscitation with optimal oxygenation and minimization of intracerebral hypercarbia and acidosis as well as the maintenance of other end-organ perfusion and metabolic equilibrium will promote the best recovery potential while addressing the underlying disease process. Prognosis is naturally dependent on the degree of irreversible cellular damage and the ability to correct the primary insult while minimizing secondary brain injury.

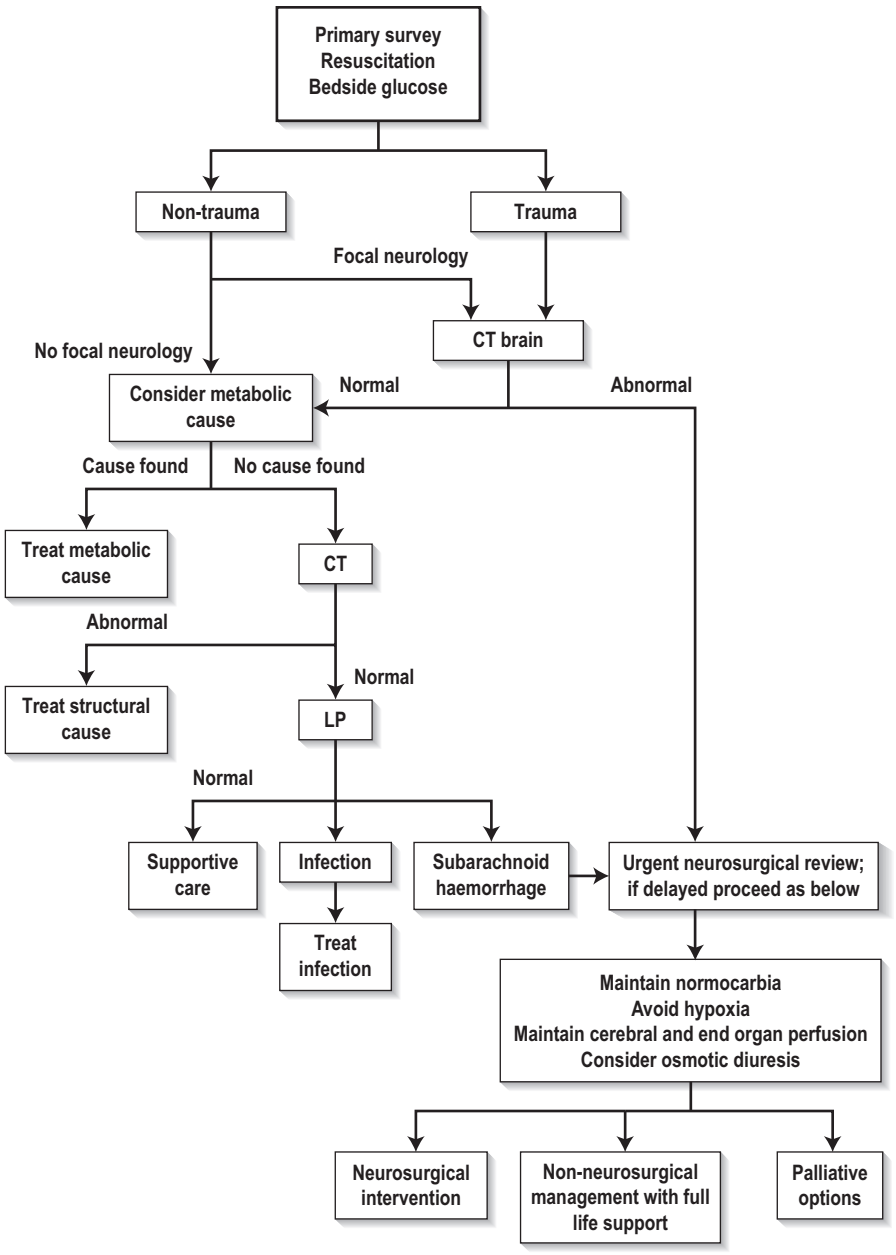

FIG. 8.4.1 Altered conscious state: treatment algorithm.

CONTROVERSIES

- The role and choice of osmotic diuretics in the management of acute elevations in intracranial pressure
- The interplay between patient and family wishes, premorbid status, prognosis and medical futility in the decision-making process determining management pathways and disposition, particularly given the uncertainties of diagnosis and prognosis early on in the ED stay

8.5 Seizures

Garry Wilkes

ESSENTIALS

1 Approximately 9% of the population will have at least one seizure in their lifetimes but only 1% to 3% will develop epilepsy.

2 The management of an acute episode is directed at rapid control of seizures, identification of precipitating factors and prevention/correction of complications.

3 Benzodiazepines and phenytoin are the principal anticonvulsant agents for acute seizures.

4 Management of drug-related seizures (including those related to alcohol) includes measures to reduce drug absorption and enhance elimination. Specific therapy is available for only a few agents. Phenytoin is usually ineffective in the management of alcohol and drug-related seizures.

5 Persistent confusion should not be assumed to be due to a post-ictal state until other causes have been excluded.

6 Investigation of first seizures should be directed by history and clinical findings. Routine laboratory and radiological investigations are not warranted for uncomplicated first seizures with full recovery.

7 It is important to distinguish pseudoseizures from neurogenic seizures in order to prevent inadvertent harm to patients and allow appropriate psychotherapeutic treatment.

8 Status epilepticus and eclampsia are severe life threats. Management plans for these conditions should be developed in advance.

9 Severe head injuries are associated with an increased incidence of post-traumatic epilepsy, half of which instances will be manifest in the first year. Phenytoin is effective as prophylaxis for the first week only.

10 Patients with epilepsy should be encouraged to have ongoing care.

Introduction

The terms 'seizure', 'convulsion' and 'fit' are often used both interchangeably and incorrectly. A seizure is an episode of abnormal neurological function caused by an abnormal electrical discharge of brain neurons. The seizure is also referred to as an ictus or ictal period. A convulsion is an episode of excessive and abnormal motor activity. Seizures can occur without convulsions and convulsions can be caused by other conditions. The term 'fit' is best avoided in medical terminology, but it is a useful term for non-medical personnel.

Epidemiology

Seizures are common. It has been estimated that 9% of the population will have at least one seizure in their lifetimes and 1% to 3% of the population will develop epilepsy. A single seizure may be a reaction to an underlying disorder, part of an established epileptic disorder or an isolated event with no associated pathology. The challenge is rapidly to identify and treat life-threatening conditions as well as to identify benign conditions that require no further investigation or treatment.

The diagnosis of epilepsy requires at least two unprovoked seizures more than 24 hours apart or a single seizure with a known predisposing cause (e.g. central nervous system [CNS] structural abnormality or interictal electroencephalographic [EEG] changes). An episode of status epilepticus is considered a single seizure. Childhood febrile and neonatal seizures are usually excluded from this definition.

Classification (see video Types of seizures https://www.youtube.com/watch?v=jrYVudPCYog)

Epileptic seizures can be classified into focal-onset and generalized types. Focal-onset seizures are further classified into simple focal (preserved consciousness) and complex focal seizures. Either may secondarily become generalized.

Generalized seizures can be divided into convulsive and non-convulsive types. Convulsive seizures are generalized tonic-clonic (grand mal) seizures. Non-convulsive generalized seizures include absence seizures (previously termed *petit mal*), myoclonic, tonic and atonic ('drop attack') seizures. Epilepsy and epileptic syndromes are also classified as focal or generalized. Each disorder can be further classified according to its relationship to aetiological or predisposing factors. Seizures can also be classified as provoked (acute symptomatic) or unprovoked ('unknown-onset'). The terms 'idiopathic' and 'cryptogenic' from previous classifications are discouraged.

Different seizure types are associated with differing aetiological and prognostic factors. A number of epileptic seizure classifications are supported by different bodies. The details of the classification systems are not as important in emergency medicine as the concept of recognizing the different seizure types and being aware of the accepted terminology (as outlined earlier) when cases are being discussed and referred.

Management principles

Given the high frequency of this condition in emergency departments (EDs), it is important to have an evidenced-based management strategy formulated in advance. The main management concepts are as follows:

- Altered mental state should be thoroughly assessed and not assumed to be due to a post-ictal state.
- Patients with known epilepsy who have recovered completely from a typical seizure require little further investigation. If they remain obtunded or have atypical features, they must be fully evaluated (e.g. through biochemical analysis, a computed tomography [CT] scan, etc.).
- Patients with epilepsy should be encouraged to seek continuing care.
- Patients at risk for recurrent seizures should be advised about situations of increased personal risk, such as driving, operating power machinery or swimming alone.

Differential diagnosis

Various conditions may be confused with epileptic seizures. Syncope is accompanied by some myoclonic activity in 90% of cases (see video Myoclonic activity during syncope https://www.youtube.com/watch?v=DOHGXoiS_Dk). Migraine, transient ischaemic attacks, hyperventilation episodes and vertigo are all important conditions to consider in the differential diagnosis. Pseudoseizures are discussed further on.

First seizures

A generalized convulsion is a dramatic event. Patients and those accompanying them will often be frightened, anxious and concerned, not only for the acute event but for what it may signify. A diagnosis of epilepsy may profoundly influence occupation, social activities, ability to drive a car and long-term health. It is therefore vital that the diagnosis be correct and explained fully to the patient and his or her relatives.

Clinical features

The first and most important task is to determine whether a seizure has occurred. As the majority have ceased at the time of presentation, the diagnosis is made primarily on history. Patients will not remember seizures other than simple partial seizures, and the reports of witnesses may be unreliable or inconsistent. With the exception of partial seizures, generalized seizures are not accompanied by an aura. Most seizures last less than 2 minutes, are associated with impaired consciousness, loss of memory for the event, purposeless movements and a period of post-ictal confusion. Although witnesses may grossly overestimate the duration, prolonged seizures, those occurring in association with a strong emotional event and those with full recall of events should be regarded with suspicion. Similarly, motor activity that is co-ordinated and not bilateral (such as side-to-side head movements, pelvic thrusting, directed violence and movement that changes in response to external cues) are less likely to be true seizures.

ED assessment is aimed at identifying associated conditions and treatable causes of seizures. The aetiology of seizures can be classified into five groups on the following basis:

- Acute symptomatic: occurring in association with a known CNS insult. Causes of this large, important group are listed in Box 8.5.1.
- Remote symptomatic: occurring without provocation in a patient with a previous history (>1 week prior) of CNS insult known to be associated with an increased risk of seizures (e.g. encephalopathy, meningitis, head trauma or stroke).
- Progressive encephalopathy: occurring in association with a progressive neurological disease (e.g. neurodegenerative diseases, neurocutaneous syndromes and malignancies not in remission).
- Febrile: patients whose sole provocation is fever. This is almost exclusively confined to children and therefore is beyond the scope of this book.
- Unknown onset (previously 'idiopathic' or 'cryptogenic'): patients without an identified precipitant. This is probably the most common group; however, this classification is by exclusion of the other causes.

A careful history is needed to decide whether this is part of an ongoing process or an isolated event. Patients may not recall previous events, may not recognize their significance or may even avoid reporting previous episodes for fear of being labelled 'epileptic', with the associated consequences. Particular attention should be paid to any history of unexplained injuries, especially when they occur during blackouts or during sleep. A history of childhood seizures, isolated myoclonic jerks and a positive family history increases the likelihood of epilepsy.

A full physical and neurological examination is mandatory. Evidence of alcohol and drug ingestion and head trauma is particularly important. A comprehensive medication history will include agents known to reduce seizure threshold in susceptible individuals (e.g. tramadol and selective serotonin reuptake inhibitors). A careful mental state examination in seemingly alert patients may reveal evidence of a resolving post-ictal state or underlying encephalopathy. Patients not fully alert should never be assumed simply to be in a post-ictal state until other causes are excluded. Evidence of underlying causes includes fever, nuchal rigidity (meningitis), cardiac murmurs (endocarditis), needle tracks, evidence of chronic liver disease, dysmorphic features and marks such as café-au-lait spots (neurofibromatosis). Complications—such as tongue biting, broken teeth and peripheral injuries—are not uncommon in generalized seizures. Stress fractures can occur, particularly in the elderly. Posterior dislocation of the shoulder is uncommon but significant and easily overlooked.

Box 8.5.1 Acute symptomatic causes of seizures

Hypoxia
Hypoglycaemia
Head trauma
Meningitis and encephalitis, including HIV disease
Metabolic, including hyponatraemia, hypocalcaemia, hyperthyroidism, uraemia and eclampsia
Drug overdose, including alcohol, antidepressants, theophylline, cocaine, amphetamine and isoniazid
Drug withdrawal, including alcohol, benzodiazepines, narcotics, cocaine and anticonvulsants
Cerebral tumour or stroke

Clinical investigations

Although it is common practice to order a variety of tests following an uncomplicated seizure, these are rarely of benefit in the fully recovered patient. Elevated neutrophil counts in blood and cerebrospinal fluid (CSF) may be seen as a result of a generalized seizure in the absence of an infectious disorder. Electrolyte abnormalities may cause seizures but are unlikely to be the cause if the patient has recovered. Serum prolactin level 20 to 60 minutes post-seizure may be helpful if the diagnosis is in doubt. An abnormal neurological examination and features of meningitis, encephalitis or subarachnoid haemorrhage are indications for cranial CT scan and lumbar puncture.

Imaging

There are no clear guidelines to the routine need for or urgency of neuroimaging following a single uncomplicated seizure. Patients with focal neurological signs, those who do not recover to a normal examination and those with a history of head trauma or intracranial pathology should all undergo cranial CT as soon as possible. The dilemma arises in patients with complete recovery and no focal signs. The incidence of abnormalities on CT in this group of patients is less than 1%. The decision as to whether and when to scan patients in this group will be determined largely by local factors. Magnetic resonance imaging (MRI) is more sensitive than CT for infarcts, tumours, inflammatory lesions and vascular lesions, but its availability may be limited.

Electroencephalography

EEG at the time of a seizure will make a definitive diagnosis. It is not usually performed in the acute setting except when non-convulsive activity is suspected. Typically an EEG is obtained electively

on an outpatient basis, when it may still indicate an underlying focus of activity and may be able to detect specific conditions.

Treatment

Once a diagnosis of first seizure has been made and intercurrent conditions have been excluded or treated, the patient may be discharged home. It must be stressed to the patient that a diagnosis of epilepsy has not been made but is being considered. When the suspicion is reasonable, the patient should be given the same precautionary advice as epileptic patients with regard to driving and other activities that may place them or others at risk.

The planning of investigation and follow-up for patients suspected of having a first seizure is best done in conjunction with a neurology service to make sure that appropriate investigations are completed in a timely fashion. Generally an inter-ictal EEG and contrast CT and/or MRI are completed prior to review.

Status epilepticus

Epidemiology and pathophysiology

Status epilepticus may be defined as 'two or more seizures without full recovery of consciousness between seizures, or recurrent epileptic seizures for more than 30 minutes'.

Status epilepticus accounts for 1% to 8% of all hospital admissions for epilepsy, 3.5% of admissions to neurological intensive care and 0.13% of all visits to a university hospital ED. It is more common at the extremes of age, with over 50% of all cases occurring in children and a disproportionately high incidence in those over 60 years of age. Status epilepticus is also more frequent in those with intellectual disability or with structural cerebral pathology, especially of the frontal lobes. Four to 16% of adults and 10% to 25% of children with known epilepsy will have at least one episode of status epilepticus during their lives; however, status epilepticus occurs most commonly in patients with no previous history of epilepsy.

Many compensatory physiological changes accompany seizures. As duration increases, these mechanisms begin to fail, with an increased risk of permanent damage. Brain damage resulting from prolonged status epilepticus is believed to be caused by excitatory amino acid neurotransmitters, such as glutamate and aspartate, leading to the influx of calcium into neuronal cytoplasm and an osmolytic cell destruction. Continuing seizure activity itself contributes to neuronal damage, which is further exacerbated by hypoxia, hypoglycaemia, lactic acidosis and hyperpyrexia. The longer an episode of status epilepticus continues, the more refractory to treatment it becomes and the more likely it is to result in permanent neuronal damage. Mortality increases from 2.7% with seizure duration under 1 hour to 32% with duration beyond this. Generalized convulsive status epilepticus is therefore a medical emergency.

Treatment

Treatment of status epilepticus is along the same lines as the resuscitation of all seriously ill patients. Management is in a resuscitation area with attention to the following:

- Rapid stabilization of airway, breathing and circulation
- Termination of seizure activity (clinical and electrical)
- Identification and treatment of precipitating and perpetuating factors
- Identification and treatment of complications

Each stage of resuscitation is made more difficult by the presence of active convulsions. Do not prise clenched teeth apart to insert an oral airway; a soft nasal airway will suffice. Place the patient in the left lateral position to minimize the risk of aspiration and administer oxygen if hypoxia is present or suspected. Intravenous access is important for drug treatment and fluid resuscitation but may be difficult in actively seizing patients. Although status epilepticus cannot be diagnosed until seizures have persisted for 30 minutes, patients still seizing on arrival at the ED should be treated with anticonvulsants immediately.

The principal pharmacological agents used are benzodiazepines and phenytoin. Opinions vary regarding the optimal benzodiazepine, with little clinical evidence to support any particular one. Lorazepam is preferred by most neurologists because of its prolonged CNS action (protective effect for 30 to 120 minutes). It typically takes 5 to 10 minutes to stop seizures and can cause hypotension. Midazolam is popular among emergency physicians for a variety of purposes. Being water-soluble, it is not irritating and can be administered intramuscularly with a fairly rapid onset of action (2 to 5 minutes). It has a short duration of action (another reason for its popularity in emergency medicine) and may require further intravenous doses or ongoing infusion. Diazepam has previously been popular owing to its extreme lipid solubility and rapid brain entry. It typically stops seizures rapidly (1 to 2 minutes). Preparations are, however, irritant, produce complications with intravenous extravasation and are unsuitable for intramuscular use. Diazepam can be administered rectally if necessary, and this technique can be taught to parents with high-risk children. All benzodiazepines share the disadvantages of respiratory depression, hypotension and short duration of clinical effect.

Phenytoin is usually used as a second-line agent in a dose of 15 to 20 mg/kg at a rate of no more than 50 mg/min. Rapid administration is associated with bradyarrhythmias and hypotension. The common practice of administering 1 g is inadequate for most adults. The effect of phenytoin does not commence until 40% of the dose has been administered; for this reason, if it is to be used, it should be commenced at the same time that intravenous benzodiazepines are given. Most people on anticonvulsants who present in status epilepticus have negligible drug levels, and the side effects from a full loading dose on top of a therapeutic level are minimal. The full loading dose should therefore be given even when the patient is known to be on therapy.

The most common causes of failure to control seizures are as follows:

- Inadequate antiepileptic drug therapy
- Failure to initiate maintenance antiepileptic drug therapy
- Hypoxia, hypotension, cardiorespiratory failure, metabolic disturbance (e.g. hypoglycaemia)
- Failure to identify an underlying cause
- Failure to recognize medical complications (e.g. hyperpyrexia, hypoglycaemia)
- Misdiagnosis of pseudoseizures

Causes of failure to regain consciousness following treatment of seizures include the medical consequences of status epilepticus (hypoxia, hypoglycaemia, cerebral oedema, hypotension, hyperpyrexia), sedation from antiepileptic medication, progression of the underlying disease process, non-convulsive status epilepticus and subtle generalized status epilepticus.

When benzodiazepines and phenytoin are ineffective, expert advice should be sought. Drugs that may be used in the control of status epilepticus are summarized in Table 8.5.1. Anaesthetic agents require expert airway control and, in some cases, inotropic support. Management in an intensive care unit is mandatory.

For all patients with status epilepticus, early consultation with intensive care and neurology services is essential in planning definitive management and disposition.

Non-convulsive seizures

Not all seizures are associated with convulsive activity. Convulsive seizures are generally easy to recognize, whereas non-convulsive seizures are more subtle and often require a high index of suspicion. These types of seizure are an important cause of alterations in behaviour and conscious level and may precede or follow convulsive episodes. Seizures can involve any of the sensory modalities, vertiginous episodes, automatism, autonomic dysfunction or psychic disturbances,

Table 8.5.1 Doses of drugs used in refractory status epilepticus

Drug	*Bolus (intravenous unless stated otherwise)*	*Maintenance infusion*
Lorazepam	0.05–0.1 mg/kg over 2–5 minutes; not to exceed 4 mg/dose; may repeat every 10–15 min	N/A
Midazolam	0.02–0.1 mg/kg	0.05–0.4 mg/kg/h
	0.1–0.2 mg/kg intramuscular	
Phenytoin/fosphenytoin	15–20 mg/kg at up to:	N/A
	Phenytoin max 50 mg/min	
	Fosphenytoin 100–150 mg/min	
Phenobarbitone	10–20 mg/kg at 60–100 mg/min	1–4 mg/kg/day
Thiopentone	5 mg/kg	1–3 mg/kg/h
Pentobarbitone	5 mg/kg at 25 mg/min	0.5–3 mg/kg/h
Propofol	2 mg/kg	5–10 mg/kg/h
Lignocaine	2 mg/kg	0.5–3 mg/kg/h

including *déjà vu* and *jamais vu* experiences. Non-convulsive seizures can easily be confused with migraine, cerebrovascular events or psychiatric conditions. The definitive diagnosis can be made only by EEG during the event.

Non-convulsive seizures may be focal or generalized. Simple and complex focal seizures account for approximately one-third of all seizures, whereas primary generalized non-convulsive seizures (absence seizures) account for 6%.

Non-convulsive status epilepticus accounts for at least 25% of all cases of status epilepticus and is diagnosed more frequently when actively considered. Absence seizures rarely result in complete unresponsiveness and patients may appear relatively normal to unfamiliar observers. Non-convulsive status epilepticus may precede or follow convulsive seizures and may easily create the perception of a cerebro-vascular or psychiatric event. The longest reported episode of absence status is 60 days and that of complex focal status 28 days.

Acute treatment of non-convulsive seizures is the same as for convulsive seizures. An estimated 50% of patients with simple focal seizures have abnormal CT scans. Long-term seizure control uses different agents from those used for convulsive seizures, highlighting the importance of involving a neurological service when follow-up is being planned.

Pseudoseizures

Pseudoseizures or psychogenic seizures are events simulating neurogenic seizures but without the accompanying abnormal neuronal activity. Differentiation from neurogenic seizures may be extremely difficult, even for experienced neurologists. Neurogenic and psychogenic seizures may coexist, making the diagnostic dilemma even more complex. Differentiation will often require video-EEG monitoring, but this facility is not available in the ED and other methods must be used. It is important to recognize pseudoseizures so as to prevent the possible iatrogenic consequences of unnecessary treatment while at the same time not withholding treatment from patients with neurogenic seizures.

Pseudoseizures are more common in women, less common after 35 years of age and rare in patients aged over 50. They may be associated with a conversion disorder, malingering, Munchausen syndrome or Munchausen syndrome by proxy.

Pseudoseizures typically last more than 5 minutes, compared with 1 to 2 minutes for neurogenic seizures. Multiple patterns of seizures tend to occur in individual patients, and post-ictal periods are either very brief or absent. Recall of events during what appears to be a generalized convulsive seizure suggests a psychogenic seizure. Extremity movement out of phase from one side to the other and head turning from side to side typify pseudoseizures. Forward pelvic thrusting occurs in 44% of patients with pseudoseizures and is highly suggestive of the diagnosis.

Several manoeuvres are useful in identifying pseudoseizures. Characteristic are eye-opening and arm-drop tests accompanied by avoidance, eyes turning away from the moving examiner and termination of the event when the mouth and nostrils are occluded. Simple verbal suggestion and reassurance are also frequently successful.

The most definitive means of identifying pseudoseizures is by ictal EEG or video-EEG monitoring. Unfortunately this is of little value in the ED. A fall in SpO_2 on pulse oximetry and a degree of acidaemia on blood gas analysis occur during neurogenic seizures but not pseudoseizures. Serum prolactin levels rise and peak three- to fourfold 15 to 20 minutes after generalized tonic-clonic seizures and then fall, with a half-life of 22 minutes. The levels do not consistently rise with partial seizures and remain normal with pseudoseizures.

Patients with pseudoseizures usually demonstrate resistance to anticonvulsant medication and many will therefore present with therapeutic or supra-therapeutic levels. Correct diagnosis will prevent unnecessary and potentially harmful treatment. Doubtful cases should be discussed with a neurology service and arrangements made for emergency EEG.

Once the diagnosis has been confirmed, it must be presented in an open and non-threatening manner. Patients often have underlying personal and/or family problems that will have to be addressed. Psychotherapy is effective, but seizures often relapse at times of stress.

Alcohol-related seizures

Alcohol contributes to half of seizures presenting to EDs. Acute toxicity and withdrawal are both associated with an increased incidence of seizures. Alcohol intoxication and chronic alcohol abuse are also associated with increased incidences of intercurrent disease, such as trauma, coagulopathy, falls, assaults and other drug intoxication, all of which further increase the likelihood of seizures. The management of seizures presumed to be alcohol-related must include a search for associated disease and other causes.

Benzodiazepines are the principal anticonvulsant agents for acute seizures. These agents are also valuable in the treatment of withdrawal. Phenytoin is ineffective in the control of acute alcohol-related seizures or as a preventative for them.

Drug-related seizures

Seizure activity in the setting of acute drug overdose is an ominous sign associated with greatly increased mortality and morbidity. The most commonly reported occur in association with cyclic antidepressants, antihistamines, theophylline, isoniazid and illicit drugs such as cocaine and amphetamines. The diagnosis and management of these are discussed in Section 25, Toxicology Emergencies.

Some medications are also associated with lowering seizure threshold in susceptible individuals. Tramadol, in particular, has been associated with new-onset seizures at normal therapeutic doses. A complete medication history is therefore essential.

Post-traumatic seizures

Post-traumatic epilepsy develops in 10% to 15% of those who have survived serious head injury. More than half will have their first seizure within 1 year. Risk factors are central parietal injury, dural penetration, hemiplegia, missile wounds and intracerebral haematomas. Early treatment with phenytoin for severe head injuries reduces the incidence of seizures in the first week only.

Seizures and pregnancy

Seizures can occur during pregnancy as part of an established epileptic process; they can occur as new seizures or may be induced by pregnancy. The most significant situations are eclampsia and generalized convulsive status epilepticus. At all times the management is directed at both mother and baby, with the realization that the best treatment for the baby will relate to optimal maternal care.

In individuals previously diagnosed with epilepsy, there is a 17% increased risk of seizures during pregnancy. Anticonvulsant levels are influenced by reduced protein binding, increased drug binding and reduced absorption of varying degrees. The final effect on free drug levels is unpredictable and is most variable around the time of delivery.

Isolated simple seizures place both mother and fetus at increased danger of injury but are otherwise generally well tolerated. Generalized seizures during labour cause transient foetal hypoxia and bradycardia of uncertain significance. Generalized convulsive status epilepticus is life threatening to both mother and fetus at any stage of pregnancy.

All anticonvulsants cross the placenta and are potentially teratogenic. The risk of malformation in children is increased from 3.4% in the general population to 3.7% in epileptic mothers. In general the types of malformation associated are not drug specific apart from the increased risk of neural tube defects associated with valproate and carbamazepine. Prenatal screening for such defects is advised in patients who become pregnant while they are taking these agents. The risk from uncontrolled seizures greatly outweighs the risk from prophylactic medication in patients with good seizure control.

The management of seizures in pregnant patients is along the same lines as that for non-pregnant patients. After 20 weeks' gestation, the patient should have a wedge placed under her right hip to prevent supine hypotension; eclampsia must also be considered. Investigation will include an assessment of foetal well-being by heart rate, ultrasound and/or tocography as indicated. Management and disposition should be decided in consultation with neurology and obstetric services.

Eclampsia is the occurrence of seizures in patients with pregnancy-induced toxaemia occurring after the 20th week of pregnancy. Toxaemia consists of a triad of hypertension, oedema and proteinuria. One in 300 women with pre-eclampsia progresses to eclampsia. Seizures are typically brief and self-terminating; usually preceded by headache and visual disturbances, they tend to occur without warning. Treatment is directed at controlling the seizures and hypertension and expedient delivery of the baby. Magnesium sulphate is effective in seizure control and is associated with a better outcome for both mother and baby than standard anticonvulsant and antihypertensive therapy.

Management of status epilepticus in pregnancy includes consideration of eclampsia, positioning in the left lateral position and assessment and monitoring of foetal well-being. Urgent control of seizures is essential for both mother and baby. Phenobarbital may reduce the incidence of intraventricular haemorrhage in premature infants and should be considered in place of phenytoin in this circumstance. Early involvement of obstetric and neurology services is essential. Pre-eclampsia and eclampsia are addressed specifically in Chapter 19.6.

Future directions

Non-invasive portable modalities allowing definitive, precise diagnosis of seizures in the ED will reduce the need for subsequent investigations in the majority of patients who do not have true epilepsy and thus permit early focused therapy. Advances in pharmacotherapy and neurosurgical techniques will also improve seizure control with minimal side effects, allowing patients to resume normal activities more effectively. Advances in neurobiology—as well as in the understanding of channels, receptors and the genetic expression of proteins—will enable the correction of underlying defects, thus removing the need for anticonvulsive therapy.

CONTROVERSIES

- Whether investigations are required for patients with uncomplicated first seizures
- The place of lumbar puncture in the investigation of first seizures

8.6 Syncope and vertigo

Rosslyn Hing

ESSENTIALS

1 It is important to distinguish between syncope and true vertigo.

2 The most common cause of syncope is neurally mediated syncope.

3 A detailed history and physical examination are more useful than extensive investigations.

4 It is essential to identify high-risk patients for the serious potential cardiac causes of syncope so that appropriate treatment can be given.

5 A key diagnostic step is to determine whether a central or peripheral cause of vertigo is more likely.

6 Dynamic manoeuvres may be both diagnostic and therapeutic.

Introduction

Syncope and vertigo are relatively common symptoms. They are often described by patients using the term 'dizziness'; however, it is essential to differentiate between the two. Syncope and vertigo both represent a significant diagnostic challenge and it is important to risk stratify patients accurately to distinguish between potentially life-threatening and benign causes.

Syncope

Syncope as a presenting symptom represents about 1% to 1.5% of all emergency department (ED) attendances. It is a symptom, not a diagnosis. It is defined as a loss of consciousness induced by the temporarily insufficient flow of blood to the brain. Patients recover spontaneously, without therapeutic intervention or prolonged confusion.

There is no simple test to distinguish between the benign and potentially life-threatening causes of syncope, but a careful history, examination and bedside investigations can help to determine appropriate disposition.

The causes of syncope are summarized in Box 8.6.1. The most common cause in all age groups is neurally mediated syncope, also known as neuro-cardiogenic or vasovagal syncope. Orthostatic hypotension and cardiac causes are the next most common.

Clinical features

Patients with syncope are often completely asymptomatic by the time they arrive at hospital. A thorough history and physical examination is the key to finding the correct cause of the syncope. The history should focus on the patient's recollection of the preceding and subsequent events, including environmental conditions, physical activity, prodromal symptoms and any intercurrent medical problems. Accounts from eyewitnesses or first responders are also vital. Medications that may impair autonomic reflexes must be scrutinized and a postural blood pressure measurement performed. Physical examination should concentrate on finding signs of structural heart disease as well as assessing any subsequent injuries.

Neurally mediated syncope causes a typical prodrome: patients complain of feeling lightheaded and faint and often describe a blurring or 'tunnelling' of their vision. This may be accompanied by other vagally mediated symptoms, such as nausea or sweating. If patients are unable or unwilling to follow the body's natural instincts to lie flat, they may collapse to the ground as they lose consciousness. This reflex brings the head level with the heart, resulting in an improvement in cerebral perfusion and a return to consciousness. During this time the patient may exhibit brief myoclonic movements, which can be mistaken for seizure activity but, in contrast with true epileptic seizures, there are no prolonged post-ictal symptoms. Fatigue is common following syncope.

Orthostatic hypotension occurs when the patient moves from a lying position to a sitting or standing position. If the required autonomic changes fail to compensate adequately, even healthy individuals will experience lightheadedness or a blurring of vision and possibly loss of consciousness. The most vulnerable people are those with blunted or impaired autonomic reflexes, such as the elderly, those on certain medications (particularly vasodilators, antihypertensive agents and β-blockers) and those who are relatively volume-depleted due to heat, excessive fluid losses or inadequate oral intake.

Cardiac syncope is more likely to present with an absent or brief prodrome. Sudden unexplained loss of consciousness should raise suspicion for a cardiac arrhythmia, particularly in the high-risk patient. Both tachycardia and bradycardia can be responsible. A syncopal event while supine is of particular concern and a predictor of a cardiac cause. Syncopal events that occur during exertion should prompt a search for structural heart disease, in particular aortic stenosis.

Risk stratification

Most of the published literature on the assessment of patients presenting to EDs with syncope has focused on identifying risk factors for mortality or an adverse cardiac outcome. These assessments include a number of scores and clinical decision rules, such as the Osservatorio Epidemiologico sulla Sincope nel Lazio (OESIL) score and the San Francisco Syncope Rule (SFSR). Patients with syncope can be divided into high- and low-risk groups, as shown in Box 8.6.2. Low-risk patients can be safely discharged for outpatient follow-up, but controversy over high-risk patients remains. It is likely that there is a significant proportion of patients in the high-risk group who actually have an intermediate risk and, given further evaluation in the ED or a short-stay unit, could also be safely discharged; however, it is more difficult to identify this subset.

Differential diagnosis

Seizures are commonly listed as a cause of syncope. Although they do cause a transient loss of consciousness, the pathophysiology is very different. Post-ictal confusion often helps to differentiate the two; however, urinary incontinence may also occur in syncope. True tonic–clonic activity must be distinguished from the brief myoclonic jerks occasionally seen in syncope.

Transient ischaemic attacks (TIAs) are often cited as potential causes for syncope, but this is rare. Only TIAs involving the vertebra-basilar territory can affect the reticular activating system of the brain to cause a loss of consciousness; however, a TIA should not be named as a cause of the

Box 8.6.1 Aetiology of syncope

Neurally mediated
- Vasovagal/neurocardiogenic
- Situational: cough, micturition, defaecation
- Carotid sinus syndrome

Cardiac
- Structural valvular disease, such as aortic stenosis
- Cardiomyopathy
- Unstable angina
- Myocardial infarction
- Bradyarrhythmias, such as sinus node disease, atrioventricular block
- Tachyarrhythmias, such as ventricular tachycardia, supraventricular tachycardia and torsades de pointes
- Pacemaker/defibrillator dysfunction
- Pulmonary hypertension
- Pulmonary embolus
- Aortic dissection

Orthostatic hypotension
- Dehydration
- Vasodilatation

Neurological
- Vertebro-basilar transient ischaemic attack
- Subclavian steal

Medication
- Anti-hypertensives
- β-blockers
- Cardiac glycosides
- Diuretics
- Antiarrhythmics
- Anti-parkinsonian drugs
- Nitrates
- Alcohol

Psychiatric

Box 8.6.2 Risk stratification for an adverse outcome

High risk
- Chest pain consistent with ischaemic heart disease
- History of congestive cardiac failure
- History of ventricular arrhythmias
- Pacemaker/defibrillator dysfunction
- Abnormal electrocardiogram (findings such as prolonged QTc interval, conduction abnormalities, acute ischaemia)
- Exertional syncope/valvular heart disease
- Age >60 years

Low risk
- Age <45 years
- Otherwise healthy
- Normal electrocardiogram
- Normal cardiovascular exam
- Prodrome (consistent with neurally mediated syncope or orthostatic hypotension)

Box 8.6.3 Aetiology of vertigo

Peripheral
- Benign paroxysmal positional vertigo (BPPV)
- Vestibular neuritis
- Acute labyrinthitis
- Ménière disease
- Ototoxicitiy
- Eighth-nerve lesions, such as acoustic neuromas
- Cerebellopontine angle tumours
- Post-traumatic vertigo

Central
- Cerebellar haemorrhage and infarction
- Vertebrobasilar insufficiency
- Neoplasms
- Multiple sclerosis
- Wallenberg syndrome (lateral medullary syndrome)
- Migrainous vertigo

syncope unless it is associated with other brain stem signs, such as cranial nerve defects or ataxia.

Syncope may also be the presenting symptom of a potentially life-threatening condition, such as pulmonary embolus, subarachnoid haemorrhage, gastrointestinal bleed or aortic aneurysm.

Clinical investigations

The only two mandatory investigations are a 12-lead ECG and blood glucose. These should add enough information to the clinical findings to stratify the patient as at high or low risk for an adverse outcome. Research has found that a serum troponin taken at least 4 hours after a syncopal event is not a sensitive predictor of an adverse cardiac outcome.

If a pulmonary embolus, subarachnoid haemorrhage, gastrointestinal bleed or aortic aneurysm is suspected, appropriate investigations based on clinical suspicion should be initiated.

Treatment

Treatment depends on the presumptive diagnosis. Patients with neurally mediated syncope require explanation and reassurance only. After ensuring that the vital signs have returned to baseline, their blood glucose and ECG are within normal limits and that they have had something to eat and drink, these patients may be discharged without further investigations.

Patients with orthostatic hypotension often require intravenous fluids and an adequate oral intake to reverse their postural blood pressure changes. Any decision regarding potential changes to chronic medications should ideally include the patient's primary care/treating doctor.

Patients who are deemed at high risk for a cardiac cause need continuous cardiac monitoring for at least 24 hours and admission for further evaluation. This may include echocardiography to identify structural heart problems and to quantify an ejection fraction or electrophysiological studies.

Prognosis

Syncope in a patient with underlying heart disease implies a poor prognosis, with data suggesting that one-third will die within a year of the episode. Overall, patients with syncope on a background of congestive cardiac failure are at the highest risk for an adverse outcome. In the absence of underlying heart disease, syncope is not associated with excess mortality.

Vertigo

Vertigo is defined as a disabling sensation whereby the affected individual feels that his or her surroundings are in a state of constant movement. It has a reported 1-year incidence of 1.4%. Like syncope, it is a symptom, not a diagnosis, and has as many causes. The difficulty is that, whereas many of the causes of vertigo are benign, it can also be a symptom of a serious neurological condition, such as vertebrobasilar stroke.

Aetiology

The causes of vertigo may be divided into peripheral and central, as shown in Box 8.6.3.

Clinical features

It is vital to establish whether the patient is suffering true vertigo as opposed to pre-syncope, loss of consciousness or mild unsteadiness. It is also necessary to clarify whether the individual has a sense of continuous motion (vertigo) or whether he or she feels 'lightheaded' or 'dizzy'.

As previously described, vertigo may be central or peripheral in origin. Peripheral vertigo tends to be more intense and to be associated with nausea, vomiting, diaphoresis and auditory symptoms, such as tinnitus or hearing loss (although hearing loss can rarely occur with vascular insufficiency in the posterior cerebral circulation, as the auditory apparatus is supplied via the anterior inferior cerebellar artery or the posterior inferior cerebellar artery). There may also be a history of ear trauma, barotrauma, ear infection or generalized illness. The onset of the vertigo tends to be subacute, coming on over minutes to hours. Benign paroxysmal positional vertigo (BPPV) has the classic history of position-induced vertigo, lasting only seconds. Central vertigo tends to be less severe and is associated with neurological symptoms and signs (e.g. headache, weakness of the limbs, ataxia, poor coordination and dysarthria). These symptoms may be the harbinger of more serious causes, such as cerebellar lesions or demyelinating diseases (Table 8.6.1).

Physical examination concentrates on any positional factors plus a detailed search for neurological signs, in particular nystagmus. This is the main objective sign of vertigo. Any spontaneous movement of the eyes must be noted, including its direction and persistence. Peripheral vertigo tends to produce unidirectional nystagmus with

Table 8.6.1 Clinical features of vertigo

	Peripheral	*Central*
Onset	Acute	Gradual
Severity	Severe	Less intense
Duration, pattern	Paroxysmal, intermittent; minutes to days	Constant; usually weeks to months
Positional	Yes	No
Associated nausea	Frequent	Infrequent
Nystagmus	Rotatory—vertical, horizontal	Vertical
Fatigue of symptoms, signs	Yes	No
Hearing loss/tinnitus	May occur	Not usually
Central nervous system symptoms, signs	No	Usually

the slow phase towards the affected side. In addition, patients with vestibular nystagmus are often able to suppress it by fixating on a stationary object.

The 'head impulse' or 'head thrust' test is a simple bedside manoeuvre that can be used to identify the affected labyrinth. With the patient fixating on the examiner's nose, the examiner holds the patient's head and performs a few high-acceleration but brief turns to either side. The patient's eyes will automatically move in the opposite direction, in order to maintain visual fixation. The test is positive when this fails to happen and, instead, the patient's eyes are seen to perform a series of catch-up movements, or 'saccades', in order to refixate on the examiner's nose. When the 'head impulse' test is positive, the lesion causing the nystagmus is extremely likely to be peripheral. The affected labyrinth is the one in the direction in which the head was moved.

The 'HINTS' examination includes the Head Impulse test, the evaluation for Nystagmus and a Test of Skew. Skew deviation is a vertical misalignment of the two eyes resulting from a central lesion. A normal head impulse test, direction-changing nystagmus or a skew deviation all suggest a central rather than a peripheral cause (http://www.6osecondem.com/the-hints-exam/).

Cardiovascular examination should focus on the risk factors for CNS thromboembolic events such as arrhythmias, murmurs and bruits.

Clinical investigations

Most patients who present with vertigo do not need laboratory tests apart from a blood glucose level. If there is a history of trauma or suspicion of a space-occupying lesion, a computed tomography (CT) or magnetic resonance imaging (MRI) scan of the brain is indicated. If differentiation from syncope is problematic, an ECG should also be performed to help rule out arrhythmias.

Dynamic manoeuvres can be both diagnostic and therapeutic. The Dix-Hallpike test can diagnose BPPV. It should not be performed in patients with carotid bruits and all patients must be warned that the test may provoke severe symptoms.

Initially the patient should be seated upright, close enough to the head of the bed so that when he or she is supine, the head will be able to extend back a further 30 to 45 degrees. To test the right posterior semicircular canal, the head is initially rotated 30 to 45 degrees to the right. Keeping the head in this position, the patient is quickly brought to the horizontal position with the head placed 30 to 45 degrees below the level of the bed. A positive test is indicated by rotatory nystagmus towards the affected ear. The test is then repeated on the left side.

Treatment

Treatment depends on the cause. If BPPV is suspected, the Dix-Hallpike test is performed to identify the affected ear. The Epley manoeuvre or 'canalith repositioning manoeuvre' aims to move any unwanted particles out of the semicircular canals and thus ease the symptoms for which they are responsible. The steps of this manoeuvre are as follows:

- The patient is seated as for the Dix-Hallpike test, with the head turned 45 degrees toward the affected ear.
- The patient is brought to the horizontal position with the head hyperextended 30 to 45 degrees below the bed.
- The head is gently rotated 45 degrees towards the midline.
- The head is then rotated a further 45 degrees towards the unaffected ear.
- The patient rolls onto the shoulder of the unaffected side, at the same time rotating the head a further 45 degrees.
- The patient is returned to the sitting position and the head is returned to the midline.

These movements may induce nystagmus in the same direction as that seen during the Dix-Hallpike test. Be aware that nystagmus in the opposite direction indicates an unsuccessful test. The manoeuvre may have to be repeated a few times.

Vestibular neuritis is unilateral and thought to be caused by a viral infection or inflammation. Episodes are acute in onset and may be severe, lasting for days; they are usually associated with nausea and vomiting. The sense of perpetual movement is present even with the eyes closed and is made worse by movement of the head. Symptomatic treatment—with medications such as antihistamines, antiemetics and benzodiazepines—is often all that is indicated. If nausea and vomiting are severe, intravenous fluid therapy may be needed. There are some reports of trials using steroids for vestibular neuritis, but there are conflicting results regarding both the short- and long-term outcomes.

Acute labyrinthitis may be viral or bacterial in origin. If it is viral, the course and treatment are similar to those of vestibular neuritis. Bacterial labyrinthitis may develop from an otitis media. The key feature here is severe vertigo with hearing loss. Patients are febrile and toxic and require admission for intravenous antibiotics.

Ménière disease comprises the classic triad of vertigo, sensorineural hearing loss and tinnitus. Attacks last from minutes to hours and may recur with increasing frequency as the disease progresses. It is caused by dilation of the endolymphatic system due to the excessive production of endolymph or problems with its reabsorption (endolymphatic hydrops). Medical management traditionally involves salt restriction and diuretics, although evidence is limited.

Vertebro-basilar insufficiency can produce vertigo, often accompanied by unsteadiness and visual changes. Symptoms may be provoked by head position and often include headache.

Importantly, however, patients with cerebellar infarction occasionally present with vertigo without other symptoms or signs of neurological impairment. Treatment involves addressing cardiovascular risk factors as well administering as antiplatelet therapy.

Migrainous vertigo is an increasingly recognized condition that is incompletely understood. In the acute setting, it poses a diagnostic challenge that will often necessitate exclusion of other central causes for vertigo, such as cerebrovascular disease.

CONTROVERSIES

- Identifying and determining disposition for syncope patients who do not fall into the high- or low-risk groups
- Role of a dedicated syncope evaluation unit
- The use of corticosteroids to treat vestibular neuritis

8.7 Weakness

Tim Green • Eileen M. Rogan

ESSENTIALS

1 The differential diagnosis of weakness in the emergency department (ED) is very broad. Careful history taking and examination with targeted investigations will help to identify most of the important causes.

2 Causes of weakness must be distinguished as neuromuscular or non-neuromuscular.

3 Most patients presenting to the ED with a complaint of weakness have a non-neuromuscular cause for their symptoms.

4 Guillain-Barré syndrome is the most common cause of acute-onset symmetrical progressive weakness in the developed world. Patients presenting with acute-onset symmetrical weakness require early assessment of airway and ventilation. Early intubation should be considered in high-risk cases. Admission to an intensive care is required for any patient with impaired ventilatory function.

5 Patients presenting with a multiple sclerosis relapse should usually be offered pulse steroid therapy in the form of methylprednisolone 1 g IV daily for 3 days (or equivalent oral dosage).

6 Supportive care is the priority in ED management in cases of weakness due to any cause.

7 If a neuromuscular cause is suspected, disposition decisions should be made in consultation with a neurologist.

8 Some patients with weakness will not be definitively diagnosed in the ED and may require referral for further investigations.

Introduction

Weakness is a subjective term that patients use to describe feelings of malaise, fatigue or frailty experienced as the result of myriad medical and psychological conditions. The *Oxford Dictionary* defines 'weak' as 'lacking the power to perform physically demanding tasks; having little physical strength or energy'.

In this chapter, we mainly consider the assessment and management of patients presenting with acute-onset, generalized, symmetrical or rapidly progressive weakness, primarily in the context of neuromuscular disease. Conditions that cause focal or unilateral weakness are not discussed in any great depth, nor is weakness related to non-neuromuscular causes. It should, however, be remembered that the latter group affects the majority of patients presenting to the emergency department (ED) complaining of weakness.

Aetiology and pathogenesis

Weakness is essentially due to a neuromuscular problem or something else. The primary goal in ED is to determine if there is actual quantitative loss of muscle strength indicative of a neuromuscular cause or whether the weakness results from a non-neuromuscular cause. The latter cases are often the result of multiple system disorders—for example, endocrine, cardiac and metabolic factors.

Neuromuscular weakness may reflect deficits anywhere along the neural pathway from the cerebral cortex to the myocyte. This pathway includes the pyramidal system as upper motor neurons (UMNs) synapse with lower motor neurons (LMNs) of the anterior spinal cord. LMN axons then descend through the anterior spinal cord to exit and synapse with myocytes. At the neuromuscular junction, LMNs release the presynaptic neurotransmitter acetylcholine (Ach) into the synaptic cleft, and post-synaptic Ach receptors then trigger depolarization of the motor end plate and contraction of the muscle cell. Pathology at any level of this neural pathway will result in weakness. An intact myelin nerve sheath, functioning calcium and sodium channels and the presence of acetylcholinesterase to limit the response are all necessary for normal neuromuscular function.

Specific signs—such as altered deep tendon reflexes (DTRs) and tone, muscle atrophy, fasciculations and distribution of weakness—aid in localizing the site of the neuromuscular pathology (Table 8.7.1).

Non-neuromuscular causes of weakness are myriad and generally reflect a combination of age, general physical and mental health factors and specific systemic disorders that co-exist to result in a general feeling of weakness or malaise (Table 8.7.2).

Pathology

Diverse pathological processes may underlie neuromuscular weakness. Of these, genetic, autoimmune and toxic causes predominate in the ED (Table 8.7.3). Patients with congenital genetic syndromes, such as muscular dystrophies or mitochondrial disorders, are rarely seen in the ED unless they are suffering from acute respiratory decompensation in the context of an acute reversible precipitant, such as pneumonia. Management of these cases will be guided by consideration of the clinical context, the stage of disease and disability and any advance care directives from the patient or their advocates.

In industrialized countries such as Australia, Guillain-Barré syndrome (GBS) is the most common cause of acute-onset neuromuscular weakness. GBS variants, multiple sclerosis (MS) and myasthenia gravis (MG) are other autoimmune disorders that precipitate ED presentations, either as de novo diagnoses or in the context of acute exacerbations. Toxic triggers—such as organophosphates, tetanus, botulism and envenomations—are relatively rare but can be fatal if not recognized and treated aggressively.

Other pathologies, such as paraneoplastic syndromes (Eaton-Lambert syndrome [ELS]) and electrolyte disturbances (e.g. hypokalaemic periodic paralysis), should be considered if the clinical context is suggestive. Poliomyelitis is an example of an infectious disease that was previously a major cause of acute-onset weakness. It has been eradicated in the Western world and is well on the way to eradication in the developing world. Post-polio syndrome is a rare late complication seen in ED.

Differential diagnosis

The differential diagnosis of weakness in the ED is very broad and it may not be possible to arrive at a definitive diagnosis during one

Table 8.7.1 Clinical signs that point to the origin of neuromuscular weakness

Sign	*UMNs*	*LMNs*	*NMJ*	*Myopathy*
Atrophy	None	Severe	Mild	Mild
Fasciculation	None	Common	None	None
Deep tendon reflexes	Hyperreflexic	Areflexic/hyporeflexic	Normal/hyporeflexic	Normal/hyporeflexic
Distribution of weakness	Pyramidal/regional	Distal/segmental	Variable/fatigable weakness	Proximal > distal
Tone	Spastic	Decreased/flaccid	Decreased/flaccid	Normal/decreased
Plantar response	Upgoing	Downgoing or absent	Downgoing or absent	Downgoing or absent

LMNs, Lower motor neurons; *NMJ*, neuro-muscular junction; *UMNs*, upper motor neurons.

Table 8.7.2 Non-neuromuscular conditions associated with weakness

Condition	*Manifestations*
Anaemia	Breathlessness and fatigue usually worse with acute-onset anaemia
Cardiac failure	Fatigue and weakness are common symptoms of heart failure in elderly patients, especially weakness in females over 50 years
Malignancy	Paraneoplastic syndromes (e.g. generalized wasting)
Psychological disorders	Depression/anxiety, psychosis, medication side effects, malingering
Malnutrition	Institutionalized patients, impoverished elderly, anorexia nervosa
Chronic fatigue syndrome	Possibly post-viral syndrome
Rheumatological disorders	Rheumatoid arthritis, systemic lupus erythematosus, fibromyalgia
Medications	Many medications have been associated with weakness; the commonly encountered ones include glucocorticoids, statins, antiretrovirals, alcohol, colchicine and polypharmacy, especially in the elderly
Acute electrolyte derangement (e.g. hypo- and hyperkalaemia, hypocalcaemia)	Acute onset weakness and/or tetany with hypocalcaemia
Sepsis	Acidosis, deranged metabolic state
Dehydration	Lethargy/fatigue
Hypothyroidism	Lethargy, cold intolerance, weight gain, weakness
Chronic disease	Respiratory, renal, hepatic failure

ED visit. Recognition of neuromuscular disorders that have the potential to deteriorate rapidly and require intensive supportive care with assisted ventilation is the most crucial element of ED diagnosis. In particular, GBS, MS exacerbations, myasthenic crises and intoxications, such as botulism, must be recognized early.

Clinical features

The diagnosis of neuromuscular disease is dependent on history, examination and specific investigation findings. A starting point for diagnosis should include a thorough history, noting in particular the following:

- Known underlying neuromuscular disorders, such as amyotrophic lateral sclerosis (ALS), muscular dystrophy, MS or MG
- Pre-existing medical conditions, such as malignancy suggesting a paraneoplastic syndrome, monoclonal gammopathy associated with chronic inflammatory polymyopathy (CIDP) or HIV infection/post-transplant immunosuppressive states associated with CIDP, polyradiculopathy or HIV myopathy
- Recent infections (diarrhoeal, viral) or major surgery associated with GBS.
- Recent exposures/ingestions suggestive of intoxications, for example botulism, organophosphate, ciguatera toxin.

Clinical findings generally reflect the site of the lesion within the motor unit (see Table 8.7.1).

Clinical investigations

Given the broad differential diagnosis possible for weakness, a broad screen of laboratory parameters—including full blood count (for anaemia or inflammation), electrolytes and renal function, liver function, thyroid function plus muscle creatine kinase (CK), inflammatory markers (erythrocyte sedimentation rate [ESR] and C-reactive protein [CRP]) as indicated—should be performed. An ECG should be obtained urgently if an electrolyte imbalance is possible. A rheumatoid screen may be suggested by clinical signs. Lumbar puncture (LP) may be indicated and can be performed to corroborate the diagnosis of GBS or MS if there are no contraindications. Specific investigations—such as brain stem evoked potentials and magnetic resonance imaging (MRI) scanning for MS—should be arranged by specialist neurology services. Chest x-ray or a computed tomography (CT) scan may be indicated to exclude thymoma in association with MG.

Treatment and prognosis

The mainstay of treatment for weakness caused by neuromuscular disorders is supportive care with a particular focus on ventilatory support commenced early rather than later, as emergency intubations are associated with higher complication rates. General supportive measures will also include maintenance of homeostasis with respect to normothermia, euglycaemia, normotension and control of any other autonomic dysregulation, such as paralytic ileus and urinary retention.

Prophylaxis against peptic ulcers and deep vein thrombosis as well as pressure area care are all crucially important in the mechanically ventilated and sedated patient. This will require admission to an ICU, but treatment is usually commenced in the ED. Early neurological consultation and ICU review are crucial, especially for conditions in which there are effective interventions, such as plasmapheresis or intravenous immunoglobulin (IVIG) administration for GBS. For acute envenomations or intoxications, supportive care is still the priority in combination with anti-venoms or antidotes when indicated.

For non-neuromuscular causes of weakness, the treatment priority is to address the underlying

Table 8.7.3 Key features of conditions associated with the symptom of weakness

Disease	*Pathophysiology*	*Assessment*	*ED management*
Primary neurological			
Guillain-Barré syndrome, most common cause of acute symmetrical weakness	Immune-mediated poly-radiculopathy Post-infective (15%–40%), esp. due to *Campylobacter* or viral infection; >50% are idiopathic	Suggestive history (e.g. diarrhoea) Symmetrical ascending flaccid weakness; loss of DTRs; early facial palsy common;±autonomic dysfunction Serial assessment of respiratory function crucial to predict need for intubation/ventilation CSF high protein with normal glucose and cell count	Supportive care; early intubation for respiratory failure Early neurology and ICU consultation Early administration of IVIG ± plasmapheresis beneficial Corticosteroids *not* indicated
Myasthenia gravis, localized variant more common Myasthenic crises/respiratory decompensation (rare) are main ED issues	Immune-mediated Ach receptor dysfunction; may be precipitated by thymic disorders	Fluctuating, fatigable weakness of voluntary muscles especially ocular muscles or proximal limbs. Cranial nerve involvement with ptosis in >25% cases; ±dysphagia, weakness of masticatory muscles; normal sensation; normal reflexes Improves with rest Serial respiratory assessment if severe Ice-pack test if there is ptosis	Supportive care Avoid potential precipitants including corticosteroids Anticholinesterase treatment as directed by neurologist
Multiple sclerosis, relapsing/remitting course most common	Immune-mediated scattered neuron demyelination; affects motor, sensory, visual and cerebellar function Classically ≥2 separate episodes of neurological dysfunction indicating white matter or spinal cord lesions at distinct locations	Acute exacerbations, acute worsening of clinical signs; variable weakness, hypertonicity, spasticity, clonus, altered pain/temp/vibration and proprioceptive senses Lhermitte sign Optic neuritis in up to 30% with acute central vision loss, afferent papillary defect, red desaturation lung puncture, MRI, evoked potentials in consultation with neurologist	Pulse methylprednisolone therapy for exacerbations Supportive care for generalized weakness Neurology consultation Long-term disease modification and lifestyle strategies (e.g. vitamin D)
Cord compression	Spinal stenosis ± malignancy or infection	Thorough neurological exam Red flags (e.g. fever, malignancy, IVDU warrant MRI)	Neurosurgical consultation Decompression, antibiotics, targeted radiotherapy as indicated
Myopathies			
Congenital Dystrophin disorders, Duchenne Muscular Dystrophy (DMD); Becker Muscular Dystrophy (BMB) DMD/BMD, mitochondrial disorders	X-linked dystrophin gene dysfunction Males affected more severely by DMD; life expectancy to early 20s; BMD of later onset less severe	Generalized weakness Usual ED presentation is acute deterioration with respiratory compromise Spirometry/respiratory assessment Mitochondrial disorders—variable episodic weakness and fluctuating consciousness	Supportive care Discussion with patient, advocates, neurologists regarding appropriateness of intensive intervention Consider advance care directives Ventilatory support as appropriate
Acquired Metabolic/electrolyte disorders Hypokalaemic periodic paralysis Endocrine Cushing disease Addison disease Thyrotoxicosis Toxic Statins, corticosteroids	Variable weakness; may be acute episodic weakness with hypokalaemia ± thyrotoxicosis Drug-induced or history of endocrine myopathies suggestive	Periodic paralysis; may be preceded by vomiting/diarrhoeal illness; may have family history Check electrolytes, especially K^+ ECG if K^+ deranged Endocrine—assess for other stigmata of endocrinopathy (e.g. cushingoid, addisonian)	Electrolyte (K^+) reconstitution Supportive care Correct endocrine abnormalities Discontinue offending medications
Intoxications			
Botulism due to *Clostridium botulinum* toxin	Deranged neurotransmission Ingested botulinum toxin prevents Ach release at NMJ	History of ingestion GI symptoms in 50% Descending flaccid paralysis Postural hypotension, diplopia, blurred vision, ptosis, dysphagia, respiratory compromise, progressing to limb weakness Ileus common	Supportive care ICU admission for ventilatory support as needed Specific antiserum in consultation with toxicology/neurology
Tetanus due to *Clostridium tetani* tetano- spasmin toxin Endemic in developing countries	Impaired inhibitory neurotransmission causing skeletal muscle spasm and rigidity Classically infected deep wounds in non-immunized patients	Suggestive history—recent wound, vulnerable patient (e.g. elderly, non-immune) Trismus/dysphagia common early; progressive to painful skeletal muscle spasms; exacerbated by minor stimuli (e.g. touch) May be a localized form Clinical diagnosis	Supportive care, ICU for ventilatory support and sedation Tetanus antitoxin Tetanus immunization is protective Antibiotics (penicillin) to treat clostridial infection

Table 8.7.3 Key features of conditions associated with the symptom of weakness—cont'd

Disease	*Pathophysiology*	*Assessment*	*ED management*
Tick paralysis due to tick toxin, ascending flaccid paralysis mimics Guillain-Barré syndrome	Impaired neurotransmission *Ixodes holocyclus* (Australian paralysis tick) Death from respiratory paralysis	Mostly children in tick-endemic area ± tick found on patient; ataxia, weakness ± extra-ocular palsy/dysphagia May progress after tick removal to generalized/respiratory paralysis	Tick removal/observation sufficient in most cases If severe, ventilatory support Antiserum administration as directed by toxicology/neurology
Marine intoxications Ciguatera Puffer fish Blue-ringed octopus	Ciguatera toxin (from reef fish) Tetrodotoxin (puffer fish, blue-ringed octopus) block sodium channels and impair neurotransmission Tetrodotoxin also acts on CTZ and impairs ventilation	History of tropical fish ingestion; onset of symptoms within a few hours Ciguatera—paraesthesias, electrical sensations in response to hot/cold Tetrodotoxin—progressive flaccid weakness with respiratory compromise	Supportive treatment esp. ventilatory support

CSF, Cerebrospinal fluid; *CTZ*, chemoreceptor trigger zone; *DTRs*, deep tendon reflexes; *ED*, emergency department; *GI*, gastrointestinal; *ICU*, intensive care unit; *IVDU*, intravenous drug user; *IVIG*, intravenous immunoglobulin; *MRI*, magnetic resonance imaging; *NMJ*, neuro-muscular junction.

disease state. This will variously include electrolyte reconstitution, rehydration, correction of thyroid function, treatment of systemic diseases and infections, optimization of organ function and psychological assessment as indicated by clinical assessment and investigations. Appropriate referral should follow. In cases where no apparent cause can be found for a complaint of weakness, an expectant approach is warranted.

The prognosis for neuromuscular disease depends on the specific condition.

Criteria for diagnosis

Table 8.7.3 summarizes the key pathophysiology, assessment findings to elucidate and management strategies for the conditions likely to present to the ED with weakness as a predominant feature.

Specific conditions

Guillain-Barré syndrome

GBS is an acute, acquired, inflammatory demyelinating polyradiculoneuropathy (AIDP) caused by autoimmune attack on peripheral nerves/nerve roots. It is the most common cause of acute progressive generalized weakness in the ED. GBS variants exist, such as the Miller-Fisher syndrome with particular ocular muscle involvement, but these are much less common. GBS has an annual incidence in the developed world of about 1 to 2 cases per 100,000 and mortality of 3% to 10%. It is more common in older people.

Pathophysiology

The pathophysiology involves an aberrant autoimmune response associated in about two-thirds of cases with an antecedent respiratory or gastrointestinal tract infection 3 weeks or less before the onset of signs. *Campylobacter jejuni* is the most commonly associated pathogen (up to 40% of cases) and a positive *C. jejuni* IgM titre is associated with a worse prognosis. Cytomegalovirus is the second most common infection associated with GBS. Others include Epstein-Barr virus, *Mycoplasma pneumoniae*, HIV and *Haemophilus influenzae*.

Clinical features

The hallmark of GBS is progressive ascending weakness with loss of DTRs and maximal weakness present within 2 to 4 weeks after onset. Proximal and distal limb muscles as well as truncal and respiratory muscles are affected. Cranial nerve involvement is common, with facial nerve palsy occurring in up to 70% of cases. Ocular muscle involvement is less common. Sensory symptoms are common but variable, with paraesthesias or even severe pain arising in some patients. Autonomic dysregulation occurs in about two-thirds of patients and can be fatal due to severe fluctuations in blood pressure and cardiac arrhythmias.

The diagnosis of GBS is based on suggestive history (e.g. recent diarrhoeal infection or major surgery), clinical features of an ascending weakness with loss of DTRs and exclusion of other pathologies.

Clinical investigations

LP should be performed; classic cerebrospinal fluid (CSF) findings are of high CSF protein and normal glucose and cell count. Mild CSF pleocytosis is common; however, the presence of CSF leucocytosis should prompt careful consideration of alternative diagnoses, such as lymphoma or HIV.

Complications

Respiratory failure may occur in up to 30% of cases and is the most life-threatening short-term complication of GBS. This is attributed to the high incidence of phrenic nerve involvement.

Treatment

Attention to ventilation is a priority of treatment. Assessment of Forced Vital Capacity (FVC) every 2 to 4 hours during the acute phase is recommended, and FVC of 10 to 12 mL/kg (<30% of predicted) is generally considered to be an indication for intubation and assisted ventilation. Other suggested criteria for elective intubation and ventilation include significant respiratory distress, fatigue, sweating, tachycardia, active aspiration and $PaCO_2$ greater than 50 mm Hg, but clinical judgement should guide the decision to intubate, particularly if the patient has co-morbidities. Suxamethonium should not be used during intubation. Swallowing difficulty and inability to lift the head or elbow off the bed are features predicting the need for intubation. Elective intubation is associated with less adverse events than a late emergency intubation, so the timing of intervention must be carefully considered. About 25% of patients with GBS who cannot mobilize and 30% to 50% of patients admitted to the ICU need mechanical ventilation. Of note, non-invasive ventilation (NIV) is not recommended for GBS and respiratory failure, especially if there is significant bulbar weakness.

In large studies, IVIG, usually 2 g/kg over 3 to 5 days has been found to be as effective as plasmapheresis in the treatment of GBS, and it is often easier to access in most hospitals.

Prognosis

Most people recover fully, but a significant minority (20%) survive with persistent neurological deficits. The most common causes of death are the complications of dysautonomia and respiratory failure.

Multiple sclerosis

MS is a chronic demyelinating condition. It is the commonest chronic neurological condition, with an estimated prevalence of 40,000 cases in Australia. Its incidence is related to latitude, with Tasmania being among the areas with the highest incidence in the world (1:1000). Sixty percent of cases occur in women. MS is frequently characterized by exacerbations and remissions. It is usually diagnosed in individuals aged 15 to 45 years.

Common relapse patterns include ataxia, proximal weakness (more frequently in the

lower limbs), urinary symptoms and cranial nerve disorders, such as optic neuritis, diplopia and vertigo. Fatigue is a common symptom in MS and should be distinguished from a focal relapse. Heat sensitivity is a common phenomenon in MS and symptoms are often worse in summer. Exacerbations associated with febrile illness can be minimized with careful antipyretic therapy.

Undiagnosed patients may present to the ED with myriad neurological symptoms, although life-threatening presentations with respiratory compromise are exceedingly rare.

Clinical investigations and diagnosis

The diagnosis is usually made when typical clinical features are supported by the findings of neuroimaging, CSF examination and evoked potentials. Nearly all MS patients show discrete white matter lesions or homogeneous periventricular lesions on T2-weighted MRI scans of the brain and/or spinal cord. Elevated protein and gammaglobulins (oligoclonal bands) and pleocytosis with mild lymphocytosis are the typical CSF findings. Delays in latencies on testing of visual, somatosensory or brain stem evoked potentials is diagnostic of demyelination in the visual pathways, posterior columns or auditory pathways, respectively.

Treatment

Relapses usually respond to brief pulse therapy with corticosteroids (methylprednisolone 1 g IV daily for 3 days or equivalent oral dosage). More severe episodes may require high-dose corticosteroids and plasmapheresis therapy.

Vitamin D has now been confirmed as an important aetiological factor in MS, and a vitamin D level of 150 to 200 nmol/L obtained by sun exposure and/or vitamin D supplementation is recommended. A range of dietary and lifestyle interventions are also associated with better outcomes in MS. Long-term disease modification therapies are increasingly available and are the remit of the neurologists. It is important to be aware of these therapies as patients may present with side effects from these increasingly potent immune-modulating drugs.

Disposition

Neurology consultation for directing investigations and management is indicated for all patients with MS exacerbations, and hospital admission is often required.

Myasthenia gravis

MG is rare but its prevalence is rising in developed countries due to earlier diagnosis and good survival rates. During exacerbations, patients are very likely to attend an ED with localized or, less commonly, generalized weakness. The disease is caused by an idiopathic autoimmune attack of post-synaptic Ach receptors leading to weakness of the muscle response to stimulus. The weakness tends to be fatigable and is usually relieved by rest. Most patients experience facial and bulbar muscle weakness; therefore dysphagia and dysarthria are common symptoms. More serious exacerbations are associated with respiratory compromise.

Myasthenic crisis, which occurs in 15% to 20% of patients (mostly within the first 2 years of diagnosis, when the disease has an unpredictable course), refers to generalized weakness with respiratory failure, requiring intubation and mechanical ventilation. Respiratory failure rarely presents in isolation. Myasthenic crisis can be precipitated by acute disease progression, intercurrent infections, pregnancy, surgery and treatment with high-dose glucocorticoids and a long list of other medications that may affect neuromuscular transmission.

Diagnosis

The diagnosis is based on clinical features and the demonstration of antibodies to the Ach receptor, which are found in about 85% of cases. Clinical suspicion of MG can be supported by a positive bedside ice-pack test in patients with ptosis, where the eyelids are covered with an ice pack for 2 minutes, bringing immediate improvement in the ptosis. The Tensilon test is now rarely performed. Electromyography (EMG) may be necessary to differentiate MG from GBS, myopathy or motor neuron disease (MND).

Treatment and disposition

Supportive care is the main priority in the ED. Neurological consultation is mandated by suspicion of MG. Treatment for MG should not be commenced until the diagnosis has been confirmed. Many patients take pyridostigmine over the long term, and the dose may be increased in exacerbations. Paradoxically, high-dose pyridostigmine can lead to acute deterioration, so treatment decisions should always be made in consultation with a neurologist.

Respiratory failure is the main life-threatening issue in acute myasthenic crisis; however, the condition tends to fluctuate, so reliable criteria for intubation are difficult to define. Serial measurement of PEF/FVC and $PaCO_2$ are recommended. Intubation is recommended for marginal or deteriorating patients, as elective intubation is associated with fewer complications. Early use of NIV (bi-phasic positive airway pressure [BiPAP]), which can reduce the need for intubation, has been shown to be of benefit in myasthenic crisis. Plasmapheresis and IVIG (2 g/kg over 3 to 5 days) have also been shown to be effective in myasthenic crisis. Corticosteroids may exacerbate the condition and should therefore be avoided unless the patient is mechanically ventilated. In some patients, thymectomy or immunosuppressive strategies are indicated.

Prognosis

The mortality of myasthenic crisis is about 4% overall, with age above 50 years and FVC below 25 mL/kg being predictors of poor outcome and a long ICU stay. Most patients with MG have a normal life span.

Cord compression/cauda equina syndrome

Patients may present with weakness from acute or chronic conditions that lead to compression of the spinal cord and nerve roots, usually due to a combination of progressive age-related spinal stenosis, infections or malignancy. Cord compression is over-represented in medico-legal claims resulting from ED presentations and a high index of suspicion is required to achieve an early diagnosis and the best outcomes. Progressive spinal stenosis is a common feature of ageing and can occur in isolation or be associated with acute disc herniations. Acute deterioration or neurological deficits of sudden onset in the presence of other systemic illness, such as fever, should be 'red flags' that prompt urgent consideration and investigation for sinister pathologies. These include malignancy (e.g. lymphoma or metastatic deposits), infection (e.g. epidural abscess or discitis, especially in high-risk groups, such as intravenous drug users [IVDUs] or patients who have had recent epidural or spinal anaesthetics) or trauma (e.g. falls in the elderly). Any patient presenting to the ED with lower limb neurological deficits, in particular with signs of bladder or bowel dysfunction, warrants urgent imaging to assess for spinal cord compression. Therapeutic interventions—including antibiotics, surgical decompression and radiotherapy—will be tailored to the individual patient following specialist consultation.

Amyotrophic lateral sclerosis (motor neuron disease)

MND/ALS is a rapidly progressive muscle atrophy and weakness caused by degeneration of both the UMNs and LMNs. It causes a variable picture of spasticity, hyperreflexia and muscle weakness with an inexorable decline to respiratory failure and dependence on mechanical ventilation, usually within 2 to 4 years. UMN or LMN bulbar muscle weakness is invariably present and complicates the condition with aspiration and impaired cough. There is no curative therapy and treatment is therefore supportive. In the ED, ALS patients usually present with acute respiratory compromise as a result an acute precipitant, such as aspiration pneumonia or a choking episode. Management of these patients will be directed at treating the precipitant and increasing respiratory

support during the period of acute exacerbation as directed by the patient and any advance care plans that he or she might have in place. NIV should be avoided due to the risks of aspiration and increased work required by already weak respiratory muscles. Medications that reduce respiratory drive, such as opiates, should also be avoided. New diagnoses are rarely made in the ED and, if so, usually present with variable UMN and LMN signs and variable weakness. Neurological consultation is mandated by such presentations.

Eaton-Lambert syndrome

ELS is a rare autoimmune paraneoplastic condition that is usually associated with small cell lung cancer. The major clinical feature is severe limb weakness as a result of autoimmune destruction of voltage-gated calcium channels in the presynaptic membrane at the neuromuscular junction, which, in turn, inhibits the release of presynaptic Ach vesicles. It often improves with exercise, which distinguishes it from MG. Tendon reflexes are variable but usually reduced. EMG is required to confirm the diagnosis. Management is to treat the underlying malignancy; therefore prognosis depends on the prognosis of the malignancy. Symptomatic treatments, such as glucocorticoids, are usually ineffective. Supportive care is the goal of ED management.

Myopathies

Congenital muscular dystrophies

The X-linked disorders Duchenne muscular dystrophy and Becker muscular dystrophy are the most common forms of congenital muscular dystrophy. Boys with Duchenne muscular dystrophy are normal at birth but, by the age of about 5 years, exhibit proximal weakness, which gradually deteriorates until they are wheelchair-dependent by age 10 to 12 years. Thereafter, the weakness progresses inexorably and the average life span is only about 21 years, after which death due to respiratory failure ensues. Becker muscular dystrophy has a later onset and slower progression; therefore immobility and respiratory complications may occur in adult life, and many patients have a normal life span. ED presentations in both of these conditions are almost always related to respiratory compromise due to disease progression or an acute precipitant, such as pneumonia. The management is supportive and aimed at treating any acute precipitants as guided by disease stage, patient preference and any advance care directives.

Mitochondrial myopathies, such as those associated with MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis and stroke) tend to present to ED similarly, with variable weakness and fluctuating conscious state on a known background of mitochondrial disorder. Ventilatory support and the attendant supportive care are the key aspects of treatment. In these cases, a brief period of mechanical ventilation can support patients through an acute exacerbation, and they may return to being relatively independent until the next acute deterioration. Management should be guided by the patient and his or her neurologist.

Inflammatory myopathies: polymyositis/dermatomyositis

Polymyositis and dermatomyositis are idiopathic inflammatory myopathies that mostly affect women over 30 years of age. Dermatomyositis is associated with a heliotrope rash, erythroderma and other skin changes and is more commonly associated with cancer. Patients present with proximal symmetrical weakness associated with muscle pain and tenderness. DTRs are intact unless weakness is severe. There are no sensory or autonomic deficits. Proximal weakness is demonstrated by asking patients to stand from a sitting position while folding their arms or by asking them to lift an object above the head. In severe cases, respiratory function may be affected. Diagnosis is based on clinical findings and elevated ESR and CK. Management is with immunosuppressive agents, primarily corticosteroids. Differential diagnosis includes HIV myopathy, viral myositis or myositis due to substances such as alcohol, statins, corticosteroids and Azidothymidine also known as zidovudine (AZT). Endocrine myopathies occur rarely.

Acute periodic paralyses

Acute periodic paralyses are an interesting group of rare disorders occasionally seen in the ED. They may be associated with normal, low or elevated serum potassium. Patients are usually well between attacks, but some can have residual muscle stiffness. A genetic defect has been linked to these diseases but, in some instances, hypokalaemia may cause acute weakness in healthy individuals.

Acute hypokalaemic periodic paralysis may be primary (i.e. familial) or secondary to excessive renal or gastrointestinal losses or endocrinopathy. Familial periodic paralysis usually occurs in Caucasian males, is autosomal dominant and may last as long as 36 hours. Attacks usually occur at night or in the early morning upon awakening and can be precipitated by a diet high in carbohydrates, rest following exercise or glucose and insulin given intravenously. Supportive care and replenishment of serum potassium are the main management priorities.

Thyrotoxic periodic paralysis associated with hypokalaemia is more common in Asian males. Treatment of the underlying disease and electrolyte disorder are the goals of treatment.

Rhabdomyolysis

Rhabdomyolysis is a disorder with many causes that leads to muscle necrosis and the release of intracellular muscle constituents into the circulation. The characteristic triad in rhabdomyolysis is weakness, muscle pain and dark urine. Causes can be classified as due to trauma or compression, exertional and non-exertional. Non-exertional causes include drugs, toxins, viruses and electrolyte abnormalities. ED management is dependent on the cause and the emphasis is on preservation of renal function.

Intoxications

Botulism

Botulism is an acute paralytic illness caused by a neurotoxin produced by *Clostridium botulinum*. It is characterized by severe descending weakness and gastrointestinal slowing. In adults, the toxin is ingested preformed in foodstuffs; in infants, the disease is usually due to ingestion of foods such as honey that contain the bacterial spores. Botulinum toxin inhibits Ach release from the presynaptic membrane of the neuromuscular junction. Early characteristic findings include normal mentation with bulbar weakness manifesting as dysphagia and extra-ocular palsies with absent papillary light reflex (which distinguishes botulism from MG). Limb weakness is more obvious proximally and DTRs are usually intact. Sensation is not affected. Postural hypotension tends to be a feature in adults. Management is supportive with ventilatory support in the ICU if necessary. An antitoxin is available.

Tetanus

Tetanus is an acute painful paralytic illness caused by the tetanospasmin toxin of the soil-dwelling organism *Clostridium tetani*. It is characterized by painful severe and uncontrolled skeletal muscle spasms. Respiratory muscle involvement leads to hypoxia and death. It remains endemic throughout the world, and most of the 1 million cases annually occur in developing countries. In the developed world, tetanus should be considered in the elderly and vulnerable groups such as the homeless and poor in particular, where tetanus-prone wounds and lack of immunization are more common. Typically, tetanus is caused by a deep penetrating wound, but up to 50% of patients have only a trivial wound, if any, evident. The onset is highly variable, from days to months. Generalized tetanus is the most common form and causes generalized skeletal muscle spasms, which can be greatly exacerbated by minor stimuli such as touching or a loud noise. Trismus or 'lockjaw' is the classic initial presenting symptom with spasm of the masseter muscle. Other early symptoms include myalgias, cramps, dysphagia and drooling. Violent muscle spasms can cause vertebral and long bone fractures. Death is due to either respiratory failure or autonomic dysfunction. The

illness is progressive, with an increase in severity over 3 to 5 days and a gradual reduction after 10 days. The diagnosis is made on clinical grounds alone. The priorities of treatment are supportive care with sedation and ventilation, administration of tetanus anti-toxin and avoidance of complications. Localized tetanus also occurs with spasms near the original wound site and rarely progresses to generalized tetanus. This variant carries a good prognosis with or without treatment.

Envenomations

Several envenomations can present to the ED with weakness as part of the clinical syndrome. These include the *Ixodes holocyclus* paralysis tick, puffer fish, blue-ringed octopus (tetrodotoxin) and reef fish (ciguatera toxin) (see Table 8.7.3). These envenomations are covered in detail elsewhere.

CONTROVERSIES AND FUTURE DEVELOPMENTS

- A number of the causes of weakness discussed in this chapter—including GBS, cord compression and MS—are often misdiagnosed in the ED or diagnosed late. Emergency physicians must maintain a high level of critical thinking to distinguish functional, non-neuromuscular and time-critical neuromuscular emergencies.
- Orthodox neurological opinion stresses the primacy of modern immune-modulating therapies for the management of relapsing-remitting MS. Recent studies suggest an equally important role for other therapeutic approaches, including vitamin D supplementation, avoidance of animal fat, promotion of a whole-food diet rich in fish and omega 3 fatty acids and meditation/stress reduction techniques.
- Plasmapheresis and IVIG are just as effective as definitive therapy for GBS, but combining the two treatments is not beneficial.
- Ventilatory support for patients with GBS should be instituted early when indicated, whereas patients with end-stage muscular dystrophy, MELAS, MND/ALS or MG present difficulties for emergency physicians balancing quality of life, potential reversibility and the patient's expressed advance care directive. Therapeutic decisions must be made with extensive consultation with the treating neurologist, patient and family. NIV may be an effective modality in patients with MG but should be avoided in cases of GBS and MNS/ALS, where intubation and mechanical ventilation is preferred.

SECTION 9

INFECTIOUS DISEASE EMERGENCIES

Edited by *Peter Cameron*

9.1 Approach to undifferentiated fever in adults

Arun Ilancheran

ESSENTIALS

1 Over one-third of patients who have fever for more than 2 to 3 days with no localizing symptoms and signs are likely to have a bacterial infection; half of these will be in the respiratory or urinary tracts.

2 An unexplained fever in a person over the age of 50 should be regarded as due to a bacterial infection until proved otherwise.

3 An undifferentiated fever in an alcoholic patient, an intravenous drug user or an insulin-dependent diabetic is generally an indication for admission to hospital.

4 Any fever in a traveller returned from a malaria-endemic area should be regarded as due to malaria until proved otherwise.

5 Severe muscle pain, even in the absence of overt fever, may be an early symptom of meningococcaemia, staphylococcal or streptococcal bacteraemia.

6 An unexplained rash in a febrile patient should be regarded as meningococcaemia until proved otherwise.

7 The diagnosis of meningococcaemia should be considered in every patient with an undifferentiated fever.

8 There will always be a small number of febrile patients whose sepsis is not initially recognized because they do not appear toxic and their symptoms are non-specific. It is essential that all such patients be encouraged to seek review if they have any clinical deterioration.

9 The omission of fever from the Sepsis 3 definition or Sequential Organ Failure Assessment (SOFA) scoring system should not preclude the clinician from considering sepsis or septic shock when a patient with an undifferentiated fever is being assessed.

Introduction

Fever is a common presenting symptom to the emergency department (ED); about 5% of patients give fever as the reason for their visit. Most patients with fever have symptoms and signs that indicate the site or region of infection. A prospective study of patients aged 16 years or older who presented to an ED with fever ≥37.9°C found that 85% had localizing symptoms and signs that suggested or identified a source of fever and 15% had unexplained fever after the history and examination.[1]

Fever with no localizing symptoms or signs at presentation is often seen in the first day or two of the illness. Patients with such a problem will ultimately prove to have a self-limiting viral infection, but others will have non-viral infections requiring treatment. Among the latter group are illnesses that may be serious and even rapidly fatal.

Over one-third of patients who have fever for more than a few days with no localizing symptoms and signs are likely to have a bacterial infection.[1,2]

If no cause is found in an adult with fever present for over 3 days, there is a good chance the patient will have a bacterial infection that needs treatment. Over half of these infections are likely to be in the respiratory or urinary tracts.[1]

The most important task in the ED for febrile patients without localizing features is not to miss early bacterial meningitis, bacteraemia (such as meningococcaemia) and early staphylococcal and streptococcal toxic shock syndromes.

Approach

The management of febrile patients varies according to the severity, duration and tempo of the illness, the type of patient and the epidemiological setting. Although steps in the management of a febrile patient in the ED, listed here, may be set out in a sequential manner, in reality the mental processes involved occur simultaneously by the bedside.

- Step 1: Identify the very ill.
- Step 2: Find localizing symptoms and signs.
- Step 3: Look for 'at-risk' patients.

Step 1: identify the seriously ill patient who requires urgent intervention

The first step in managing febrile patients is to identify those in need of immediate resuscitation, urgent investigations and empirical therapy. The presence of any of the following features justifies immediate intervention: shock, coma/stupor, cyanosis, profound dyspnoea, continuous seizures and severe dehydration.

Step 2: identify those with localized infections or easily diagnosable diseases

Having excluded those who need urgent intervention, the doctor has more time to attempt a diagnosis. The history and physical examination are usually sufficient to localize the source of community-acquired fever in most cases, especially if the illness has been present for several days.

History

A precise history remains the key to diagnosis of a febrile illness. An inability to give a history and to think clearly is a sign of potential sepsis.

Illness

An abrupt onset of fever, particularly when accompanied by chills or rigors and generalized aches, is highly suggestive of an infective illness.

Localizing symptoms, their evolution and relative severity, help to identify the site of infection; localized pain is particularly valuable in this way.

The severity and course of the illness can be assessed by the patient's ability to work, to be up and about, to eat and sleep and the amount of analgesics taken.

Previous state of health

Underlying diseases predispose patients to infection at certain sites or those caused by certain specific organisms. Knowledge of any defects in the immune system is similarly helpful. For example, asplenic patients are more prone to overwhelming pneumococcal septicaemia and renal transplant patients to *Listeria* meningitis.

A past history of infectious diseases, particularly if properly documented, may be useful in excluding infections such as measles and hepatitis. Immunocompromised patients are at significantly higher risk compared with the standard population for contracting an infective illness.

Predisposing events

Recent operations, accidents and injuries and medications taken may be the direct cause of the illness (e.g. drug fever or rash from co-trimoxazole, ampicillin) or may affect the resistance of the patient, predisposing to certain infections. Concurrent menstruation raises the possibility of toxic shock syndrome.

Epidemiology

Information on occupation, exposure to animals, hobbies, risk factors for blood-borne viruses and travel overseas or to rural areas may suggest certain specific infections (e.g. leptospirosis, acute HIV infection, hepatitis C, malaria, etc.).

Contact with similar diseases and known infectious diseases

This information is useful in the diagnosis of problems such as meningococcal infection, viral exanthema, respiratory infection, diarrhoea and zoonoses.

Examination

Physical examination in the febrile patient serves two purposes: to assess the severity of the illness and to find a site of infection.

Bedside assessment of severity and 'toxicity' based on intuitive judgement is frequently wrong and many patients with severe bacterial infections do not appear obviously ill or toxic.

Physical examination may yield a diagnosis in a febrile patient who has not complained of any localizing symptoms. The following checklist of special areas to be examined is often useful:

- Eyes: Conjunctival haemorrhages are seen in staphylococcal endocarditis and scleral jaundice may be present before cutaneous jaundice is obvious.
- Skin: Rashes of any sort, especially petechial rash; cellulitis in the lower legs may present with fever and constitutional symptoms before pain in the leg develops. Evidence of intravenous drug use should be sought at the common injection sites. Be sure to examine the pannus or skin folds in the morbidly obese patients.
- Heart: Murmurs and pericardial rubs may be heard.
- Lungs: Subtle crackles may be heard in pneumonic patients without respiratory symptoms.
- Abdominal organs: Tenderness and enlargement without subjective pain may be the only clue to infections in these organs.
- Assess the groin, particularly in a diabetic patient, for signs of necrotizing infection (example: Fournier gangrene).
- Lymph nodes: Especially the posterior cervical glands. Tenderness of the jugulodigastric glands is a good sign of bacterial tonsillitis.
- Sore throat may be absent in the first few hours of streptococcal tonsillitis. Examination of the throat may give the diagnosis. Oedema of the uvula is also a useful sign of bacterial infection in that region.
- Marked muscle tenderness is a frequent sign of sepsis.
- Neck stiffness may be a clue to meningitis in a confused patient who cannot give a history.
- Any area that is covered (e.g. under plasters or bandages) must be examined for evidence of sepsis. There are two caveats when local symptoms and signs are being assessed:
- Localizing features may not be present or obvious early in the course of a focal infection (e.g. the absence of cough in bacterial pneumonia, sore throat in tonsillitis or diarrhoea in gastrointestinal infections in the first 12 to 36 hours of the illness).
- Localizing features may occasionally be misleading. For example, diarrhoea, which suggests infection of the gastrointestinal tract, may be a manifestation of more generalized infection, such as gram negative septicaemia, and crepitations at the lung base may indicate a sub-diaphragmatic condition rather than a chest infection.

Step 3: look for the 'at-risk' patient

If no diagnosis is forthcoming after the first two steps, the next task is to identify the 'at-risk' patient who may not appear overtly ill but who, nonetheless, requires medical intervention. This applies particularly to those with treatable diseases that can progress rapidly.

Four sets of pointers are helpful in identifying these patients: the type of patient (host characteristics), exposure history, the nature of the non-specific symptoms and how rapidly the illness evolves.

Clinical pointers: type of patient

Clinical manifestations of infection are often subtle or non-specific in young children, the elderly and the immunocompromised. The threshold for intervention in these patients should be lowered. The issue of fever in children is not addressed in this chapter.

Elderly patients Elderly patients with infections often do not mount much of a febrile response and fever may be absent in 20% to 30% of these patients.[3]

Infectious diseases in the elderly, as in the very young, often present with non-specific or atypical symptoms and signs and may progress rapidly.[4]

In adult patients with unexplained fever, up to one-third may have bacteraemia or a focal bacterial infection. This proportion is even higher in those over the age of 50 years.[1] In the elderly, a fever above 38°C indicates a possible serious infection[5] and is associated with an increasing risk of death.[6]

The urinary tract is the most frequent site of infection and source of bacteraemia; symptoms of urinary tract infection are frequently absent in the elderly. The respiratory tract is the next most common site of infection; fever and malaise may be the only clues of pneumonia in the elderly. Urinalysis and chest x-ray will identify about half of occult infections.[1]

An unexplained fever in a person over the age of 50 years should be regarded as being caused by a bacterial infection until proved otherwise and is generally an indication for admission to hospital.

Alcoholic patients Alcoholic patients present with multiple problems, many of which cause fever. Most are caused by infections, the commonest of which is pneumonia. Multiple infections may occur at the same time.[7]

Non-infectious causes of fever frequently coexist with infections and conditions such as subarachnoid haemorrhage, alcoholic withdrawal and alcoholic hepatitis and require admission.

The initial history and physical examination in the alcoholic may be unreliable and diagnosis may be difficult.

Alcoholic patients with fever for which no obvious cause is found should be admitted to hospital for investigations and observation.

Injecting drug users The risk of injecting drug users acquiring serious or unusual infections is high through repeated self-injection with non-sterile illicit substances, the use of contaminated needles and syringes and poor attention to skin cleansing prior to injections.[8]

Many intravenous drug users presenting with fever have a serious infection. Some have obvious focal infections, such as cellulitis and pneumonia. Others present simply with fever and bacteraemia, in which case endocarditis must be suspected.

Clinical assessment cannot differentiate trivial from potentially serious conditions in these patients.[8] A history of chills, rigors and sweats strongly suggests the presence of a transient or ongoing bacteraemia. Back pain may be a subtle symptom of endocarditis or vertebral osteomyelitis.

It is difficult to distinguish the patient with endocarditis from other drug users with fever due to another cause. Hospitalization of febrile injecting drug users is prudent when 24-hour follow-up is not possible. Intravenous drug use in the previous 5 days is a predictor of occult major infection and is an indication for admission to hospital.[9]

Patients with diabetes mellitus Diabetic patients are more prone to developing certain bacterial infections.[1] A diabetic patient with an unexplained fever is more likely to have an occult bacterial infection than a non-diabetic patient. In general, an insulin-dependent diabetic patient, especially if over 50 years of age, with fever and no obvious source of infection should be investigated and preferably admitted.

Febrile neutropaenic patients Febrile neutropaenic patients (absolute neutrophil count <500/μL or <1000/μL and falling rapidly) must be hospitalized regardless of their clinical appearance. Infections may become fulminant within hours in these patients and the clinical manifestations of their infective illnesses are frequently modified by the underlying disease, therapy received and coexisting problems.

Splenectomized patients Splenectomized patients with fever must be very carefully assessed because of their increased risk of overwhelming bacterial infection. If the fever cannot be readily explained, admission for intravenous antibiotics is usually indicated.

Other immunocompromised patients Fever in transplant patients (renal, hepatic or cardiac) and those with HIV infection is not an absolute indication for admission, but the threshold of intervention should be considerably lowered and they are best assessed by their usual treating doctors.

Patients recently discharged from hospital may have hospital-acquired infections or infections caused by multi-resistant organisms. Recent operations or procedures may be a clue to the site of infection.

Clinical pointers: exposure history

Overseas travellers or visitors Returned travellers or overseas visitors may have diseases such as malaria and typhoid fever that need early diagnosis and treatment. Any fever in a traveller returned from a malaria-endemic area should be regarded as due to malaria until proved otherwise.

Influenza in febrile returned travellers is a concern to EDs worldwide. Outbreaks of avian influenza occur periodically in bird populations throughout Asia. Although the virus does not typically infect humans, direct bird-to-human transmission of H5N1 influenza has been documented. The virus is highly pathogenic and the mortality of the disease is high. Travellers acquiring influenza overseas may also introduce this infection. Most cases occur within 2 to 4 days after exposure, but incubation is as long as 8 days. Suspected influenza infection requires isolation and respiratory precautions. The peak season is generally during the winter months but can vary, especially in the tropics.[10] The impact of influenza is now wide-reaching, with international travel becoming commonplace and the rise of influenza syndromes like MERS-CoV and SARS. The use of rapid diagnostic tests is increasing to meet the surveillance needs of institutions such as airports and hospitals.[11] The World Health Organisation (WHO) recommends rapid diagnosis for influenza when the result will influence a clinical decision. SARS[12] and MERS CoV are particular examples of epidemics that had incredibly high mortality rates and put hospitals and governments under extreme pressure during their outbreaks, prompting international responses and WHO guidance and surveillance.[13]

Although rare, viral haemorrhagic fever in returned travellers represents a true medical emergency and a serious public health threat. Viral haemorrhagic fevers are caused by several distinct families of virus, including Ebola and Marburg, Lassa fever, the New World arenaviruses (Guanarito, Machupo, Junin and Sabia) as well as Rift Valley fever and Crimean Congo haemorrhagic fever viruses. Most exist in Africa, the Middle East or South America. Although some types cause relatively mild illnesses, many can cause severe, life-threatening disease. Viral haemorrhagic fever should be considered in any febrile patient who has returned from an area in which viral haemorrhagic fever was endemic, especially if they have come into contact with blood or other body fluids from a person or animal infected with viral haemorrhagic fever or worked in a laboratory or animal facility handling viral haemorrhagic fever specimens. All these infections have incubation periods of up to 2 to 3 weeks, so it may be possible to exclude viral haemorrhagic fever on epidemiological grounds

alone. Isolation measures should be instituted immediately in these persons.[14]

Staff working in EDs should be aware of regional outbreaks of unusual pathogens. These are reported by state and national departments of health. Returning travellers who are unwell will commonly go directly to an ED, and this may be a critical point to limit further spread.

Contact with animals A contact history with animals, either at work or at home, is frequently the clue to a zoonosis, particularly if the illness is a perplexing fever of several days' duration. The occurrence of multiple cases at work or at home should also make one suspect these infections early.

Contact with meningococcal and *Haemophilus* meningitis Close contacts of patients with these infections have a high risk of acquiring the same infections. Early symptoms may be subtle and a high index of suspicion must be maintained.

Clinical pointers: non-specific clinical features There are several non-specific clinical features whose presence should suggest the possibility of sepsis. These warrant careful scrutiny even when the patient does not appear toxic. They are by no means specific indicators of serious problems and there will be many false positives. However, ignoring them is frequently the cause of missed or delayed diagnosis of sepsis (Box 9.1.1).

Severe pain in muscles, neck or back Severe muscle pain, even in the absence of overt fever, may be an early symptom of meningococcaemia or staphylococcal or streptococcal bacteraemia. It is also a feature of myositis and necrotizing fasciitis.

Impairment of conscious state A change in conscious state may be the sole presenting manifestation of sepsis, especially in the elderly.

Box 9.1.1 Clinical pointers: non-specific clinical features ('alarm bells')

- Severe pain in muscles, neck or back
- Impairment of conscious state
- Vomiting, especially in association with headache or abdominal pain
- Severe headache in the presence of a normal cerebrospinal fluid
- Unexplained rash
- Jaundice
- Severe sore throat or dysphagia with a normal-looking throat
- Repeated rigors

Vomiting Unexplained vomiting, especially in association with headache or abdominal pain, should raise concern. Vomiting without diarrhoea should not be attributed to a gastrointestinal infection. It is a common symptom of central nervous system (CNS) infections and occult sepsis.

Severe headache in the presence of a normal cerebrospinal fluid This is especially important in a person who seldom gets headaches. Severe headache in a febrile patient with normal CSF should not be diagnosed as a viral infection; many focal infections (e.g. pneumonia and bacterial enteritis) may also present in this manner. CSF may be normal in cerebral abscess and in the prodromal phase of bacterial meningitis.

Unexplained rash An unexplained rash in a febrile patient should be regarded as meningococcaemia until proved otherwise, even in the absence of headache or CSF pleocytosis.

Jaundice Jaundice in the febrile patient is associated with a greatly increased risk of death, admission to an intensive care unit (ICU) and a prolonged hospital stay.[6] Jaundice in a febrile patient is unlikely to be due to viral hepatitis but occurs in serious bacterial infections, such as bacteraemia, cholangitis, pyogenic liver abscess and malaria.

Box 9.1.2 Clinical pointers: evolution of illness

- Those presenting early (<24 h)
- Those presenting with rapidly evolving symptoms
- Patients presenting to emergency department on more than one occasion over a 24- to 48-h period

Sore throat or dysphagia Severe sore throat or dysphagia with a normal-looking throat is frequently the presenting symptom of *Haemophilus influenzae* epiglottitis in adults.

Repeated rigors Although repeated rigors may occur in some viral infections, they should generally be regarded as indicators of sepsis, in particular abscesses, bacteraemia, endocarditis, cholangitis and pyelonephritis.

Clinical pointers: evolution of illness

How rapidly the illness evolves is often an indication of its severity. Previously healthy individuals do not seek medical attention unless they are worried. Notice should be taken of any person seeking help within 24 hours of the onset of illness or a person whose illness appears to have progressed rapidly within 24 to 48 hours (e.g. from being up and about to being bedridden). Similarly, the patient who presents to the ED on more than one occasion over a 24- to 48-hour period warrants a careful workup (Box 9.1.2).

Step 4: a final caveat

A major concern in the management of undifferentiated fever in adults is missing the diagnosis of meningococcal bacteraemia when the patient does not appear ill on presentation.

There are a number of infections that must be treated rapidly to minimize morbidity and mortality (Table 9.1.1). With the exception of meningococcal bacteraemia, there are usually some clues in the history or physical examination.

Meningococcal infection is peculiar in its wide spectrum of severity and variable rate of progression in different individuals. It may be fulminant and cause death within 12 hours or it may assume a chronic form that goes on for weeks.

Table 9.1.1 Infections requiring urgent treatment

Disease	*Clues*
Meningococcaemia	Myalgia, rash. May be none
Falciparum malaria	Travel history, blood film
Bacterial meningitis	Headache, change in conscious state, cerebrospinal fluid findings
Post-splenectomy sepsis	Past history, abdominal scar
Toxic shock syndromes	Presence of shock and usually a rash
Infections in febrile neutropaenia	Past history, blood film
Infective endocarditis	Past history, murmur, petechiae
Necrotizing soft tissue infections	Pain, tenderness, erythema and swelling in skin/muscle, toxicity
Space-occupying infection of head and neck	Localizing symptoms and signs
Focal intracranial infections	Headache, change in conscious state, neurological signs, computed tomography findings

When a patient presents with fever and a petechial rash, meningococcaemia can easily be suspected if one remembers a golden rule of medicine that 'fever plus a petechial rash is meningococcaemia (or staphylococcal bacteraemia) until proved otherwise'. However, only 40% of meningococcal diseases present with a petechial rash.

It is less well known that the early meningococcaemic rash may be macular (i.e. one that blanches with pressure). This is the basis of another golden rule in infectious disease: early meningococcal rash may resemble a non-specific viral rash.

Rarely, meningococcal disease presents with symptoms and signs of a localized infection other than meningitis (e.g. pneumonia, pericarditis or urethritis). These presentations should not pose any management problems.

The risk of missing the diagnosis increases markedly when the patient with meningococcal disease presents with fever and non-specific symptoms without a rash. An abrupt onset of fever and generalized aches may be due to influenza, but it could also be due to meningococcaemia.

It is prudent to single out meningococcal disease and ask oneself, 'Could this patient have meningococcaemia?' If in doubt, the safest course is to take cultures, give antibiotics and admit.

Clinical investigations

Most febrile patients seen in the ED justify a fever workup.

Full blood examination is of limited use. White cell count (>15 × 10^9/L), marked left shift, neutropaenia or thrombocytopaenia are pointers to a possible bacteraemia or occult bacterial infection, but they may also be seen in viral infections.[15] Similarly, non-specific markers of inflammation, such as C-reactive protein and erythrocyte sedimentation rate, have not been shown to be useful in predicting outcomes for febrile patients in the ED.[16]

Urinalysis and urine culture should be done in febrile adults over the age of 50 years unless the pathology clearly lies in another body system. However, if the history does not suggest urinary sepsis and the dipstick urinalysis is normal, then urine cultures are usually negative.[17]

A chest x -ray is usually indicated unless a definite diagnosis has been made (e.g. chickenpox, tonsillitis).

Blood cultures should be done in anyone suspected of having bacteraemia, endocarditis or meningitis, in compromised patients with a fever, all febrile patients over the age of 50 years and, possibly, in anyone with an unexplained high fever. It should be noted that only 5% of blood cultures in this setting will be positive and less than 2% will alter clinical management.[18] In general, a patient considered 'sick enough' to warrant blood cultures should be admitted to hospital or followed up within 24 hours.

Disposition

Patients who have any of the following features are in need of resuscitation, followed by workup and admission: shock, coma/stupor, cyanosis, profound dyspnoea, continuous seizures and severe dehydration.

With few exceptions, the following groups of febrile adults should be investigated and admitted:

- Those over 50 years of age
- Patients with diabetes mellitus
- Alcoholic patients
- Injecting drug users
- Immunologically compromised patients
- Overseas travellers or visitors
- Those with 'alarm bells', as described in Step 3.

In general there should be close liaison with the admitting unit and the issue of empiric therapy for septic patients should be discussed. For the dangerously ill (e.g. those with septic shock or bacterial meningitis), antibiotics should be commenced almost immediately.

There is an increasing tendency to start antibiotics in the ED as soon as possible so as to reduce the length of hospital stay. Time to antibiotic therapy is used as a key performance indicator for the ED (e.g. for febrile immunocompromised patients).

Patients who do not require intervention after the basic workup in the ED are discharged home after a period of observation. Because of the time taken to interview the patient, perform investigations and wait for the results, the patient will usually have been observed for 1 to 2 hours and progression or lack of progression may help in deciding what to do. During observation one must be aware that the apparent improvement of the patient may be the result of pain relief or a fall in temperature due to administered antipyretics.

Arrangement must be made for the patient to be reviewed by his or her general practitioner or at the hospital. This is an essential component of the care of a febrile patient seen in an ED.

There is no easy way of detecting occult bacterial sepsis. The infectious process is a dynamic one and the doctor must maintain contact with the patient or family during the 24 to 72 hours following the initial visit.

Patients with fever above 39°C must be seen within 24 hours. Review by a doctor within 6 to 12 hours may be necessary in those who have had a lumbar puncture and is advisable in those who have had blood cultures ordered. A verified phone number should be clearly recorded in the medical history.

All febrile patients discharged from the ED should be encouraged to seek review if there is any adverse change to their condition. A patient re-presenting to the ED provides an opportunity to ensure that he or she is being managed appropriately and to rectify any errors.

Fever due to most common viral infections will resolve by about 4 days. Many other infections will be diagnosed when new symptoms or signs appear.

If fever persists beyond 4 to 5 days without any localizing symptoms or signs, a less common infection or non-infective cause should be suspected and the patient thoroughly investigated. In this situation, the threshold of admission to hospital should be low.

The establishment of ED short-stay units allows fast-track treatment and observation, usually for 24 to 48 hours, for carefully selected febrile patients who are not suitable for immediate discharge home.

Future research directions

- The subject of undifferentiated fever of short duration in the adult has not been well studied. There are few data on the spectrum of diseases producing this clinical problem.

CONTROVERSIES

- Whether empirical antibiotics should be given to adult patients with undifferentiated fever of short duration in order to minimize the risk of death from unrecognized sepsis or meningitis, This is a perennial question and there are no algorithms capable of directing the management of this problem.
- The safe and ideal course of action is to admit for observation all those patients who are ill enough to warrant a blood culture or a lumbar puncture. The limitation of hospital beds precludes this policy and there will be unnecessary admissions. The introduction of ED short-stay units provides an alternative for selected patients.

9.2 Meningitis

Andrew Singer

ESSENTIALS

1 **Bacterial meningitis can be a rapidly progressive and fatal illness. A high level of suspicion is necessary, as well as rapid diagnosis and treatment.**

2 **Eighty-five percent of cases have headache, fever, meningism and mental obtundation, but these are often absent or diminished in very young or old patients, those partially treated with oral antibiotics and those with some form of immunocompromise.**

3 **Treatment should not be delayed if lumbar puncture cannot be performed within 20 minutes of arrival in the emergency department. Blood cultures should be taken prior to the first dose of antibiotics if at all possible.**

4 **The combination of a benzylpenicillin and a third-generation cephalosporin will treat most cases of suspected bacterial meningitis and should be given as soon as the diagnosis is suspected (benzylpenicillin is sufficient in the pre-hospital setting).**

5 **Steroids are potentially of benefit to both adults and children with bacterial meningitis, reducing the incidence of deafness and other neurological complications in *Haemophilus influenzae* and *Streptococcus pneumoniae* infections. They should be given either before or with the first dose of antibiotic.**

Introduction

Definition

Meningitis is an inflammation of the leptomeninges, the membranes that line the central nervous system, as well as the cerebrospinal fluid (CSF) in the subarachnoid space. It is usually the result of an infection but can be due to an inflammatory response to a localized or systemic insult.

Classification

Meningitis is usually classified according to the aetiology or location as bacterial, aseptic (viral, tuberculous, fungal or chemical) or spinal (where the infection specifically affects the spinal meninges).

Aetiology

Bacterial

Bacterial meningitis is a serious cause of morbidity and mortality in all age groups. The causes vary according to age, as shown in (Box 9.2.1). Both *Neisseria meningitidis* and *Streptococcus pneumoniae* may be associated with a fulminant sepsis, including a purpuric rash and septic shock.

Aseptic

Aseptic meningitis may be due either to an immune response to a systemic infection (usually viral) or to a chemical insult.

Viral

Enteroviruses are the most common cause of meningitis, often in clusters of cases. Herpesviruses often cause meningitis as part of a more generalized infection of the brain (meningoencephalitis) or as part of an immune response to a systemic infection. A generalized viraemia may also cause aseptic meningitis owing to an immune reaction without direct infection.

Fungal

Fungal causes of meningitis, especially those due to *Cryptococcus neoformans*, tend to occur in immunocompromised patients, such as those with HIV/AIDS or those on immunosuppressant medication or cancer chemotherapy. It can occur in immunocompetent individuals as well, particularly the elderly.

Tuberculous

Tuberculous meningitis is rare in industrialized countries but can occur in all age groups. It tends to follow an insidious course, with a lack of classic signs and symptoms. Diagnosis is often difficult, owing to the low yield from CSF staining and the 4-week time frame required to culture the organism. Suspicion should be high in patients with immunocompromise or chronic illness. It tends to have a high mortality.

Spinal

Spinal meningitis is usually bacterial and due to direct spread from a localized infection in the spine.

Epidemiology

The epidemiology of meningitis is different for groups according to age as well as to immunocompetence.

- Neonates: Box 9.2.1 shows the main causes of bacterial meningitis in neonates. There is an overall incidence of 0.17 to 0.32 cases per 1000 live births. There is 26% mortality; it is even higher in premature infants.

Box 9.2.1 Causes of meningitis

Viral
Echovirus 6, 9,11, 30
Coxsackieviruses A9, A16, B1, B5, B6
Enterovirus 71 H
Herpes simplex 1 and 2 viruses
Cytomegalovirus
Varicella zoster virus
Epstein-Barr virus

Bacterial
Neonates (<3 months old):
Group B streptococcus *(Streptococcus agalactiae)*
Escherichia coli
Listeria monocytogenes
Coagulase-negative
Staphylococcus aureus
Pseudomonas aeruginosa

Children (<6 years old):
Haemophilus influenzae type b
Neisseria meningitidis
S. pneumoniae
Adults:
N. meningitidis (especially in young adults)
S. pneumoniae
L. monocytogenes (especially in adults over age 50)
Klebsiella pneumoniae
S. aureus
E. coli (in the immunocompromised)

Other
Mycobacterium tuberculosis
Cryptococcus neoformans (especially in the immunocompromised)
Aseptic

- Children: *Haemophilus influenzae* type b (Hib) used to be a common causative organism but immunization has significantly reduced its incidence. *N. meningitidis* has 13 serogroups. Six serogroups (A, B, C, W, X and Y) are associated with invasive disease. The incidence has declined significantly due to a number of factors including immunization (MenB in New Zealand and MenC in Australia). In Australia, there has been a recent increase in notifications of MenY.[1] Around 10% to 12% of isolates of *S. pneumoniae* are penicillin-resistant, especially in children.[2]
- Adults: *N. meningitidis* and *S. pneumoniae* are common causes in all age groups, with *N. meningitidis* predominating in adults under 24 years of age. *Listeria monocytogenes* is more common in adults over 50 years and immunocompromised or alcoholic patients. The overall incidence in adults is 3.8 per 100,000 population. More unusual organisms occur in patients following neurosurgery or chronic illness, such as alcoholism, hepatic cirrhosis, chronic renal failure and connective tissue disease (gram negative rods [GNRs], coagulase-negative *Staphylococcus aureus*, *Mycobacterium tuberculosis*, *Klebsiella pneumoniae*).
- Patients with HIV/AIDS: *C. neoformans* is relatively common, with an incidence of 5 per million of population or 10% of HIV-infected patients. Tuberculosis, *Listeria*, *Klebsiella* and syphilis are also causes of meningitis in this group, as well as viral causes of meningoencephalitis.
- Tuberculous meningitis occurs in around 2% of patients with TB and around 10% of HIV-infected patients with TB. It has a poor prognosis, with 20% mortality.

Pathogenesis

Initially there is colonization of the infectious agent, commonly in the nasopharynx. Other infections, such as otitis media or sinusitis, may spread from already established foci. There is either haematogenous or local spread to the meninges and subarachnoid space, with inflammation of this area and the production of a purulent exudate approximately 2 hours after invasion of the area. The inflammatory response is initiated by bacterial subcapsular components, such as lipo-teichoic acid in *S. pneumoniae* and a lipo-oligosaccharide in *H. influenzae* and other gram negative endotoxins. These substances stimulate the release of cytokines, such as interleukin-1 and -6, tumour necrosis factor (TNF) and arachidonic acid metabolites as well as the complement cascade. There is a subsequent increase in neutrophil and platelet activity, with increased permeability of the blood-brain barrier. This response is often stronger after the initial destruction of bacteria by antibiotics. If the infection is left untreated, fibrosis of the meninges may occur. In viral and aseptic meningitis, there is a more limited inflammatory response, with mild to moderate infiltration of lymphocytes. In the more chronic cases, such as those due to fungi or tuberculosis, the exudate is fibrinous, the main cells being a mixture of lymphocytes, monocytes/macrophages and plasma cells. The base of the brain is most commonly affected.

Presentation

History

There are some differences in the history with different causes of meningitis, which may allow an early differential diagnosis to be made. There are no pathognomonic symptoms or signs for meningitis, so a high index of suspicion is necessary.

The combination of fever, headache, meningism and mental obtundation is found in approximately 85% of cases of bacterial meningitis; early in the course, however, symptoms may be subtle.[3] It is also a common pattern in viral or aseptic meningitis, where obtundation is less of a feature. In fungal or tuberculous meningitis, these symptoms are much less common (seen in less than 40% of cases of cryptococcal meningitis). Elderly patients or those who have had recent neurosurgery may present with subtle or mild symptoms and lack a fever.

The headache is usually severe and unrelenting. It may be either global or located in a specific area. The main symptoms of meningism are nuchal rigidity (neck stiffness) and photophobia. The nuchal rigidity is clinically important when the patient complains of a painful restriction of movement in the sagittal plane (i.e. forwards and backwards only). Up to 35% of cases have associated nausea and vomiting.

As a general rule, the height of the fever is a poor indication of the possible cause, although the fever may often only be mild in tuberculous or fungal meningitis or in bacterial meningitis that has been partially treated by antibiotics. The spectrum of mental obtundation can range from mild confusion to bizarre behaviour, delirium or coma. The severity of obtundation is a good indication of the severity of the illness.

Focal neurological signs occur in around 10% to 20% of cases of bacterial meningitis but are also associated with cerebral mass lesions such as toxoplasmosis or brain abscess. They are also a feature of tuberculous meningitis. Seizures are relatively uncommon (13% to 30%) but may occasionally be the only sign of meningitis if the patient has been partially treated with oral antibiotics.

There may also be associated systemic symptoms. Myalgias and arthralgias are often associated with viral causes, but they may also be the sole presenting symptom in meningococcal meningitis. HIV/AIDS patients may show stigmata associated with that disease.

The course of the illness may also indicate the cause. Meningococcal or pneumococcal meningitis is frequently characterized by a rapid, fulminating course, often going from initial symptoms to death over an interval of hours. Viral causes tend to lead to a slower course over days. Fungal or tuberculous meningitis shows a more chronic course over days to weeks, with milder symptoms.

Risk factors for meningitis include the extremes of age, pre-existing sinusitis or otitis media, recent neurosurgery, CSF shunts, splenectomy, immunological compromise and chronic diseases such as alcoholism, cancer, connective tissue disorders, chronic renal failure and hepatic cirrhosis.

Examination

The physical examination will often reflect symptoms elicited in the history, with fever, physical evidence of meningism, stigmata of AIDS, and so on.

As stated earlier, neck stiffness is clinically significant only when it occurs in the sagittal plane. There will be a restriction of both passive and active movement. Other tests to elicit meningism include the Kernig and Brudzinski signs, although these are present in only 50% of adult cases of bacterial meningitis. The Kernig sign is elicited by attempting to extend the knee of a leg that has been flexed at the hip with the patient lying supine and the other leg flat on the bed. The sign is positive if the knee cannot be fully extended due to spasm in the hamstrings. The test can be falsely positive in patients with shortening of the hamstrings or other problems involving the legs or lumbar spine. In the Brudzinski sign, flexing the head causes the thighs and knees to also flex. It can also be tested in children by the inability to touch the nose with the flexed hips and knees in the sitting position. These are both late signs.

Focal neurological signs should be a cause for concern as they can indicate a poorer prognosis.

Papilloedema is rare and late, as is a bulging fontanelle in infants; both should alert one to alternative diagnoses.

A rash, often starting as a macular or petechial rash on the limbs, is seen in sepsis due to *N. meningitidis* and *S. pneumoniae*. A petechial rash is a particularly serious sign and is an indication to start antibiotics immediately. A maculopapular rash is also a feature of viral causes.

Investigations

Lumbar puncture

A CSF sample via a lumbar puncture (LP) is an important source of information for making the diagnosis and determining the likely aetiology and treatment. Treatment should not be delayed if there will be more than a 20-minute delay before the LP is performed and there is a reasonable clinical suspicion that a bacterial cause is present. Blood cultures should be ordered prior to the administration of antibiotics.

Indications

- Symptoms suggestive of meningitis, especially the combination of fever, headache, neck stiffness and photophobia
- Any patient with fever and an altered level of consciousness
- Fever associated with seizures, especially in a neonate, older child or adult
- Seizures in any patient who has been on oral antibiotics

Precautions

- Deep coma: A patient with a Glasgow Coma Scale (GCS) score of 8 or less should have the LP delayed until he or she is stable and more conscious. A normal brain computed tomography (CT) scan does not exclude the risk of uncal herniation in this group.
- Focal neurological signs: The patient should have CT scan first, to exclude a space-occupying lesion; if present, it could increase the risk of cerebral herniation following the LP.
- Surgery to the lumbar spine.
- Local skin infection around the lumbar spine.

The main features to note during LP are the opening pressure and the physical appearance of the CSF. The sample should be sent for Gram stain, culture, sensitivities, polymerase chain reaction (PCR) analysis for bacteria and herpes simplex virus, a cell count and protein and glucose levels. If fungal meningitis is suspected, an India-ink stain and cryptococcal antigen screen should be requested. If tuberculous meningitis is suspected, multiple 5-mL samples of CSF will be required to increase the likelihood of a positive result. If antibiotics have previously been administered, a bacterial antigen screen should also be requested.

Turbid CSF is indicative of a significant number of pus cells and is an indication for the immediate administration of antibiotics.

The pattern of cell counts and glucose and protein levels is shown in Table 9.2.1. This is only a guide and the clinician must also be guided by the complete clinical picture.

A white cell count (WCC) of more than 1000/μL with a predominantly neutrophilic pleocytosis is considered positive for bacterial meningitis. Ten percent of cases, especially early in the course of the illness, may have a predominance of lymphocytes. As a general rule, bacterial meningitis is characterized by a raised CSF protein and a low CSF glucose level. The ratio of CSF to serum glucose levels is also lowered. The combination of CSF glucose below 1.9 mmol/L, CSF:serum glucose ratio below 0.23, CSF protein above 2.2 g/L and either a total WCC above 2000/μL or a neutrophil count greater than 1180/μL has been shown to have a 99% certainty of diagnosing bacterial meningitis.[4] Aseptic meningitis will often have cell counts near the normal range. This does not exclude infection with less common agents, such as herpesviruses or *L. monocytogenes*.

Computed tomography scan

CT scanning of the brain is indicated as a prelude to LP in the presence of focal neurological signs, mental obtundation or abnormal posturing. It must be noted, though, that a normal CT scan does not entirely exclude the risk of raised intracranial pressure in bacterial meningitis; therefore those with the mentioned signs should have LP delayed until they are conscious and stable.

Table 9.2.1 Expected cerebrospinal fluid values in meningitis

Parameter	*Normal range*	*Bacterial*	*Viral*	*Fungal or TB*
Pressure (cm H_2O)	5–20	>30	Normal or mildly raised	
Protein (g/L)	0.18–0.45	>1.0–5.0	<1.0	0.1–0.5
Glucose (mmol/L)	2.5–3.5	<2.2	Normal	1.6–2.5
Glucose ratio—CSF/serum	0.6 (0.8 in infants)	<0.4 (allow 2–4 h equilibration)	0.6	<0.4
White cell count/μL	<3, usually lymphocytes (if the tap is traumatic, allow 1 WBC for every 1000 RBC)	>500 (90% PMNs)	<1000, predominantly monocytes (10% are >90% PMNs, 30%–40% >50% PMNs)	100–500
Gram stain	No organisms	60%–90% positive	No organisms	

CSF, Cerebrospinal fluid; *PMNs*, polymorphonuclear leucocytes; *RBC*, Red Blood Cells; *TB*, tuberculosis; *WBC*, White Blood Cells.

Microbiology

Apart from microscopy and culture of CSF, there are a number of other methods that may allow the causative organism to be identified.

Skin lesion aspirate

In cases where a petechial rash is present, a Gram stain or culture from some of the skin lesions may yield the causative organism. This has a reported sensitivity of 50%.[5]

Throat swab

Throat swabs are useful in identifying a bacterial cause spread by nasopharyngeal carriage; a throat swab should be obtained in a case of suspected bacterial meningitis.

Polymerase chain reaction

This potentially allows identification of the causative organism and even the serotype for organisms such as meningococcus. The test can be performed on CSF or ethylenediaminepentaacetic acid (EDTA) blood samples and may remain positive for up to 72 hours after the commencement of antibiotics. In CSF, the reported sensitivity is greater than 95%; in blood its sensitivity is 87%.[5]

Serology

Tests to detect Immunoglobulin M (IgM) to specific organisms are available for meningococcus and some viruses. For meningococcus, the test has a sensitivity and specificity of 97% and 95%, respectively, but it is reliable only in adults and in children over 4 years of age and takes 5 to 7 days after onset of the illness to reach diagnostic levels.

Antigenic studies

Latex agglutination, immune-electrophoresis or radioimmunoassay techniques can be used to screen for antigens from *S. pneumoniae*, Hib, group B streptococcus (*S. agalactiae*), *Escherichia coli* K1, *N. meningitidis* and *C. neoformans*. The tests can be performed on serum, CSF or urine. Serum or urine samples tend to allow greater sensitivities (around 96% to 99%) than CSF (82% to 99%). The test is no more sensitive than either a positive Gram stain or the presence of CSF pleocytosis in untreated cases. The main purpose of antigenic studies is to allow rapid identification of the causative organism in cases confirmed by the CSF findings or in cases where partial treatment with antibiotics renders the CSF sterile on culture. In many laboratories, these tests have been superseded by PCR methods.

General investigations

Full blood count (FBC), urea and electrolyte levels (UECs), blood cultures and C-reactive protein (CRP) can assist in assessment of the patient.

Blood cultures should be ordered prior to administering antibiotics. In most cases of bacterial meningitis, a blood culture will grow the causative organism. Identification can be improved by a combination of blood culture, CSF Gram stain and PCR or antigen testing.

Differential diagnosis

- Generalized viral infections, with meningism as a feature.
- Encephalitis: This is a more generalized viral infection of the brain. Clinically, it may be indistinguishable from meningitis.
- Brain abscess: This tends to produce focal signs due to local pressure at the site of the abscess.
- Focal cerebral infections, such as those due to *Toxoplasma gondii* in HIV/AIDS patients.
- Subarachnoid haemorrhage: This will often produce identical symptoms of meningism, but generally without other evidence of infection, such as fever.
- Migraine and other vascular headaches: Again, photophobia and neck stiffness are common features.
- Severe pharyngitis with cervical lymphadenopathy causing neck stiffness.

Management

Management depends on the likely causative agent and the severity of the illness.

General

Patients should rest in bed, particularly following an LP. A quiet, darkened room will be beneficial to those with headache or photophobia. Simple analgesics with or without codeine may be used to treat the headache. Opiates may be required in severe headache.

Sedation may be necessary if the patient is very agitated or delirious. Suitable drugs are diazepam 5 to 10 mg IV or midazolam 2 to 10 mg IV or IM with or without the addition of an antipsychotic, such as droperidol 2.5 to 10 mg IV or IM or chlorpromazine 12.5 to 50 mg IV or IM.

Seizures should be treated appropriately, initially with a benzodiazepine, then maintained with phenytoin or phenobarbitone. Meningitis can occasionally be associated with status epilepticus, which should be treated in the standard way.

Patients with raised intracranial pressure may need pressure monitoring and measures to reduce the pressure, such as nursing the patient in a 30-degree head-up position and administering hyperosmotic agents such as mannitol or hypertonic saline. Obstructive hydrocephalus requires appropriate neurosurgical treatment with CSF shunting.

If septic shock has intervened, it should be treated in the usual way, with IV fluids and inotropes.

Antimicrobials

The choice of antimicrobial agent will be determined by the likely causative organism and is therefore determined primarily by age and immune status. It is important not to delay antibiotic therapy for investigations such as LP or CT and the antimicrobial should be administered as soon as the diagnosis is suspected. Table 9.2.2 shows the recommended choice of antimicrobial for different situations and organisms. Table 9.2.3 shows the recommended dosage of each. As a general rule, the combination of a third-generation cephalosporin and benzylpenicillin will cover most organisms in all age groups. It is important to note that there is emerging resistance to penicillins in *S. pneumoniae* (currently 10% to 12% of isolates in Australia). If gram positive diplococci are found or *S. pneumoniae* is identified on antigen or PCR testing, vancomycin should be added to the therapy.[6]

Steroids

Steroids have been shown to improve the prognosis of bacterial meningitis in both adults and children in high-income countries. They can lead to a reduction in complications, such as sensorineural deafness and short-term neurological deficits. The benefit appears to occur in infections from *H. influenzae* or *S. pneumoniae*. No benefit has been demonstrated with respect to mortality. Steroids are usually administered as dexamethasone 0.15 mg/kg (up to 10 mg) IV q6h, and are indicated only if they can be started before or with the first dose of antibiotics. They should then be continued for 4 days if one of the previously mentioned organisms is confirmed. The main adverse effect is gastrointestinal bleeding, which may be reduced by limiting treatment to 2 days.[7]

Disposition

All cases of bacterial meningitis will require admission for IV antibiotics as well as supportive therapy. They often require intensive therapy, especially if septic shock has supervened. Viral meningitis will usually require supportive therapy only, but this may necessitate admission. Mild cases of viral or aseptic meningitis with a clear diagnosis can safely be sent home.

Prognosis

Over the last 20 years the mortality of bacterial meningitis has ranged from 6% to 20%, and it is higher in the very young or very old. Meningitis in immunocompromised individuals carries a high mortality of up to 50%. Bacterial meningitis in children can lead to a number of long-term sequelae, such as sensorineural hearing loss, learning difficulties, motor problems, speech delay, hyperactivity, blindness, obstructive hydrocephalus and recurrent seizures. These sequelae are less common in adults.

Table 9.2.2 Choice of antimicrobial in meningitis

Organism	*First-line drug*	*Second-line drug*	*Duration*
Pre-hospital	Benzylpenicillin	Ceftriaxone (if penicillin-allergic)	
Neonates	Cefotaxime *plus* ampicillin *plus* vancomycin (if MRSA suspected)		
Organism unknown	Cefotaxime or ceftriaxone *plus* benzylpenicillin (if *Listeria* suspected) *plus* vancomycin (if *Streptococcus* or *Staphylococcus* suspected)	Vancomycin *plus* ciprofloxacin or moxifloxacin (if penicillin-allergic)	7–10 days
Haemophilus influenzae type b	Cefotaxime or ceftriaxone	Benzylpenicillin or ciprofloxacin	7–10 days
Neisseria meningitidis	Benzylpenicillin or cefotaxime or ceftriaxone	Ciprofloxacin or chloramphenicol (particularly if penicillin-allergic)	5–7 days
Streptococcus pneumoniae	Benzylpenicillin (if susceptibility known)	Cefotaxime or ceftriaxone or vancomycin (if resistant to penicillin)	10 days
Listeria monocytogenes	Benzylpenicillin	Trimethoprim + sulfamethoxazole	3–6 weeks
Cryptococcus neoformans	Amphotericin *plus* flucytosine	Fluconazole	4–6 weeks
Streptococcus agalactiae	Benzylpenicillin		
Herpes simplex	Acyclovir		14 days

MRSA, Methicillin-resistant *Staphylococcus aureus*.
(Adapted from Therapeutic Guidelines Limited. *Therapeutic Guidelines: Antibiotic*, version 15; 2014.)

Table 9.2.3 Antibiotic doses in treating meningitis

Antibiotic	*Adult dose*	*Child dose*	*Route*	*Frequency*
Cefotaxime	2 g	50 mg/kg	IV	q6h
Ceftriaxone	4 g	100 mg/kg	IV	Daily
Benzylpenicillin	2.4 g	60 mg/kg	IV	q4h
Ampicillin		50 mg/kg	IV	q6h
Trimethoprim + sulphamethoxazole	160 + 800 mg	4 + 20 mg/kg	IV	q6h
Chloramphenicol	1 g	25 mg/kg	IV	q6h
Acyclovir	10 mg/kg	20 mg/kg in full-term neonates, 10 mg/kg otherwise	IV	q8h
Amphotericin B	1 mg/kg	1 mg/kg	IV	Daily
Flucytosine	25 mg/kg	25 mg/kg	IV or PO	q6h
Vancomycin	1.5 g (reduce dose to 1 g if renal impairment)	15 mg/kg	IV	q6h (reduce frequency in neonates)
Ciprofloxacin	400 mg	10 mg/kg	IV	q12h
Moxifloxacin	400 mg	10 mg/kg	IV	q12h

(Adapted from Therapeutic Guidelines Limited. *Therapeutic Guidelines: Antibiotic*, version 15; 2014.)

Prevention

Prophylaxis should be offered in cases of *N. meningitidis*[5] or *H. influenzae* type b infection to the following persons:

- Household or household-like contacts: those who lived in the same house (or dormitory-type room) or were having an equivalent degree of contact with the case in the 7 days prior to the onset of the case's symptoms until completion of 24 hours of appropriate antibiotic treatment. (in Hib, if less than 24 months old or less than 4 years and incompletely immunized against Hib).
- Passengers immediately adjacent to the index case on a trip of 8 hours' or longer duration.
- Any person who has potentially shared saliva (such as eating utensils or drink bottles) or had other intimate contact with the index case.
- Health care workers who have given mouth-to-mouth resuscitation to an index case or had unprotected close exposure to large-particle respiratory droplets during airway management.

Appropriate regimens for meningococcus are as follows:

- Ciprofloxacin 500 mg orally (250 mg for children over 5 and 30 mg/kg up to 125 mg for children under 5) as a single dose. This is

preferred for adults, children and females on oral contraceptives.
- Ceftriaxone 250 mg (125 mg in children <12 years of age) IM in 1% lignocaine. This is preferred in pregnant women.
- Rifampicin 600 mg orally q12h for 2 days (5 mg/kg in neonates <1 month, 10 mg/kg in children). This is preferred in young children.
- Appropriate regimens for Hib are:
- Rifampicin 600 mg PO QD for 4 days (10 mg/kg in neonates <1 month, 20 mg/kg in children).
- Ceftriaxone 1 g IM QD for 2 days (50 mg/kg in children).

If the index case is less than 24 months old, Hib vaccination should be given as a full course as soon as possible after recovery. Unvaccinated contacts under 5 years of age should be immunized as soon as possible. Casual neighbourhood or hospital contacts are not required to receive prophylaxis.

Meningococcal vaccine should be considered in populations where cases are clustered. The vaccine is currently recommended for exposure to serogroups C, A, W or Y.

CONTROVERSIES

- Should all patients have a CT scan before lumbar puncture? CT is required only for patients with focal neurological signs or those who are comatose, where lumbar puncture should be delayed until they are more stable.
- When to use steroids? There is no demonstrated benefit of steroids outside of being given before or with the first dose of antibiotics in meningitis caused by *H. influenzae* b or *S. pneumoniae*.

9.3 Septic arthritis

Christopher Carman

ESSENTIALS

1 **Early diagnosis and treatment are critical for the prevention of irreversible joint destruction.**

2 **Diagnosis is based on clinical features and synovial fluid examination; imaging techniques have a role in difficult cases.**

3 ***Staphylococcus aureus, Streptococcus*** **and** ***Neisseria gonorrhoeae*** **are the most frequent pathogens in adults and older children.** ***Methicillin-resistant staphylococcus aureus*** **(MRSA) is an emerging problem, particularly among intravenous drug users. Fungal, mixed bacterial and exotic organisms are rarely seen outside of the intravenous drug using population.**

4 **Successful treatment hinges on rapid and complete joint lavage and high-dose parenteral antibiotics guided by culture results.**

5 **Outcomes are good in paediatric and gonococcal subgroups, but the presence of chronic arthritis or polyarticular involvement is associated with up to 15% mortality and 50% chronic joint morbidity.**

Introduction

Septic arthritis is defined as bacterial infection of the synovial space. The knee is the most commonly affected joint in adults and the hip joint in the paediatric age group.[1] Intravenous drug users have a predisposition toward axial joint infections. Septic arthritis is commonly monoarticular and monomicrobial.

Aetiology, pathogenesis and pathology

Septic arthritis occurs as a consequence of a number of pathological processes: inoculation resulting from a penetrating injury or procedure, direct spread from an adjacent infective process such as osteomyelitis, cellulitis, bony or soft tissue abscess. Most commonly it may result from haematogenous spread, as in sepsis or as a consequence of endocarditis. Once a joint is inoculated, an acute inflammatory reaction with hypersecretion of synovial serous or seropurulent exudate occurs. As the infection progresses, articular cartilage is eroded both through direct bacterial enzymatic destruction and as a consequence of the release by inflammatory and synovial cells of proteolytic enzymes. If the inflammation is not treated, loss of articular cartilage fluid eventually leads to healing by bony ankylosis or joint fibrosis.[2] Co-morbidity or deficient host defences are risk factors for infection[3] and can be associated with more rapid and severe disease (Table 9.3.1).

The majority of cases are community acquired and occur in children and young adults.[4] Prosthetic joint surgery and the invasive management of chronic arthritis are factors in the increased prevalence observed in older age groups.

Epidemiology

The incidence of proven and probable septic arthritis in Western Europe is 4 to 10 per 100,000 patients per year. This is more prevalent in lower socioeconomic groups in both Northern Europe and Australia.

The prevalence is 29 cases per 100,000 in the indigenous population, with a relative risk of 6.6 compared with the European Northern Territory Australian population.[5]

Table 9.3.1 Risk factors for septic arthritis

Risk factors	*Examples*
Direct penetration	Trauma Medical (surgery, arthrocentesis), intravenous drug use
Joint disease	Chronic arthritis
Host immune deficit	Glucocorticoid or immunosuppressive therapy HIV infection Chronic illness Cancer

Table 9.3.2 Synovial fluid characteristics

Characteristic	*Septic arthritis*	*Non-septic arthritis*	*Non-inflammatory effusion*
Colour	Yellow/green	Yellow	Colourless
Turbidity	Purulent, turbid	Turbid	Clear
Leucocytes/μL	10–1 million	5–10,000	<1000
Predominant cell	PMN	PMN	Monocyte

PMN, Polymorphonuclear leucocyte

The incidence of septic arthritis is increasing and is linked to an increase in orthopaedic-related infection, an ageing population, more invasive procedures being undertaken and an enhanced use of immunosuppressive treatment.[5]

Clinical features

History

This will usually reveal the recent onset of a painful, hot, swollen joint, most commonly the hip or knee, although any joint may be affected. Systemic features of fever or rigors should be sought, plus the presence of any risk factors.

Examination

Typical findings include a hot, tender joint held in a position to minimize joint space pressure, with marked limitation of passive or active movement owing to pain. An effusion will be evident in most cases. A polyarticular presentation is more common in gonococcal infection or in the setting of chronic arthritis. In general,fever is low-grade and few patients will appear 'toxic' and unwell. The elderly and immunosuppressed may present non-specifically with anorexia, vomiting, lethargy or fever.

Differential diagnosis

Non-septic arthritis, crystalline arthritis or synovitis may be differentiated on clinical features and joint fluid analysis. Fractures will generally be evident on joint radiographs, but the detection of osteomyelitis may require more advanced imaging techniques, such as nuclear or computed tomography (CT) scanning. Rheumatic fever and brucellosis are rare causes.

Clinical investigations

Synovial fluid examination and culture

Aspiration should be performed promptly with local anaesthetic and a large-bore needle for cell count, crystals, Gram stain and culture to confirm the diagnosis. Typical findings in septic arthritis and its differential diagnoses are shown in Table 9.3.2.[6]

Most infections are acute and bacterial (Table 9.3.3),[6] although fungal and mycobacterial pathogens have been recognized in chronic and periprosthetic infections.

Other laboratory investigations

Blood cultures should always be ordered and may be positive in up to 50% of cases. Inflammatory markers (erythrocyte sedimentation rate [ESR] and C-reactive protein [CRP]) may be elevated, typically with a neutrophil-predominant leucocytosis. CRP may be negative if the infective organism is of low virulence.[7] These are non-diagnostic investigations but aid in monitoring response to therapy. Further research may in future provide additional diagnostic aids (Box 9.3.1).

Imaging studies

Plain radiographs should be obtained in all cases prior to aspiration: they may reveal effusions or local oedema and help to exclude alternative conditions, particularly fracture and peri-articular malignancy. Ultrasound is very sensitive in detecting effusions and excellent for facilitating needle aspiration.

Fluoroscopy may also be used. Nuclear medical studies are very sensitive early but not specific for sepsis. CT and magnetic resonance imaging (MRI) have a small role in difficult joints (e.g. hip and sacroiliac).

Criteria for diagnosis

This depends on positive culture of synovial fluid from an affected joint, a positive Gram stain or blood culture in the context of an inflamed joint suspicious of sepsis, macroscopic pus aspirate and appropriate response to antibiotics.[8]

Management

Arthroscopic washout has gained increasing favour in both adults and children, offering a more rapid return to normal function, although arthrotomy and open washout is still utilized for severe and periprosthetic infections.[9–11]

Antibiotic therapy is initiated after culture specimens have been obtained, with clinical presentation and Gram stain guiding the choice of agents. All regimens must include an anti-staphylococcal agent with gram negative cover as indicated by the clinical setting.

Suggested initial empiric regimen[12]

Flucloxacillin: 2 g (25 to 50 mg/kg up to 2 g) IV q6h. If gram-negative bacteria are suspected, add ceftriaxone 2 g IV. If methicillin resistance is suspected, add vancomycin 1 g (25 mg/kg) IV q12h. Confirmed gonococcal infections require the addition of a single dose of azithromycin 1g PO. Consult therapeutic guidelines in the context of penicillin hypersensitivity.

Table 9.3.3 Bacterial causes of septic arthritis

Age group	*Typical bacteria*
Children	*Staphylococcus aureus* Group A streptococci (B in neonates) *Haemophilus influenza*
Young adults	*Neisseria gonorrhoeae* *S. aureus*
Older adults	*S. aureus* Gram-negative species[a] Group A streptococci

[a]*Pseudomonas* spp. and Enterobacteriaceae.

Box 9.3.1 Likely developments in the future

Synovial and haematologic cellular markers to distinguish septic arthritis from other sources of non-traumatic joint pain may become available to the emergency physician.

- Synovial fluid lactate assay
- Synovial probe based polymerase chain reaction technique to identify the bacterial pathogen
- Delta neutrophil index assay to determine burden of infection

From Carpenter CR, Schuur JD, Everett WW, Pines JM. Evidence-based diagnostics: adult septic arthritis. *Acad Emerg Med.* 2011;18:781–96.
See references 15 and 16.

Definitive therapy will be tailored to later laboratory identification of the organism and its sensitivities.

The duration and route of therapy remain controversial but, in uncomplicated acute cases, parenteral antibiotics will be required for at least 3 days in children and 2 weeks in adults, with a total treatment duration of 3 to 6 weeks.[13,14] Specific organisms, such as *Neisseria* spp., will respond more rapidly, whereas chronic infections and co-morbidity will necessitate aggressive and more prolonged therapy.

General care—with initial joint rest, appropriate analgesia and physical therapy—is important. Admission is mandatory pending source control. Thereafter, ongoing therapy may be monitored on an outpatient basis or via domiciliary hospital services.

Prognosis

This depends upon the organism, patient co-morbidity and the adequacy and rapidity of treatment. Gonococcal and paediatric infections have a generally good response, with low rates of ensuing joint morbidity. Polyarticular sepsis in rheumatoid arthritis has been associated with mortality rates of up to 15% and major morbidity in up to 50% of survivors.[2,6,13]

Prevention

Safe sexual practice can reduce gonorrhoeal infections. Strict aseptic technique, good patient selection and prophylactic antibiotics help to prevent cases associated with invasive joint procedures. The overall incidence of infection after arthroplasty ranges from 0.5% to 2%.[2]

CONTROVERSIES

- The total duration of therapy has gradually been reduced, but the optimum duration is unclear, as is the balance between parenteral and oral routes.[14]
- Consensus has not been reached on the best method of joint drainage. Arthroscopic techniques provide the mainstay, although arthrotomy is still utilized, particularly in periprosthetic infections.[9–11]
- Difficulties still exist in the differentiation of septic arthritis from new-onset non-septic arthritis, especially when polyarticular joint fluid analysis and medical imaging are used, but nuclear and CT scanning techniques may have difficulty in distinguishing infective from non-infective inflammation.

9.4 Urinary tract infections

Sean Arendse

ESSENTIALS

1 **Urinary tract infection (UTI) is the most common bacterial infection.**

2 **By age 32, 50% of women will report at least one UTI.**

3 **Sexual activity is the most important risk factor in young women.**

4 **Most UTIs are caused by *Escherichia coli*, but *Staphylococcus saprophyticus* is responsible for up to 15% of infections in young, sexually active women.**

5 **There is a genetic predisposition in some women to recurrent UTI.**

6 **For the majority of outpatients with typical symptoms, urine culture is not necessary.**

7 **In hospitalized patients, urinary catheterization produces infection in 10% of patients per day.**

8 **Asymptomatic bacteriuria should not be sought or treated except in pregnant women and in patients about to undergo significant urological procedures.**

Introduction

Urinary tract infections (UTIs) is the most common bacterial infection and the major cause of gram negative sepsis in hospitalized patients.[1,2]

Definitions

Urinary tract infection

The term *urinary tract infection* is non-specific and may refer to a variety of clinical conditions, including asymptomatic bacteriuria (ASB), urethritis, cystitis, female urethral syndrome and acute and chronic pyelonephritis. The most common clinical presentations are cystitis and acute pyelonephritis, although the clinical distinction between these diagnoses may not be as straightforward as the terms imply, with up to 50% of patients having unrecognized pyelonephritis. [3]

UTI is considered in two main groups: simple (or uncomplicated) and complicated. Simple UTI occurs in an otherwise healthy person with a functionally and anatomically normal urinary tract, most commonly a young non-pregnant female. A complicated UTI is one associated with anatomical abnormality, urinary obstruction or incomplete bladder emptying due to any cause: instrumentation or catheterization, pregnancy or significant underlying disease, such as immunosuppression or diabetes mellitus.

Significant bacteriuria

Significant bacteriuria most commonly refers to more than 10^5 bacteria per millilitre of urine, reported as colony forming units per millilitre (cfu/mL). This usually represents infection as opposed to contamination (see 'Quantitative culture', further on), although there are significant exceptions to this generalization (see 'Urethral syndrome', later).

Asymptomatic bacteriuria

Asymptomatic bacteriuria refers to significant bacteriuria in the absence of symptoms of infection.

Epidemiology

UTI is very common, particularly in women, in whom age, degree of sexual activity and the form of contraception used are all factors that affect the incidence and prevalence of infection.

Although the overall rate of infection is difficult to estimate, since UTI is not a reportable disease, the self-reported incidence of UTI in a US health survey was 12.1% among women and 3% among men. By age 32, 50% of women will have had at least one UTI.[4] In non-pregnant women aged 18 to 40 years, the rate of infection has been stated to be between 0.5 and 0.7 per person per year, with much higher rates in pregnancy.[5]

In males, the prevalence of bacteriuria beyond infancy is 0.1% or less. Between the ages of 21 and 50, infection rates may be as low as 0.6 to 0.8/1000.[6] With increasing prostatic disease, the frequency of bacteriuria may rise to 3.5% in healthy men and to more than 15% in hospitalized men by age 70.[7] Homosexual men are at increased risk of UTI.

In the presence of chronic disease and with institutionalization of the elderly, the incidence of bacteriuria may be as high as 50%, although this is most commonly asymptomatic.[8]

Aetiology

The aetiology of uncomplicated UTI has remained unchanged for decades, although increased antibiotic resistance in the bacteria responsible has been well documented. In community-acquired UTI, *Escherichia coli* accounts for 75% to 90% of cases, *Staphylococcus saprophyticus* accounts for 5% to 15% (especially in young, sexually active women), with enterococci and gram negative organisms, such as *Klebsiella* spp. and *Proteus mirabilis*, responsible for 5% to 10%.[9,10] Which bacteria are isolated is influenced by factors such as whether the infection is initial or recurrent; the presence of obstruction, instrumentation or anatomical abnormalities; and whether the patient is an inpatient or outpatient. In simple acute cystitis, the most common presentation of UTI, a single organism is usually isolated. On the other hand, in complicated UTI, *E. coli* is isolated in 20% to 50% of cases and non–*E. coli* organisms, such as *Proteus* and *Klebsiella* species, are more commonly seen. In the presence of structural abnormalities, it is more common to isolate multiple organisms, and antibiotic resistance is frequently found.[10]

Pathogenesis

In healthy individuals, the perineum, vagina, vaginal introitus and urethra as well as periurethral areas each have their respective flora and are normally colonized by bacteria that differ from those commonly associated with UTI—that is, by non-pathogens. The periurethral area may become colonized by such UTI-causing (uropathogenic) bacteria, which then ascend via the urethra into the bladder and thence may ascend further to the kidney, causing pyelonephritis. The reservoir for these bacteria is the gastrointestinal tract.[4] There are host and bacterial mechanisms involved in determining whether a UTI will occur.

Host mechanisms

Anatomic considerations (men) and prostatic secretions

In males, the length of the urethra, its separation from the anus and the presence of prostatic secretions all contribute to the prevention of colonization and subsequent UTI.

Sexual activity, contraceptive practices, use of diaphragm/spermicides

Sexual activity is the most important risk factor for acute cystitis, with recent or frequent sexual activity increasing that risk. The use of a diaphragm with a spermicide (an inhibitor of normal vaginal flora) promotes vaginal colonization with uropathogenic bacteria and has also been shown to increase the risk of UTI.[4]

Secretor/non-secretor status

Blood group antigens are secreted in the body fluids by some women. The urethral and periurethral mucosae in women who do not secrete these antigens (non-secretors) in their body fluids have a higher affinity for bacterial adhesins (see later) than the mucosae of women who do. These non-secretors are more susceptible to recurrent infections.[11]

Entry of bacteria into the bladder

Instrumentation of the bladder (see later) is a well-recognized mechanism by which bacteria are introduced into the bladder. Other factors have been considered but have not been conclusively demonstrated. These include frequency and timing of voiding, hormonal changes and personal hygiene habits.[12]

Bladder defence mechanisms

The healthy bladder can normally clear itself of bacteria. Three factors are involved: (1) voiding; (2) urinary bacteriostatic substances—such as organic acids, high urea concentrations and immunoglobulins; and (3) active resistance by the bladder mucosa to bacterial adherence.

Obstruction

This may be extrarenal (congenital anomalies, such as urethral valves, calculi, benign prostatic hypertrophy) or intrarenal (nephrocalcinosis, polycystic kidney disease, analgesic nephropathy). Complete obstruction of the urinary tract predisposes to infection by haematogenous spread. In the absence of such obstruction, haematogenous seeding of bacteria to the kidneys accounts for about 3% of infections. Partial obstruction does not have this effect.

Vesicoureteric reflux

Incompetence of the vesicoureteric valve is a congenital problem that is five times more common in boys than in girls but tends not to be a significant factor in adults. It allows infected urine to ascend to the kidney and is the most common factor predisposing to chronic pyelonephritic scarring.

Instrumentation

Although any instrumentation of the urinary tract predisposes to infection, catheterization is the most common of these. A single catheterization will result in UTI in 1% of ambulatory patients but, in hospitalized patients, 10% of women and 5% of men will develop a UTI after one catheterization. Once in place, catheters produce infection in up to 10% of patients per day and nearly all catheterized patients will be bacteriuric by 1 month.[13] All chronically catheterized patients are bacteriuric.

Pregnancy

Changes to the urinary tract occur normally during pregnancy as a result of both anatomical alterations and hormonal effects: dilatation of the ureters and renal pelves, decreased peristalsis in the ureters and decreased bladder tone. These changes begin before the end of the second month. The prevalence of bacteriuria rises with age and parity. A large proportion of asymptomatic bacteriuric women develop symptomatic pyelonephritis later in pregnancy, with significant increases in toxaemia and prematurity (see 'Asymptomatic bacteriuria', later).

Diabetes mellitus

The relationship between diabetes mellitus on the one hand and ASB and UTI on the other has been debated. Current evidence indicates that ASB is more common in diabetic women than in those who are not diabetic. The evidence in men is less clear. Good evidence from prospective studies for an increased incidence of symptomatic urinary tract infection in diabetics is lacking. What appears clear is that diabetes is a significant and independent risk factor for pyelonephritis, complicated UTI, urosepsis, hospitalization and other, often rare, complications (such as emphysematous pyelonephritis, papillary necrosis and candidal infections). The precise pathogenetic mechanism is unclear but involves many factors not necessarily related to glycaemic control.[14–16]

Ageing

UTI is the most frequent bacterial infection in residents of long-term-care facilities. ASB is highly prevalent in residents of long-term-care facilities, with up to 30% of men and 50% of women showing such bacteriuria. The likelihood of bacteriuria correlates with the degree of functional

impairment. Several factors may be involved: chronic degenerative neurological diseases may impair bladder function as well as bladder and bowel continence, prostatic enlargement in men and oestrogen deficiency in women can both lead to incomplete bladder emptying, and the use of devices—such as indwelling catheters or condom drainage—predisposes to bacteriuria.[8]

Bacterial factors

A number of studies[17–19] have shown that the strains of *E. coli* (and a number of other gram negative bacteria) that cause UTI are not just the most prevalent in the bowel of the patient at the time of the infection but have specific characteristics, termed virulence factors, that give them certain capabilities: increased intestinal carriage, persistence in the vagina and the ability to ascend and invade the normal urinary tract. Thus there are clearly uropathogenic strains of these bacteria. In cases of complicated UTI (e.g. those associated with reflux, obstruction or foreign body), these virulence factors are not significantly involved.

Presentation

History

A careful history should be taken in any patient presenting with symptoms of apparent UTI, looking for risk factors for complicated or recurrent infection (such as previous UTIs and their treatment, the presence of known anatomical abnormalities and investigations or instrumentation, the possibility of pregnancy and history of diabetes mellitus), as well as seeking to identify those patients with urethritis and vaginitis. In men, the most common cause of recurrent lower tract UTI is prostatitis. Therefore evidence of prostatitis, such as chills, dysuria and prostatic tenderness, should be sought.

Lower tract infections (cystitis) typically present with irritative micturition symptoms, such as dysuria and frequency, suprapubic discomfort and sometimes macroscopic haematuria. There is usually no fever. Women presenting with dysuria and frequency without vaginal discharge or irritation have a 90% probability of cystitis.[20] The classic symptom complex of loin pain, fever (>38°C), chills and urinary symptoms is usually associated with pyelonephritis. Severe pain should raise suspicion of a ureteric calculus that, combined with infection, poses a greater risk of sepsis and of permanent injury to the kidney.

Patients with chronic indwelling catheters usually have no lower tract symptoms at all but may develop loin pain and fever.

In elderly patients, particularly those in long-term-care facilities, the long-held view that symptoms of increased confusion and reduced mobility in the absence of fever are due to urinary tract infection has been cast into doubt (see 'Treatment of specific groups: elderly patients', further on).[8]

Examination

The clinical signs of lower UTI are few and non-specific; however, patients should be examined to exclude other causes for their symptoms, particularly vaginitis in women and prostatitis in men. The presence of renal angle tenderness associated with fever, chills and dysuria suggests pyelonephritis.

Investigations

The key step in the diagnosis of UTI is examination of the urine, most commonly a midstream specimen of urine (MSU). Catheterization is appropriate in patients with altered mental state or those who cannot void because of neurological or urological reasons. Suprapubic aspiration is commonly used in paediatric practice but can be used in adults if other techniques have failed or cannot be used.

The next step is to look for the presence of pyuria; subsequently the specimen may be sent for quantitative culture and antibiotic sensitivity testing. Testing for haematuria, proteinuria and nitrites may be of supportive value but the results are not diagnostic.

Reagent test strips

In considering the use of reagent strips in the diagnosis of UTI, it should be noted that variations in published sensitivity and specificity exist. These may be due to (1) the use of different brands of reagent strips; (2) the use of different 'gold standards' against which comparison is made (e.g. counting chamber or cells/high-power-field counts, 'cut-off' criterion of the test used); (3) the nature of the study (blinded, unblinded); (4) the reader of the test (lab worker, doctor, nurse); and, most importantly, (5) the clinical setting or target population (e.g. symptomatic ED patients rather than an asymptomatic population in a clinic or office environment)—in other words, the pre-test probability.

A reagent strip test for leucocyte esterase is now the most common screening test for pyuria (see later). Taken alone, this has a sensitivity of 48% to 86% and a specificity of 17% to 93% for detecting pyuria (as defined further on). A positive predictive value (in symptomatic individuals) of 50% and a negative predictive value of 92% make this a valuable test for screening the emergency department (ED) population. Most studies indicate that when the combination of leucocyte esterase and nitrite is considered, the sensitivity of the test is 68% to 88% and a negative test excludes the presence of infection.[21] Recent work by Sultana and others has shown that reagent strips significantly improve the clinician's accuracy in diagnosing UTI in symptomatic ED patients.[22] The clinical probability of UTI must be considered when such screening tests are used. In the patient with typical urinary tract symptoms, such a test may provide an adequate screen. It should, however, be used with great caution in the presence of fever of unknown cause in the elderly, the patient with an indwelling catheter or the patient with an impaired mental state, as pyuria and the implied bacteriuria may not be the cause of the problem.

Pyuria

Pyuria indicates inflammation in the urinary tract and, as a sign of infection, is second only to bacteriuria determined by quantitative culture (see later). The 'gold standard' definition of pyuria is based on early work involving measurement of the rate of excretion of polymorphs in the urine. This work showed that excretion of 400,000 polymorphs per hour was always associated with infection and was also found to be represented by 10 polymorphs per cubic millimetre in a single (unspun) midstream urine (MSU).[23] Thus 'significant pyuria' was defined as 10,000 polymorphs per millilitre of urine. It was subsequently shown that more than 96% of symptomatic patients, defined as having significant bacteriuria, had significant pyuria and conversely that less than 1% of asymptomatic people without bacteriuria have this degree of pyuria. Other definitions of pyuria, such as more than 5 leucocytes per high-power field, are based on examination of either the urinary sediment or of centrifuged urine and are inherently inaccurate because they cannot be standardized but are nevertheless often used.[24] 'Sterile' pyuria indicates the presence of significant pyuria without the presence of bacterial growth in standard culture (Box 9.4.1).

Nitrites

This reagent strip-based test is dependent on the bacterial reduction of urinary nitrate to nitrite, a function of coliform bacteria but not of *Enterococcus* spp. or *Staphylococcus saprophyticus*. The test has a low sensitivity (45% to 60%), better specificity (85% to 98%) but a high false-negative rate (about 45% in many studies). False-negative results are likely if the infecting organism is gram positive

Box 9.4.1 Common causes of sterile pyuria

- Non-specific urethritis in males
- Prostatitis
- Renal tract neoplasm
- Renal calculi
- Catheterization
- Renal tuberculosis
- Previous antibiotic treatment

or *Pseudomonas*, if the diet lacks nitrate or if there is diuresis or extreme frequency, as a period of bladder incubation is necessary to form nitrites.

Haematuria

Although a frequent accompaniment of UTI, this finding is non-specific, as there are many other causes of haematuria.

Proteinuria

Most commonly with UTI, protein excretion is less than 2 g/24 h. It is another common but non-specific finding.

Quantitative culture

Urine culture is not essential in the management of the pre-menopausal sexually active female with an uncomplicated UTI, as the probability of UTI in these patients is 90%.[20] Culture should always be performed in patients with recurrent infection, possible pyelonephritis, potentially complicated UTI, males, the elderly or in cases where the cause of infection is not clinically evident. In symptomatic patients, a single specimen with a bacterial count in urine of greater than 10^5 colony forming units (cfu) per millilitre has a 95% probability of representing infection.[25] However, it has been shown that 30% to 50% of women with symptoms of dysuria will have bacterial counts less than 10^5 cfu/mL.[26] Of these, about half have bacterial UTI with low numbers of bacteria. The rest may be considered in two groups; one group has urethritis due to *Chlamydia trachomatis* or *Neisseria gonorrhoeae* and the other has negative cultures and may have *Ureaplasma urealyticum* urethritis. In men, counts as low as 10^3 cfu/mL suggest infection.[27]

In patients with indwelling urethral or suprapubic catheters or those who intermittently self-catheterize and have symptoms or signs of UTI, a colony count of $\geq 10^3$ cfu/mL of more than one bacterial species in a single catheter or MSU specimen if the catheter has been removed within the previous 48 hours does indicate UTI.[28]

Blood cultures

Blood cultures are normally not taken in afebrile patients with symptoms of cystitis. Current evidence indicates that blood cultures do not alter management and are therefore unnecessary in the majority of cases of uncomplicated pyelonephritis since the infecting organism can be isolated from a urine specimen.[29,30] Blood cultures should be taken in the following circumstances:

- Recent instrumentation
- Known anatomic abnormality
- Failure of empiric treatment
- Immunosuppression
- Significant co-morbidity, such as diabetes mellitus
- Major sepsis
- Fever of unclear cause

Imaging

Imaging is not required in cases of uncomplicated cystitis. In pyelonephritis, imaging should be performed if there is

- Pain suggestive of renal colic or obstruction
- Failure to defervesce within 72 hours
- Rapid relapse on cessation of antibiotic treatment or within 2 weeks
- Infection with an unusual organism

These circumstances have been shown to be associated with stones or renal scarring. Computed tomography (CT) scanning is the preferred modality as it has greater sensitivity for demonstrating not only stones and obstruction but also rare gas-forming infections, haemorrhage and inflammatory masses.

Management

Ideally, treatment of UTI should rapidly relieve symptoms and prevent short-term complications such as progression from cystitis to pyelonephritis and subsequent sepsis or long-term sequelae, such as renal scarring, and prevent recurrences by eliminating uropathogenic bacteria from vaginal and perineal reservoirs. Treatment should be cost-effective and have few or no side effects.

There is no evidence that non-specific treatments, such as pushing fluids or attempting to alter urinary pH, change the outcome of normal antibiotic treatment; however urinary alkalinizers should not be used with quinolones due to an increased risk of crystalluria.

Antibiotic treatment

Serum levels of antibiotics are largely irrelevant in the elimination of bacteriuria. Reduction in urinary bacterial numbers correlates with the sensitivity of the organism to the urinary concentration of the antibiotic. Inhibitory concentrations are usually achieved in the urine after oral doses of the commonly used antibiotics. On the other hand, blood levels are vitally important in the treatment of bacteraemic or septic patients or those with renal parenchymal infections. Worldwide the incidence of multi-drug-resistant *E. coli* is increasing, especially organisms with extended spectrum β-lactamase resistance (ESBL). In Australia these make up less than 3% of community UTI Isolates, but they should be considered in high-risk groups such as

1. International travellers to antibiotic-resistant areas within the last 6 months
2. Those who have recently used antibiotics
3. Patients in long-term-care facilities
4. Cases where the first-line antibiotics have failed

Clinicians should always refer to the latest available guidelines. Empirically the choice of antibiotic is based on the clinical presentation and the bacteria likely to be involved (Table 9.4.1).

We should also keep in mind that in community-acquired UTI approximately 20% of the *E. coli* organisms isolated are resistant to trimethoprim and that if the patient has had trimethoprim in the last 3 months we should consider an alternative antibiotic.

Management of specific groups

Frequency dysuria syndrome: presumed simple cystitis

A non-pregnant, non-diabetic woman first presenting from the community with typical lower urinary symptoms should have vulvo-vaginitis excluded and an MSU taken and examined or tested by dipstick for pyuria. If pyuria is confirmed, culture of the urine specimen is not necessary and treatment should be commenced empirically (Fig. 9.4.1).

There is now good evidence that short-course treatment in this group of patients is effective in both treating the infection and eradicating uropathogenic strains of bacteria from reservoirs. Three-day treatment is superior to a single dose in eradicating the reservoirs of uropathogenic organisms, thereby reducing the incidence of recurrence. Longer courses have an increased incidence of side effects but not higher cure rates. The antibiotic of choice for 3-day treatment is trimethoprim.[31,32] The emergence of trimethoprim-resistant uropathogens has been well documented in some communities. The subsequent overuse of fluoroquinolones as first-line agents has resulted in a rapid rate of development of resistance to these agents in parts of Europe and North America.[34,35] In general fluoroquinolones should not be used as first-line agents for simple cystitis.[31] Awareness of local antibiotic resistance patterns is thus an important factor in choice of the most appropriate antibiotic.

Amoxicillin/clavulanic acid, nitrofurantoin and cephalexin are suitable for 5-day therapy, but amoxicillin alone should not be used as there is a high incidence of resistant *E. coli* in community-acquired UTI. If there is no clinical response, MSU should be sent for culture and, in sexually active women, treatment for *C. trachomatis* commenced (doxycycline 100 mg bid). In non–sexually active women, further treatment is guided by the results of sensitivity testing. Short-course treatment is inappropriate in women who are at risk for UTI (despite lower tract symptoms), which includes those with a history of previous infections due to resistant organisms, with symptoms for more than 1 week or those with diabetes mellitus.

Males with UTI should be investigated for urinary tract abnormality and associated prostatic or epididymal infection. Such individuals must

Table 9.4.1 Choice of treatment depending on bacteria involved (see text)

Condition	*Bacteria involved*	*Suggested treatment*[31,32]
Acute simple cystitis	*Escherichia coli, Enterococcus faecalis, Staphylococcus saprophyticus, enterococci, Proteus* spp., *Klebsiella* spp., *Pseudomonas* spp.	1. Trimethoprim 300 mg qd for 10–14 days[a], **OR** 2. Cephalexin 500 mg q6h for 5 days **OR** 3. Amoxicillin/clavulanate 875/+125 mg q8h for 5 days, **OR** 4. Nitrofurantoin 100 mg q12h for 5 days in women only[b] Males or patients with recurrent infection should be treated for up to 14 days. Norfloxacin 400 mg q12h for 7 days in resistant infection only
Acute uncomplicated pyelonephritis	*E. coli, E. faecalis, S. saprophyticus, enterococci, Proteus* spp., *Klebsiella* spp., *Pseudomonas* spp.	**Mild infection: oral treatment** Amoxicillin/clavulanate 875/125 mg q12h for 10–14 days, **OR** 1. Cephalexin 500 mg q6h for 10–14 days, **OR** 2. Trimethoprim 300 mg/day for 10–14 days **Severe infection** iv Gentamicin PLUS Amoxy/ampicillin 2 g IV, 6 hourly, **OR** patients with penicillin hypersensitivity Ceftriaxone 1g iv daily, **OR** Cefotaxime 1g IV 8 hourly
UTI with structural abnormalities (complicated) and in inpatients	Increased frequency of *Proteus* spp., *Pseudomonas* spp., *Klebsiella* spp., enterococci, staphylococci	**Treatment should be guided by culture and sensitivity testing. The following are a general indication only**[33]:
Catheter-associated UTI	*E. coli, Proteus* spp., *Klebsiella* spp., *Pseudomonas* spp., enterococci, staphylococci	Treat only if symptomatic Change catheter Treat as for 'complicated UTI'
Dysuria with low bacterial numbers (urethral syndrome)	*Ureaplasma urealyticum*[c]	Doxycycline in young women
Prophylaxis in patients with recurrent infections		Trimethoprim 150 mg at night **OR** Cephalexin 250 mg at night

[a]Contraindicated in pregnancy.
[b]In men, nitrofurantoin does not achieve reliable concentrations and is therefore not recommended.
[c]NB: may have chlamydial or gonococcal urethritis.
UTI, Urinary tract infection

have a urine culture initially and should have at least 14 days of treatment with any of the agents used for treatment of young women with simple cystitis (see Table 9.4.1).[31] In men over 50 years of age, there is a high probability of invasion of prostatic tissue and treatment may have to be continued for 4 to 6 weeks.

Recurrent urinary tract infection

Recurrent UTI is defined as a symptomatic UTI that follows resolution of a previous UTI. These may be re-infections (with the same organism or another) or relapses (regrowth of the same organism within 2 weeks of treatment). Re-infections are more common than relapses, but the two may be indistinguishable.[36] It is important to consider the risk factors specific to the age and gender of the patient (e.g. sexual activity and use of spermicides in the young pre-menopausal woman or the higher rate of ASB in the older patient). A careful search for causes and reversible factors (e.g. of complicated UTI due to stone or obstruction, previously undiagnosed diabetes mellitus, prostatitis in males) should be made together with urine culture and sensitivity testing. Treatment is generally as for pyelonephritis, with an appropriate antibiotic guided by the results of sensitivity tests for at least 10 to 14 days. Female patients may benefit from post-intercourse or maintenance prophylaxis with, for example, cephalexin 250 mg or trimethoprim 150 mg at night for several months. There has recently been burgeoning interest in the use of cranberry juice, either as juice or in tablet form, for UTI prophylaxis. Evidence is variable, but a recent Cochrane review of 24 studies concluded that cranberry juice cannot be recommended for UTI prevention.[37]

Acute pyelonephritis

Patients presenting with the typical symptoms of pyelonephritis are at risk for bacteraemia or sepsis syndrome and therefore must rapidly have adequate concentrations of appropriate antibiotics delivered to both the blood and urine. In order to meet this requirement, particularly in patients who are vomiting, parenteral (intravenous) treatment is usually required initially but seldom for longer than 24 to 48 hours, by which time the patient is usually afebrile and not vomiting.

The choice of antibiotics is of necessity empirical at this stage. In cases of mild infection in patients who are not vomiting, 10-day treatment with one of the antimicrobials used for simple cystitis is appropriate, with ciprofloxacin or norfloxacin reserved for resistant organisms or proven *Pseudomonas aeruginosa*. For severe infections, parenteral ampicillin or amoxycillin (2 g q6h) together with gentamicin (4–6 mg/kg and up to 7 mg/kg as the initial dose for severe sepsis) are appropriate, with a third-generation cephalosporin as an alternative to gentamicin when the use of aminoglycosides is contraindicated. In patients with hospital-acquired infections and suspected gram negative sepsis or infections with *Pseudomonas aeruginosa*, broader-spectrum agents—such as ceftazidime, piperacillin/tazobactam, ticarcillin/clavulanic acid and imipenem—perhaps in combination with aminoglycosides, may be required. Parenteral treatment is followed by oral therapy for 2 weeks.

The use of short-stay observation units is now a standard part of the practice of emergency medicine. The safety and efficacy of treatment of pyelonephritis in such units with intravenous antibiotics and fluid administration, followed by oral therapy, is widely accepted.[38] 'Hospital in the Home (HITH)' programmes are also now commonplace, allowing close supervision of these patients by hospital-based staff and once- or twice-daily intravenous antibiotic administration at home. The efficacy and safety of HITH is well established but requires careful patient selection to exclude those at risk for complicated infections. Appropriate follow-up is essential, although repeat urine cultures are not recommended in asymptomatic patients following simple pyelonephritis.[39,40]

Pregnancy

UTIs in pregnancy are associated with an increased incidence of premature delivery and low-birth-weight infants. This has also been

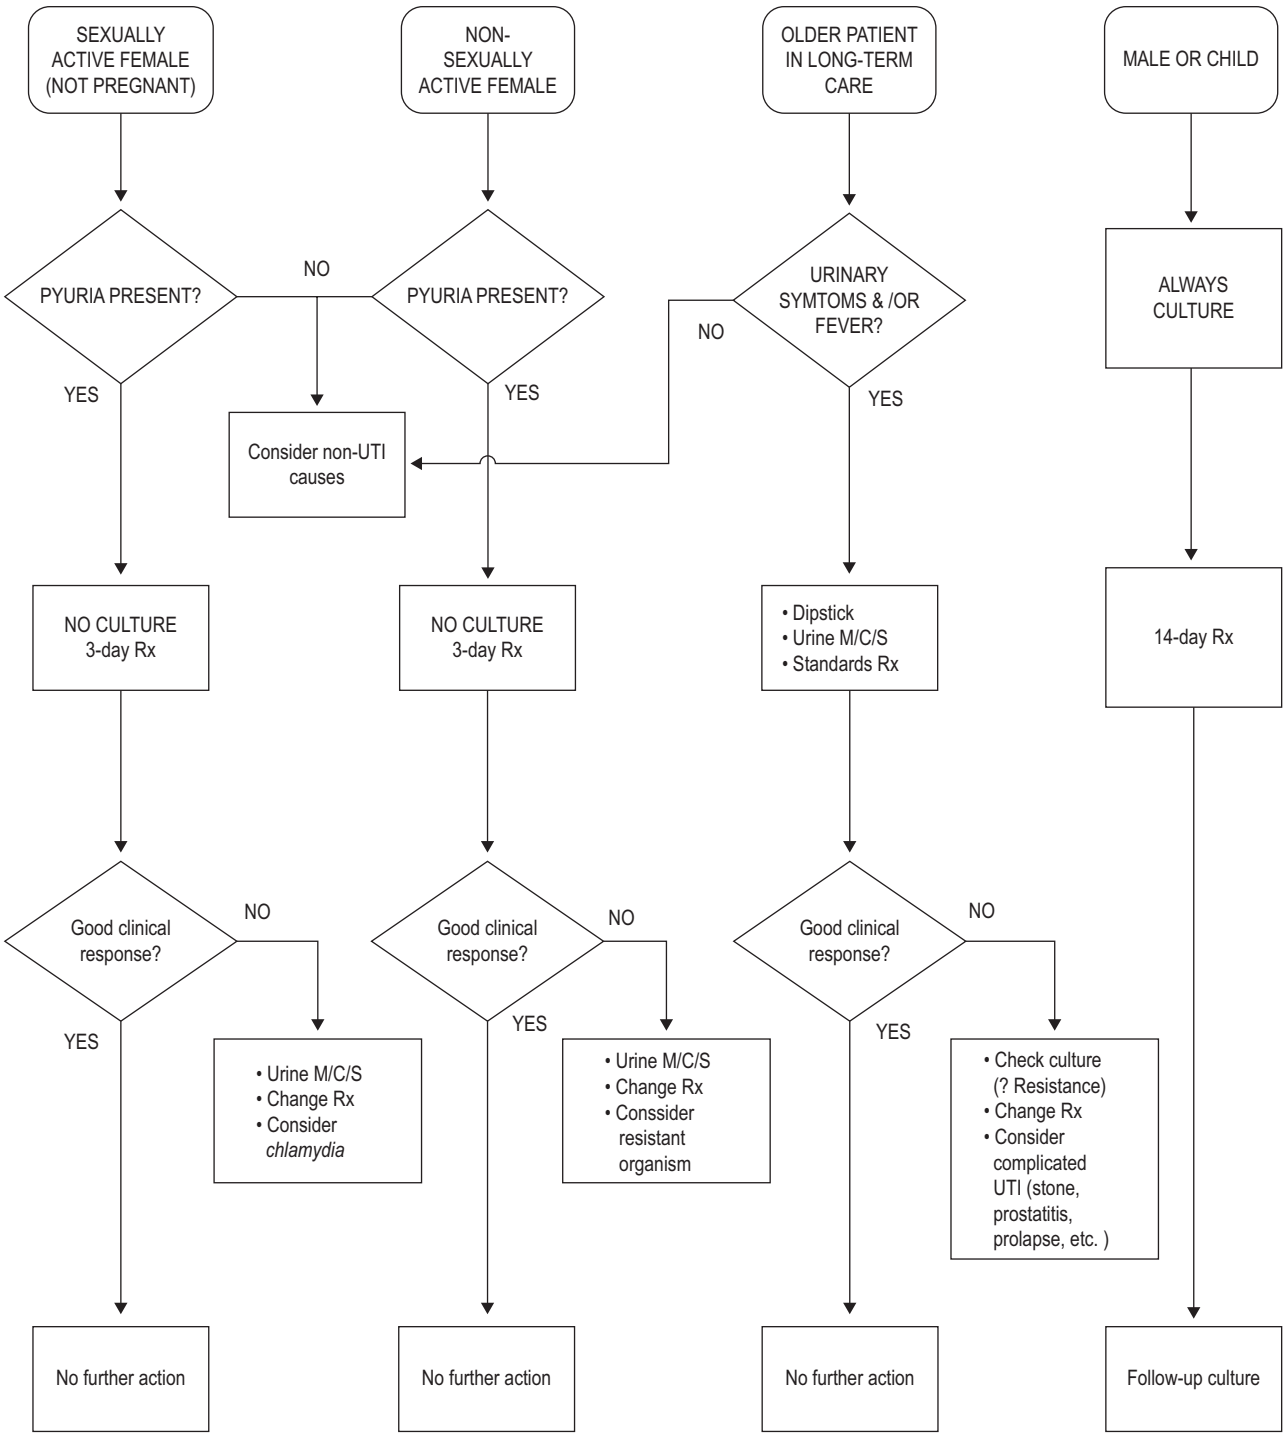

FIG. 9.4.1 Suggested flowchart for the management of simple cystitis.

demonstrated to occur with ASB, although up to 40% of asymptomatic women develop acute pyelonephritis later in pregnancy. Therefore screening for bacteriuria and treatment of pregnant women is essential and urine must be sent for culture and antibiotic sensitivity testing. Three-day courses of treatment are not widely recommended, although it may be reasonable to use them with close follow-up in an effort to reduce antibiotic usage. However, 10-day treatment courses are the norm. Cephalexin, nitrofurantoin or amoxycillin/clavulanate are appropriate for use in pregnancy, Sulpha drugs and trimethoprim being contraindicated.[31]

Complicated urinary tract infection

As there is a greater range of organisms causing infection in these circumstances and a higher probability of antibiotic resistance, urine culture is essential and initial empiric treatment must cover the broader spectrum of organisms potentially involved. If possible, antibiotic treatment should be delayed until the results of urine culture and antibiotic sensitivities are known. If empirical therapy is instituted, management should be reviewed as soon as such results are available.[33] Trimethoprim or a quinolone is appropriate for mild infections. More serious infections may need combinations of agents, such as aminoglycosides with amoxicillin or imipenem/cilastatin.

Catheter-associated urinary tract infection

Catheter-associated UTIs (CA-UTI) are the most common nosocomial infections. In patients with short-term catheters who develop infection, the catheter must be removed or changed and treatment instituted as for complicated UTI. For those with chronic indwelling catheters (such as patients with spinal injuries), bacteriuria is universal and treatment is indicated only in the presence of symptoms such as fever, chills or loin pain. Patients with chronic spinal injuries may present with autonomic dysreflexia syndrome, the symptoms of which include sudden hypertension, muscle spasm and sweating with or without fever. Antibiotic selection should again be based on culture or empirically as for complicated UTI. The most important strategy for the prevention of CA-UTI is minimizing catheter use and duration whenever possible. Preventive strategies based on use of methenamine, cranberry juice or prophylactic antibiotics at time of catheterization or catheter change are not supported by evidence.[28,31]

Elderly patients

As previously stated, ASB and UTI are very common in older patients and more so with increasing functional impairment. Symptomatic infection is a significant cause of morbidity and mortality, as this age group also has a higher incidence of bacteraemia associated with pyelonephritis, and septic shock commonly follows. Given the high rate of ASB, the diagnosis of UTI in such individuals is difficult. The traditional view that non-specific symptoms—such as increased confusion (without fever), falling or deteriorating mobility—are due to UTI has been called into question. Evidence indicates that UTI should be considered only in patients with fever or specific genitourinary symptoms or both. In patients with non-specific symptoms, non-infective causes should be sought; in the case of fever alone, other potential sources of infection must be considered.[8]

Antibiotic treatment of symptomatic UTI in the elderly patient is no different initially from that of younger patients; however, it should be borne in mind that a greater variety of organisms may be cultured in this age group and urine for culture should be obtained at the outset whenever possible.

Asymptomatic bacteriuria

ASB is defined as the presence of significant bacteriuria (as previously defined) in a person without signs or symptoms of UTI. The presence of pyuria per se should not be taken to indicate bacteriuria; a quantitative culture is essential for the diagnosis. Current evidence indicates that many patient groups may be harmed or at least may not benefit from antibiotic treatment for ASB. Antibiotics should therefore not be given to the following:

- Pre-menopausal, non-pregnant women
- Diabetic women
- Older people either living in the community or in institutions
- Patients with long-term indwelling catheters

Conversely, two significant groups receive clear benefit from antibiotic treatment for ASB: pregnant women and patients about to undergo urological procedures in which mucosal bleeding is anticipated (e.g. Transurethral resection of the prostate [TURP]).

Pregnant women with ASB have a 20- to 30-fold increased risk of developing pyelonephritis during pregnancy, with consequent premature delivery and low-birth-weight infants. Therefore pregnant women should be actively screened for ASB in early pregnancy and treated as for uncomplicated cystitis (without nitrofurantoin), with repeat cultures to confirm bacterial clearance. Periodic re-testing is recommended.

Patients who undergo urological procedures with mucosal bleeding (e.g. TURP) have a 60% rate of bacteraemia, with sepsis in 6% to 10%. These patients should be screened for ASB prior to the procedure and antibiotic treatment commenced shortly prior to the procedure and continued until after the procedure or removal of the post-procedure catheter.[41]

Disposition

Patients with simple UTI should have follow-up to confirm clinical cure. Failure of symptomatic improvement in 48 hours may indicate antibiotic resistance, which requires urine culture to elucidate. Recurrence of symptoms within 1 to 2 weeks may indicate occult renal infection and necessitates urine culture and at least 7 days' treatment.

Prognosis

In adults with normal urinary tracts, UTI does not cause long-term sequelae. In the presence of urinary tract abnormalities, infection may be a factor in producing renal damage or altering its rate of onset. Imaging of adults as part of their follow-up should detect this group of patients.

CONTROVERSIES

- The level of bacteriuria representing infection—traditional 10^5 cfu/mL or lower counts, such as 10^2 cfu/mL.
- Best first-line treatment of uncomplicated cystitis in the face of emerging resistance of uropathogens to common antibiotics such as trimethoprim and fluoroquinolones.
- The role of blood cultures as part of the investigation of pyelonephritis. Although traditionally used, they add little to the diagnosis and management.
- Asymptomatic bacteriuria in older, institutionalized patients—differentiation from symptomatic infection and appropriate management.

9.5 Skin and soft-tissue infections

Cecil S. Johnny

ESSENTIALS

1 **The time-honoured principles of soft tissue infection management and judicious evidence-based use of antibiotics remain the basis of treatment and the prevention of further complications.**

2 **These infections are common and range from mild to rapidly progressive and life threatening; early clinical recognition and treatment are paramount in reducing morbidity and mortality.**

3 **Deep soft tissue infections have high morbidity and mortality and, unless treated aggressively, can rapidly result in loss of a limb or the death of the patient.**

4 **Unusual organisms, including organisms not usually considered to be pathogenic, frequently cause serious infections in the immunocompromised, diabetic individuals and patients with hepatic disease.**

5 **There has been an increasing worldwide prevalence of community-acquired methicillin-resistant *Staphylococcus aureus* (CAMRSA) associated with skin and soft tissue infections (SSTIs) in the last decade.**

Introduction

Skin and soft tissue infections (SSTIs) are among the most common reasons for emergency department (ED) presentations and admissions to the hospital. SSTIs are a diverse group of etiologically and anatomically distinct infections, with bacteria responsible for the majority of presentations in the ED. The pathogenesis of these infections usually involves the direct inoculation of bacteria as a result of violation of the skin or its defences, although infection may also spread from a distant source via the haematogenous or lymphatic systems. The severity of infections encountered may range from mild to life threatening. Most recommendations for the diagnosis and treatment of SSTIs are based on tradition or consensus, as there are few randomized clinical trials on the subject. Some of the challenges to the emergency physician include the following:

- Early and accurate diagnosis of the type of infection, based on clinical judgement and limited use of laboratory and radiological investigations
- Early identification of potentially high-risk situations when the initial presentation is seemingly innocuous by looking at patient factors (e.g. diabetes, immunosuppression) and local factors (bite wounds, site of infection, e.g. orbital cellulitis)
- Role of antibiotics: (1) appropriate choice of pharmacotherapeutic agent where indicated, taking into account the emergence of new infections and changing bacterial resistance patterns; (2) optimal route of delivery (i.e. topical versus oral versus initial intravenous or intramuscular bolus, followed by oral antibiotics versus intravenous therapy); (3) duration of the antibiotic treatment
- Need for surgical intervention (e.g. drainage of abscess, early debridement in necrotizing fasciitis)
- Disposition: outpatient versus inpatient care

Epidemiology and aetiology

The incidence of SSTIs has recently increased worldwide, mainly due to expansion of the aging population, comorbidities and the emergence of community-acquired methicillin-resistant *Staphylococcus aureus* (CAMRSA). The majority of SSTIs are caused by aerobic gram positive bacteria, commonly *Staphylococcus aureus* and group A streptococcus. gram negative, anaerobic or mixed organisms usually cause deeper, more complicated infections, commonly seen in the immunocompromised host. The increased prevalence of CAMRSA associated with SSTIs poses a challenge because there are high rates of treatment failure and relapse (Table 9.5.1).[1,2]

Table 9.5.1 Causes of skin and soft tissue infections

Risk factor/setting	*Expected pathogen*
Simple cutaneous infection	*Staphylococcus aureus*. Also *S. epidermidis*, *S. hominis*, *S. viridans*
Perianal, genital, buttocks, ungual and cervical areas	*Bacteroides fragilis*, *Escherichia coli*, *Klebsiella* and *Proteus*
Immunocompromised host	*Cryptococccus neoformans*, *Coccidioides*, *Aspergillus*, *M. kansasii*, *M. tuberculosis* and *Yersinia enterocolitica*
Human bite	*Eikenella corrodens*, *Fusobacterium*, *Prevotella*, streptococci
Dog bite	*Pasteurella multocida*, *Capnocytophaga canimorsus*
Cat bite	*P. multocida*
Injection drug abuse	*S. aureus*, *Clostridium* spp., *E. corrodens*, *Stsphylococcus pyogenes*
Body piercing	*S. aureus*, *S. pyogenes*, *P. aeruginosa*, *Clostridium tetani*
Hot tub/wading pool	*Pseudomonas aeruginosa*
Freshwater injury	*Aeromonas hydrophila*
Saltwater injury	*Vibrio vulnificus*
Fish tank exposure	*Mycobacterium marinum*

Examination

History

When a history is being taken, it is important to elicit the following:

- Any event leading to a breach in skin integrity, which may precipitate an infection (e.g. human, insect or animal bite, 'clenched fist' injury, excoriation, fungal infection or puncture wound). This is important because it will help in determining the likely pathogen and choice of antibiotics as well as the need to rule out any potential foreign body that may be embedded in the wound.
- The speed with which the infection has progressed, which serves to indicate how aggressive the infection is and the urgency of needed treatment.
- Patient factors that may complicate treatment of the infection, such as
  - History of immunosuppression (e.g. diabetes, steroid use, chronic liver disease, alcoholism, malnourishment, HIV, oncology patients on chemotherapy, nephrotic syndrome).
  - Recent use of antibiotics, (i.e. failed treatment).
  - History of prosthetic heart valves, mitral valve prolapse with regurgitation, previous history of endocarditis.
  - Chronic venous stasis or lymphoedema in limbs; surgery that includes lymph node dissection or saphenous vein resection.
  - Intravenous drug use (IVDU).
- Tetanus immunization status.
- Contamination with soil or water, which would suggest unusual pathogens as the cause of the infection.

Physical examination

- Identification of signs of sepsis: haemodynamic instability, pyrexia, 'toxic'-looking patient.
- Specific features of the infection to help narrow down the diagnosis (e.g. raised erythematous margins in erysipelas; presence of bullae and crepitus or tenderness out of proportion to physical signs, which are suggestive of necrotizing fasciitis; fetid odour, suggesting anaerobic infection; green exudates typical of *Pseudomonas* spp.).
- The extent of the infection (e.g. mapping areas of erythema to track progress, fluctuance that indicates a likely abscess, or lymphangitic spread).
- Location of the infection, as involvement of certain critical areas (e.g. head, face, hands, perineum) may require more intensive inpatient management and specialist consultation.
- Complicating factors that might impair successful treatment (e.g. IVDU, the presence of prosthetic heart valves).

Investigations

The diagnosis of SSTIs is essentially clinical. Laboratory and radiological investigations play a secondary and limited role in routine evaluation but may be useful in the ED management of immunocompromised patients or those with signs and symptoms of severe sepsis. In such situations, the following parameters should be considered[3]:

- Full blood examination with differential: Marked leucocytosis, leucopaenia or an extreme left shift in the white cell differential; new-onset anaemia or thrombocytopaenia may suggest sepsis syndrome.
- Urea/creatinine: Elevated levels suggest intravascular volume depletion or renal failure.
- Creatine kinase: Elevated levels may indicate myonecrosis caused by necrotizing fasciitis.
- Tests to rule out diabetes mellitus: There is a strong association between SSTI and diabetes as well as a higher rate of complications.
- Blood cultures: These are recommended only in patients with systemic toxicity and wound cultures indicating severe purulent and deep soft tissue infection. The yield from blood cultures is less than 10% and may be compounded by false-positive results.[4]

Patients with a chronic, recurrent or unusual infection should have their immune status checked, including serology for HIV. Soft tissue radiographs may demonstrate a foreign body or gas in deep tissues. Ultrasonography is extremely useful in evaluating soft tissue infections for the presence of abscesses as well as for guiding drainage and the removal of foreign bodies. Computed tomography (CT) or magnetic resonance imaging (MRI) may be needed to define the depth and extent of the infective process in deep soft tissue infection.

Management

Key points in the management of SSTIs include the following:

- Appropriate use of antibiotics and timely surgical intervention
- Analgesia and supportive measure such as limb elevation
- Tetanus prophylaxis if indicated.
- Disposition

Analgesia

Oral or parenteral analgesia should be prescribed, as most patients with SSTIs will present with pain. Simple measures—such as immobilization, elevation, heat or moist warm packs—should not be overlooked, as they may help to alleviate pain in cellulitis. Abscess pain is best resolved by timely incision and drainage.

Antibiotic therapy

Antibiotics are recommended for patients with signs of systemic toxicity, high fever, tachycardia, for those who look unwell or are immunocompromised. They are also needed for infection in high-risk areas (hands, perineal region or face) and where deep tissue infection is suspected.

It is important for the emergency physician to recognize patients with serious SSTIs and to initiate timely and appropriate care. The choice of antibiotic is often empiric and thus must be guided by the patient's history, record of recent hospitalization and knowledge of the typical range of pathogens associated with each type

of infection and their resistance patterns. The antibiotic of choice is the one that has proven efficacy against the range of expected pathogens is associated with minimal toxicity and is cost-effective. Where possible, narrow-spectrum antibiotics should be used in preference to broad-spectrum ones.[5] Guidelines on antibiotic therapy are often deliberately non-prescriptive, reflecting the wide variety between differing patient populations, resistance patterns, risk for methicillin-resistant *Staphylococcus aureus* (MRSA) and local governance policies. It is also prudent to remember that SSTI clinical trials often exclude the most severely ill patients and may be powered to demonstrate non-inferiority only. The Infectious Diseases Society of America has released guidelines for treating SSTIs, including CAMRSA infections.[6] Unlike those in inpatient or chronic care settings, emergency physicians more frequently have to initiate empiric antibiotics based on clinical judgement and prevailing anti-biograms due to the absence of culture and susceptibility results.

Current agents active against the common pathogens including MRSA and licensed for treating complicated SSTIs include linezolid, daptomycin and tigecycline. Novel approaches like phage therapy and novel antimicrobial therapy (oritavancin and tedizolid), which has equal efficacy with a better safety profile and shorter regimen, are under investigation.[7]

Surgical intervention

Effective treatment of abscesses and carbuncles and large furuncles entails incision, drainage of pus and breaking up of loculations, followed by regular dressings. Necrotizing fasciitis requires *early* aggressive surgical debridement together with broad-spectrum antibiotics in order to achieve a good outcome.[6]

Tetanus and other prophylaxis

All traumatic wounds should be considered to be tetanus-prone and treated accordingly. The patient's immunization status should be confirmed and, where appropriate, tetanus toxoid plus tetanus immunoglobulin should be administered. Rabies prophylaxis should be considered for all feral and wild animal bites and in geographical areas where there is a high prevalence of rabies.

In cases involving human bites, consideration should also be given to screening for blood-borne pathogens such as hepatitis B virus, hepatitis C virus, HIV and *Neisseria gonorrhoea*.

Disposition

Good candidates for the observation/short-stay unit include patients likely to respond to empirical therapy as well as those with a low likelihood of infection or with unusual and/or resistant organisms.

Patients who have signs of systemic toxicity, involvement of vital structures (fingers, hands, face and neck; genitourinary, scrotal and anal regions), who are unable to take oral medication, and/or have failed outpatient therapy or who are immunocompromised are highly likely to require admission. Other prognostic factors include low serum bicarbonate, elevated creatinine, elevated creatine kinase and marked left shift polymorphonuclear neutrophils. The emergency physician must also be alert to scenarios requiring not just inpatient care but also urgent subspecialty consultation (e.g. necrotizing fasciitis).

Superficial skin infections

Clinical presentation

Patients usually present with complaints of localized pain, erythema and swelling. They may be on oral antibiotics and have not responded to them. The patient may present with signs of cellulitis and regional lymphadenopathy. Frequently an indurated fluctuant swelling may be elicited, indicating the presence of an abscess. If the patient is febrile or there is systemic involvement, his or her immune status must be examined. A diligent history should be taken to assess whether a foreign body associated with an abscess may be present. Ultrasonography is extremely useful in identifying this in such cases.

Impetigo

Impetigo is the commonest bacterial skin infection in children, usually caused by *Staphylococcus pyogenes* or *S. aureus*. It is highly contagious and there are two types: nonbullous (70%) and bullous (30%). Local wound care with a topical antibiotic (mucipirocin) often suffices, but oral antibiotics (first-generation cephalosporin or erythromycin) may be needed in cases with extensive or bullous lesions.

Folliculitis

Folliculitis is a superficial, purulent infection of the hair follicles. Most cases are caused by *S. aureus*, but *Pseudomonas aeruginosa* infection can occur when folliculitis is associated with specific exposures (e.g. hot tubs and spas). Treatment is supportive with topical therapy. Removal of the hair in limited infections usually results in rapid resolution.

Furuncle and carbuncle

A furuncle is a purulent infection of hair follicles that involves the subcutaneous tissue. Furuncles most commonly occur on the back, in the axillae or on the lower extremities. When the infection extends to involve several adjacent follicles, resulting in a coalescent inflammatory mass, the lesion is termed a carbuncle. Furuncles are often seen in patients with poorly controlled diabetes mellitus and in the immunocompromised. Small furuncles are best treated with moist heat. Larger furuncles and all carbuncles require incision and drainage.

Antibiotics are indicated if there is extensive surrounding cellulitis, the patient has a fever or diabetes or if he or she is immunocompromised, in which case di(flu)cloxacillin (500 mg q6h PO), cephalexin (500 mg q6h) or clindamycin (450 mg q8h PO) can be used.

Erysipelas

Erysipelas is an acute infection involving the cutaneous lymphatics of the superficial layers of the skin. The lesion is inflamed, indurated and elevated with a well-demarcated margin. It is often preceded by prodromal symptoms such as malaise, generalized aches, chills and high fever (5% of these patients will have bacteraemia). It is most often caused by Group A streptococci, with streptococcal toxins playing a part in the inflammatory response (other causes are non–group A streptococci, *Haemophilus influenzae*, *S. aureus* and *Streptococcus pneumoniae*). Contrary to popular belief, the commonest presentations involve the lower limbs, followed by the face and arms. Common risk factors include obesity, chronic oedema, previous leg surgery, leg ulcers, intertrigo, increasing age and medical comorbidities like hypertension, diabetes and peripheral vascular disease. Erysipelas may rapidly progress to cellulitis, abscess formation and, occasionally, fasciitis. Bullous erysipelas occurs in about 5% of the cases and is common in women and patients with renal or liver disease. It is associated with higher rates of MRSA infection.

Penicillin is the first line of therapy, followed by first-generation cephalosporins, macrolides and vancomycin (MRSA infections). Treatment includes elevation of the affected part, analgesia and the management of a possible underlying cause.

Herpetic whitlow

Herpetic whitlow is a superficial infection commonly affecting the fingers and characterized by intense pain, erythema and vesicle formation. It is caused by the herpes simplex virus (type 1 or 2). It commonly affects children and young adults and is often an occupational hazard for health workers. Diagnosis is usually clinical, and treatment is mainly supportive. Use of antivirals may reduce the duration of symptoms. Incision and drainage is contraindicated as this may cause bacterial superinfection or systemic spread.

Cellulitis

Cellulitis is an acute infection of the epidermis, dermis and subcutaneous fat, and it has a propensity to spread. In an immunocompetent

individual, infection is caused by bacteria that normally colonize the skin, principally *S. aureus* and group A β-haemolytic streptococci. Predisposing factors include conditions leading to a disrupted cutaneous barrier and/or impaired local host defences, such as trauma and inflammatory dermatoses (e.g. eczema, oedema from venous insufficiency or lymphatic obstruction).

Despite its common occurrence, there is a paucity of published research on issues such as criteria for antibiotics, admission and severity assessment. The presence of an underlying abscess should be considered if there is no response to antibiotic therapy. Bedside soft tissue ultrasonography is a useful tool that is increasingly available in EDs.

Treatment is guided by the site and extent of infection, clinical comorbidities and sometimes also social circumstances. Supportive care, such as elevation of the affected part and analgesia, is important.

Recommended antibiotics include penicillin such as di(flu)cloxacillin (2 g q6h IV) or a first-generation cephalosporin such as cephazolin (2 g q8h IV) and vancomycin in suspected MRSA infection.

Broad-spectrum antibiotics may be required in special settings, such as in patients with diabetes, or infection in particular anatomical areas. Anaerobes or gram negative organisms have been identified in 95% of affected diabetic foot ulcers, with *S. aureus* found in approximately 33%.

Infections that originate from wounds involving the feet may be due to *P. aeruginosa*; they are also associated with osteomyelitis of the foot. Antibiotic treatment should consist of an antipseudomonal β-lactam such as carbenicillin or a third-generation cephalosporin such as ceftriaxone and an aminoglycoside.

Cellulitis is a well-known complication in women who have undergone axillary lymph node dissection and surgery for breast cancer. The major mechanism is thought to be an altered lymphatic and/or venous circulation related to the surgical procedure and to radiation therapy. Empiric antibiotic therapy is again targeted at *S. aureus* and β-haemolytic streptococci. If the patient has received recent chemotherapy and is neutropaenic, then the antibiotic regimen must be broadened to include coverage for aerobic gram negative bacilli, including *P. aeruginosa*.

Facial cellulitis, including periorbital and orbital cellulitis, is a serious infection occurring in both adults and children. The causal organisms include *S. aureus*, *H. influenzae* type b and *S. pneumoniae*. They may arise from an infected paranasal sinus, direct inoculation or haematogenous spread. Radiological evaluation, including CT scanning, may be necessary to identify the extent of infection, which may serve to guide treatment. The antibiotic of choice is flucloxacillin 2 g q6h IV plus ceftriaxone 2 g daily in case of suspected orbital cellulitis.

Abscesses

Pilonidal abscess

Pilonidal abscesses occur in the natal cleft and arise from disruption of the epithelium, causing the formation of a pit lined with epithelial cells; this may become plugged with hair and keratin, leading to inflammation and abscess formation. Treatment involves incision and drainage, usually in the operating theatre, although smaller abscesses can be drained in the ED. They are usually associated with mixed organisms, both aerobic and anaerobic.

Hidradenitis suppurativa

This is a chronic inflammatory skin disease of the upper apocrine sweat glands in the groin and axillae, resulting in recurrent nodule formation, inflammation and abscesses. Risk factors include female sex, obesity, smoking and follicular occlusion disorders. Organisms include *S. aureus, S. viridans* and *Proteus* spp. Treatment includes both medical and surgical management as indicated. Due to the chronic nature of the disease, the treatment is best coordinated by a specialist surgeon.

Bartholin abscess

This abscess occurs due to the obstruction of a Bartholin duct and the resulting inflammation. Isolates are usually polymicrobial, including both aerobes and anaerobes. *N. gonorrhoeae* and *C. trachomatis* may also be involved. Treatment is incision, drainage and marsupialization of the cyst in the operating theatre.

Acute paronychia

This is a superficial infection of the lateral aspect of the nail, which may proceed to abscess formation. Common organisms involved are *S. aureus* and streptococcal species. Incision and drainage is required in case of abscess formation.

Perianal abscess

These are the commonest of the anorectal abscesses (60%), which arise from the anal crypts and are located near the anal verge. Patients frequently complain of pain on defaecation and sitting. Perianal abscesses may be associated with inflammatory bowel disease and fistula formation. Treatment should be incision and drainage in the operating theatre under general anaesthesia. When the abscess is superficial and 'pointing', drainage in the ED is possible.

Infected cutaneous cysts

These are quite common, affecting around 20% of adults. They can occur anywhere on the body except the palms and soles.

Treatment

Incision and drainage of cutaneous abscesses is the key to treatment. Some patients require antibiotic therapy. Patients who are immunosuppressed or who have diabetes mellitus should be treated empirically with appropriate antibiotic therapy. Patients at risk of developing bacterial endocarditis require prophylactic antibiotics prior to incision and drainage. The treatment of superficial skin abscesses has in recent years been complicated by the emergence of MRSA. Proponents of the practice of 'routine culture' of abscess fluid say that surveillance of antimicrobial susceptibility allows therapeutic adjustment. Detractors point out that for simple abscesses, incision and drainage without antibiotics is usually sufficient; thus, if antibiotics are not considered clinically useful, it is unlikely that culture results will alter the management.

Deep soft tissue infections

Necrotizing fasciitis

Necrotizing fasciitis is a rare, rapidly progressing and life-threatening infectious process involving primarily the superficial fascia (i.e. all the tissue between the skin and underlying muscles, that is, the subcutaneous tissue). Patients usually present with the triad of exquisite pain—often out of proportion to initial physical findings—swelling and fever. Early diagnosis is sometimes thwarted by the paucity of cutaneous findings early in the course of the disease. The clinician should have a high index of suspicion based on the clinical presentation as well as the patient's underlying co-morbidities (diabetes, alcoholism and immunosuppression).

Numbness of the involved area is characteristic of advanced necrotizing fasciitis; this is a result of infarction of the cutaneous nerves. Eighty percent of cases show clear origins for an accompanying skin lesion (insect bite, minor abrasion, furuncle, and IVDU injection site); in the remaining 20%, however, no skin lesion can be found.[8,9]

Patients appear extremely toxic with high fever, tachycardia and malaise. Pathognomonic features include extensive undermining of the skin and subcutaneous tissues, with separation of the tissue planes. The subcutaneous tissues may have a hard, wooden feel. Bullous lesions and skin ecchymoses may also be evident. Crepitation may be clinically evident and gas may be visualized on x-ray in some 80% of patients. The gas is typically layered along fascial planes. CT or MRI may aid in confirming the clinical suspicion. Laboratory values may be used in risk scoring (e.g. the Laboratory Risk Indicator for Necrotizing Fasciitis [LRINEC], which has been validated prospectively and has a high sensitivity and positive predictive value of 92% in patients with scores

of 6 points and above). Patients with scores of 5 points and below are considered at low risk of necrotizing fasciitis.[10,11]

Bacteria involved in this infection are usually mixed: *S. aureus*, haemolytic streptococci, gram negative rods and anaerobes. Sometimes only group A streptococci, either alone or in combination with *S. aureus*, are found. Aggressive therapy is essential, as mortality approaches 50%. Immediate extensive surgical intervention to open and debride the wound is required, as myonecrosis may be present.[12] Appropriate antimicrobial therapy should be commenced immediately: meropenem (1 g q8h IV) plus clindamycin (600 mg q8h IV) plus vancomycin 15–20 mg/kg/dose q8–12h IV. Hyperbaric oxygen therapy should be considered.

Fournier gangrene is a form of necrotizing fasciitis involving the scrotum, penis or vulva and is usually seen in diabetic patients. It usually originates from perianal or urinary tract infections (which extend into the periurethral glands) and can progress rapidly. The management is early recognition and surgical debridement as well as intravenous antibiotics.

Gas gangrene

Gas gangrene is an acute life- and limb-threatening deep tissue infection, also known as clostridial myonecrosis. Aetiological agents include *Clostridium perfringens*, *C. histolyticum*, *C. septicum* and *C. novyi*. *C. perfringens* is the most common cause in traumatic gas gangrene, whereas spontaneous gangrene is principally associated with *C. septicum*. This infection is characterized by the rapid development (often within hours) of intense pain in the region of a wound, followed by local swelling and a haemoserous exudate. A characteristic foul smell is also a good indication of the diagnosis. The area becomes tense and may develop a bluish and bronze or dusky discoloration. The presence of gas is typical, although that may be a late finding. It is frequently found on x-ray, where it has a feathered pattern as gas develops within the muscle itself. Aggressive treatment is required, as the patient may present in an advanced stage with tachycardia, altered mental status, shock and haemolytic anaemia.

Classically, the gas gangrene occurs in extensive and/or deep wounds with predisposing factors, including vascular compromise, diabetes and the presence of foreign bodies. Gram stain frequently reveals relatively few white blood cells and large numbers of club-shaped gram positive rods.

Early surgical intervention is essential, including wide debridement of necrotic muscle and other tissues, administration of high-dose penicillin (benzylpenicillin 2.4 g q4h IV), clindamycin (600 mg q6h IV) and hyperbaric oxygen therapy. Early hyperbaric oxygen therapy has been shown to lead to an improved outcome.[6,10–14]

It should be noted that the presence of gas certainly raises the suspicion of a deep tissue infection, including gas gangrene but that it may also be present because of previous wound manipulation, self-injection of air, localized gas abscess or other gas-producing organisms, including anaerobes, *E. coli*, streptococci and staphylococci.

Pyomyositis

Pyomyositis is the presence of pus within individual muscle groups; the usual culprit is *S. aureus*. A positive blood culture yield is found in only 5% to 30% of cases. Typical presenting symptoms include localized pain in a single muscle group, usually in an extremity, and fever. Ultrasonography or CT may be warranted to differentiate the condition from a suspected deep vein thrombosis.

Toxic complications of wound infections

A number of bacteria produce toxins that result in systemic symptoms.

Tetanus

Tetanus, albeit rare in developed countries, still occurs despite the fact that immunization is completely effective in preventing it. All wounds should be treated as tetanus-prone. Tetanus can occur with trivial wounds that may not even be apparent. The incubation period is variable, ranging from 3 days to several weeks after inoculation, and the disease is more severe at the extremes of age. Difficulty in swallowing and a fever with progression to stiffness and trismus is pathognomonic. Tetanus is also associated with autonomic nervous system dysfunction. Occasionally localized tetanus may occur with muscle spasm in the area adjacent to the wound. This is sometimes associated with cranial nerve dysfunction. Treatment is largely supportive, often requiring deep sedation, paralysis and ventilation for prolonged periods. Antibiotic therapy with high-dose penicillin should also be given in addition to tetanus immunization and tetanus immunoglobulin.[15]

Toxic shock syndrome

Toxic shock syndrome (TSS) is a life-threatening multisystem disease caused by an inflammatory immune responses to toxogenic strains of *S. aureus*. TSS has been classically associated with the use of tampons, although 10% to 40% of cases are not related to menstruation. Non-menstrual cases occur after childbirth, abortions, in bone and skin infections including postoperative wound infections, burns, mastitis and varicella-related cellulitis. The wound itself may look insignificant. There is a rapid onset of fever, usually above 38.9°C, hypotension and an initial diffuse and later desquamating erythematous rash. Multi-organ involvement may include muscular (myalgia), neurological (headache, altered sensorium) and gastrointestinal (nausea, diarrhoea) symptoms. Occasionally *S. aureus* can be cultured locally, although blood cultures are rarely positive. Antibiotics do not affect the course of TSS but may lower the recurrence rate by 59% to 73%. An anti-staphylococcal agent should be given with an aminoglycoside. Patients are frequently haemodynamically compromised, requiring aggressive fluid resuscitation and inotropic support. Debridement of necrotic wounds, if present, and elimination of the source of infections (e.g. removal of the tampon) should be carried out urgently. A similar syndrome can develop due to infection with group A β-haemolytic streptococci. This is known as 'wound' or 'surgical' scarlet fever. Treatment is the same as for TSS.

Special infections

Human bites

Human bite wounds may occur as a result of an accident, deliberate biting or closed-fist injuries. The bacteriology reflects the normal oral flora of the biter: streptococci in 50% to 80% of wounds, staphylococci, *Eikenella corrodens* and anaerobic organisms. Therapy consists of irrigation and topical wound cleansing; prophylactic antibiotics should be initiated as early as possible in all patients regardless of the appearance of the wound.

Clenched-fist injuries over the metacarpophalangeal joint warrant hospitalization for formal washout and intravenous antibiotics. Appropriate antibiotic choices include amoxicillin-clavulanate (875 + 125 mg q12h PO) or piperacillin-tazobactum (4+0.5 g q8h IV). In cases of penicillin allergy, metronidazole plus doxycycline or ciprofloxacin may be used.

Animal bites

Most such bites are from dogs (80%) or cats, but bites from exotic pets and feral animals also occur. *Pasteurella* and *Bacteriodes* spp. are the most common bacterial isolates and *Capnocytophaga canimorsus* can cause bacteraemia and fatal sepsis, especially in patients with underlying liver disease or asplenia. Infected bites presenting less than 12 hours after injury are more likely to be infected with *Pasteurella* spp., whereas those presenting after 24 hours are more likely to be infected with staphylococci or anaerobes. Wounds should be cleansed with sterile normal saline and infected wounds should not be closed. Cat bite wounds have less crush injury and

wound trauma than dog bites but lead to a higher proportion of osteomyelitis and septic arthritis. The oral agent of choice for both dog and cat bites is amoxicillin/clavulanate, with clindamycin plus ciprofloxacin as an alternative. Intravenous options include second-generation cephalosporins, piperacillin/tazobactam and carbapenems. Established infection usually responds to 7 to 10 days of therapy. Rabies prophylaxis should be considered for all feral and wild animal bites and in geographic areas where there is a high prevalence of rabies.

Water-related infections

Water-related infections may be caused by unusual organisms. *Vibrio vulnificus*, *Vibrio alginolyticus* and other non-cholera vibrios are found in salt and brackish water and can result in serious and life-threatening infections, especially in patients with hepatic disease. Aggressive infection can progress rapidly over 2 to 4 hours. It is associated with saltwater exposure or the ingestion of raw shellfish. Infections can mimic gas gangrene, with rapid progression and tissue destruction; septicaemia may occur and can be fatal. If parenteral therapy is required, a third-generation cephalosporin can be combined with an aminoglycoside and/or doxycycline.

Exposure to fresh or brackish water (rivers, mud, caving) can result in infection with the gram-negative bacillus *Aeromonas hydrophila*.[16] *Aeromonas* infections can result in superficial skin infections, myositis and septicaemia. Treatment consists of administration of ciprofloxacin 500 mg q12h PO.

Mycobacterium marinum, *M. ulcerans*, *M. chelonei*, *M. gordanae* and *M. fortuitum* are found in fish tanks and can result in 'fish fancier's finger'. After 2 to 6 weeks of incubation, an ulcerating granuloma develops. Treatment options include clarithromycin, trimethoprim/sulfamethoxazole or a combination of ethambutol and rifampicin. Systemic infection is uncommon.

Handlers of saltwater fish may develop infections due to *Erysipelothrix rhusiopathiae*; this causes erysipeloid, a type of cellulitis.[17] It also causes infections in people handling fish, poultry, meat and hides. Coral cuts are often infected with *Streptococcus pyogenes*; other marine pathogens may be involved (including *Vibrio* species). Treatment should consist of penicillin or ciprofloxacin.

Mastitis

Infections of the breast can occur in both sexes and in patients of all ages; however, breast infections are most common in nursing mothers. The prevalence in Australia is estimated at 20%.[18] *S. aureus* is the most common pathogen in infective mastitis.

Treatment consists of regular emptying of the breast. If breastfeeding must be stopped because of the severity of the infection or the risk to the neonate, a pump or manual expression methods should be employed (at least temporarily). If symptoms are not resolving within 12 to 24 hours of effective milk removal and analgesia, antibiotic treatment should be commenced to prevent abscess formation. Around 11% of these patients will have abscess formation if not appropriately treated. Options include di(flu)cloxacillin (500 mg q6h PO) or cephalexin (500 mg q6h PO) or clindamycin (450 mg q8h PO) for at least 5 days. Severe infections may require parenteral or more prolonged therapy. Local care to the region is also important, including warm compresses, breast support, analgesia and the application of a moisturizing cream to the nipple and areolar region. Patients who develop an abscess will require percutaneous aspiration or open drainage.[19]

Decubitus ulcers

These are cutaneous ulcers caused by prolonged pressure resulting in ischaemic necrosis of the skin and underlying soft tissue. They are most commonly found in patients who are bedbound, particularly elderly nursing home patients and patients with sensory deficits. Immobility, compounded by vascular insufficiency and neuropathy, results in ulcer formation; Unless these lesions are treated aggressively, serious complications can follow.[20] Complications include cellulitis and deep soft tissue necrosis, osteomyelitis, septic thrombophlebitis, bacteraemia and sepsis. Culture of the ulcer invariably reveals a mixed bacterial flora of both aerobes and anaerobes, which do not distinguish between colonization and tissue infection. The most common organisms found are staphylococci, streptococci, coliforms and a variety of anaerobes. Antibiotics are required for patients with clinical signs of sepsis or osteomyelitis.

Varicose ulcers

These are superficial ulcers of the lower limbs caused by oedema and poor tissue drainage as a result of dysfunction of the venous system. They are more common in the elderly and obese and may be chronic, therefore healing is often difficult. Complications include cellulitis and occasionally bacteraemia. Culture of the ulcer variably reveals a mixed bacterial flora of both aerobes and anaerobes that cannot help to distinguish colonization from tissue infection. The most common organisms found are staphylococci, streptococci, coliforms and a variety of anaerobes.

Treatment consists of debridement of necrotic tissue, pressure area and general nursing care, as well as treatment of infection if present. Antibiotic treatment is indicated only where there is systemic evidence of infection or a complicating infection, such as osteomyelitis or bacteraemia. Surgical debridement is frequently as important if not more important than antibiotic therapy, particularly where the bacterial infection is localized.

Diabetic foot infections

Foot infections are a common complication of diabetes and require both local (foot) treatment and systemic (metabolic) optimization, which is best undertaken by a multidisciplinary team including surgeons, podiatry services and the endocrinologist or physician.

The peripheral neuropathy associated with diabetes leads to the loss of protective pain sensation and results in repetitive injuries followed by the development of ulcers that become infected. Vascular insufficiency and impaired immune function contribute to the increased risk of acute and chronic infection. Infections in foot ulcers are often polymicrobial, and both the number of bacterial groups and bacterial density are thought to affect healing.[17] Aerobes include *S. aureus*, coagulase-negative staphylococci and streptococci. Enterobacteriaceae and *Corynebacterium* are common. Anaerobes, which have been isolated from up to 48% of patients, include *Bacteroides* and *Clostridium* spp. The presence of anaerobes is associated with a high frequency of fever, foul-smelling lesions and the presence of an ulcer. Cultures obtained using curettage following debridement should be used in preference to wound swabs to identify causative organisms and sensitivities.

Local signs and symptoms predominate and include those secondary to infection, vasculopathy and neuropathy. Pain and tenderness are often minimal due to the neuropathy and pulses are frequently reduced or absent. Wound infections must be diagnosed clinically on the basis of local (and occasionally systemic) signs and symptoms of inflammation. Laboratory (including microbiological) investigations are of limited use for diagnosing infection except in cases of osteomyelitis. Radiography and/or a bone scan may be warranted to exclude osteomyelitis.

A systematic review[21] reported that there is no strong evidence for any particular antimicrobial agent in the prevention of amputation, resolution of infection or ulcer healing. For mild to moderate infections with no evidence of osteomyelitis or septic arthritis, consider amoxicillin/clavulanate (875 + 125 mg q12h PO) for at least 5 days. Alternatives include ciprofloxacin 500 mg q12h with clindamycin 600 mg q8h. For severe limb- or life-threatening infections, intravenous piperacillin/tazobactam 4+0.5 g q8h or ticarcillin/clavulanate 3 + 0.1 g q6h are acceptable for empiric therapy. Prolonged use of antibiotics may be required, especially in the setting of osteomyelitis or septic arthritis.

Surgical-site/postoperative wound infection

They are the most commonly occurring adverse events in patients who have undergone surgery, accounting for as much as 38% of nosocomial infections in postoperative patients. Surgical-site infections are usually diagnosed by the usual features of inflammation, which may manifest late in morbidly obese patients or those with deep wounds. Most bacterial wound infections present with fever only after 48 hours. Earlier symptoms may be seen in *S. pyogenes* and clostridial infections.

The treatment generally requires opening of the sutures, evacuation of any collection and ordering wound cultures. However, the physician should be mindful of the type and site of surgery and should always involve the concerned surgical team. There has been a paucity of evidence regarding the use of antibiotics combined with drainage,[22] but expert consensus generally advocates the use of empirical antibiotics for patients with temperature above 38.5°C and/or a pulse rate greater than 100/min in the presence of obvious wound infection.[6]

Post-traumatic wound infection

The goals of wound care are to avoid infection and to achieve a functional and cosmetically acceptable outcome. Adequate wound management requires a thorough history, with particular attention directed at factors adversely affecting healing. Factors such as the extremes of age, diabetes, chronic renal failure, malnutrition, alcoholism, obesity and patients on immunosuppressive agents lead to an increased risk of infection and impaired wound healing. Wounds located in highly vascular areas, such as the scalp or face, are less likely to become infected than wounds in less vascular areas.

In order to reduce the incidence and severity of infection, wounds must be thoroughly cleansed and irrigated. Devitalized tissue should be debrided, injuries to associated structures excluded and the wound closed appropriately. The method of closure depends on the location of the wound, the level of contamination and the age of the wound. Wounds that should not be closed because of a high risk of infection, such as heavily contaminated wounds, should be treated by delayed primary closure. Where primary closure is possible, the wound should be closed and a protective non-adherent dressing applied for a minimum of 24 to 48 hours, with both the wound and the dressing kept dry.[23]

The use of prophylactic antibiotics is not recommended except where there is significant bacterial contamination, foreign bodies, the patient is immunosuppressed or the wound is the result of a bite (human or animal) or associated with an open fracture. Most wounds can be treated with amoxicillin/clavulanate (875 + 125 mg q12h PO) or metronidazole (400 mg q12h PO) plus di(flu)cloxacillin (500 mg q6h PO). Broad-spectrum antibiotics should be limited to heavily contaminated lesions and bite wounds and to immunosuppressed patients.

Intravenous drug users

Intravenous drug users frequently develop SSTIs at injection sites and at times may be polymicrobial. The reasons include contaminated drug paraphernalia, alteration of skin flora, poor nutrition and immune function (many have hepatitis B, C and HIV), injection under the skin (skin popping), extravasation and tissue necrosis.[24] Intravenous drug users frequently have mixed gram-positive and gram-negative infections, particularly anaerobes including *Klebsiella*, *Enterobacter*, *Serratia* and *Proteus*. Some develop fungal infections, including candidaemia. Subacute bacterial endocarditis and endocarditis must be considered in IV drug users presenting to the ED. If endocarditis is not suspected, treatment should consist of flucloxacillin 2 g IV q6h and gentamicin 5 to 7 mg/kg/day as a single daily dose.

CONTROVERSIES

- The timing and method of closure of contaminated or 'old' (more than 6 hours since injury) wounds.
- The prophylactic use of antibiotics in patients with 'clean' wounds.
- Choice of antibiotics in treating skin and soft tissue infections: narrow-spectrum first-generation cephalosporin or broad-spectrum third-generation cephalosporin? Should antibiotics be used to cover gram negative, gram positive organisms, anaerobes and aerobes?
- Can more patients be treated as outpatients using parenteral therapy or after early discharge once the acute toxic phase is over?
- Management of cutaneous abscesses: are antibiotics necessary after incision and drainage? Are cultures of the abscess fluid needed?

9.6 Hepatitis

Helen E. Stergiou • Biswadev Mitra

ESSENTIALS

1 **Acute and chronic viral hepatitis is of global public health importance.**

2 **Definitive diagnosis may be delayed in the emergency setting.**

3 **Supportive care is fundamental in the acute management of hepatitis.**

4 **Prevention of viral hepatitis is possible via the introduction of public health programmes that include appropriate education regarding high-risk practices.**

Introduction

Hepatitis is a non-specific clinicopathological term that encompasses all disorders characterized by hepatocellular injury and histological evidence of a necroinflammatory response. An important distinction is that between acute and chronic viral hepatitis. *Acute viral hepatitis* is a process of self-limited liver injury of less than 6 months' duration.[1] *Chronic viral hepatitis* is diagnosed on pathological criteria and is characterized by a duration of more than 6 months.

Clinical presentations of viral hepatitis

Patients with acute viral hepatitis may be asymptomatic; those with only mildly deranged liver function tests (LFTs) may be symptomatic with or without jaundice or may present with fulminant disease (severe liver failure, which develops within 8 weeks of symptom onset).

Various clinical phases characterize acute viral hepatitis. The incubation phase is the time between the original infection and the initial symptoms during which viral replication occurs, providing laboratory evidence of hepatitis. During the pre-icteric phase, non-specific symptoms evolve, such as malaise, fatigue, anorexia, nausea, vomiting, myalgias, arthralgias and abdominal discomfort. If fever is present, it is generally of low grade. Cough, coryza, pharyngitis and a distaste for alcohol and tobacco smoke may be evident. Meningoencephalitis may rarely occur.

The icteric phase features a variable degree of jaundice, dark urine (bilirubinuria), pale stools (absence of bile pigment in the stool), pruritus, hepatomegaly and splenomegaly. During the convalescent phase, symptoms resolve, as do liver enzyme abnormalities. In patients presenting to the emergency department (ED) during the pre-icteric phase, the diagnosis may be challenging given the non-specific symptomatology. If a patient presents during the icteric phase, focused history taking, examination and the appropriate investigations should result in a definitive diagnosis.

Laboratory investigations

Blood test abnormalities are a prominent aspect of acute viral hepatitis. Serum transaminases are typically elevated at greater than 500 U/L and often more than 1000 U/L.[2] Alanine aminotransferase (ALT) may characteristically test higher than aspartate aminotransferase (AST). Alkaline phosphatase may be normal or mildly elevated. Serum bilirubin is variably elevated and is usually divided between conjugated and unconjugated fractions. Albumin and the prothrombin time should be normal unless hepatic synthetic function is significantly impaired. Neutropaenia and lymphopaenia may be transient. Severe acute hepatitis may cause hypoglycaemia.

Management

In cases of acute viral hepatitis, the fundamental management is supportive care. Many of these patients can be managed on an outpatient basis. Patients require hospitalization when they have intractable vomiting with inadequate oral intake and demonstrate clinical features of liver failure. A well-balanced diet is beneficial. It is recommended that alcohol be avoided during the acute phase, but there is no definitive evidence that alcohol consumption post-recovery causes either relapses or progression to chronic disease. Given that the liver is involved in the metabolism of a plethora of drugs, all medications must be prescribed with special care to patients with acute hepatitis.

In managing fulminant hepatic failure, it is imperative that potential patients be identified as early as possible. In the emergency setting, intubation and the concomitant critical care may be necessary for patients with progressive encephalopathy.

Prevention and immunization

Prevention of viral hepatitis is possible via the introduction of public health programmes, improved sanitation and vaccination programmes. Post-exposure prophylactic regimens are particularly relevant to health care workers.

Hepatitis A virus

As the most common cause of viral hepatitis, hepatitis A virus (HAV) contributes significantly to the global burden of disease. Multiple genotypes exist and infection with one genotype confers immunity against others. (See Table 9.6.1 for virology.)

Epidemiology

HAV is highly endemic in developing countries and can often be traced to contaminated water or food.

Natural history

Virus is excreted in the stool of the infected person for 1 to 2 weeks prior to and for 1 week after the onset of symptoms. A non-specific prodrome may be followed by jaundice and tender hepatomegaly. The clinical severity of the illness increases with age, with more than 80% of children being asymptomatic. HAV has been associated with extrahepatic features, such as cutaneous vasculitis, renal failure, pancreatitis, bradycardia and, rarely, convulsions, transverse myelitis and aplastic anaemia. Relapsing hepatitis has been described in 20% of those with HAV infection. Relapses are generally benign and may occur 4 to 15 weeks after the original illness. Complete recovery is the typical outcome. Fulminant hepatic failure occurs in less than 1% of cases.[1] Chronic infection never ensues.

Laboratory investigations

Serum antibody is present from the onset of HAV disease in both Immunoglobulin M (IgM) and Immuniglobulin G (IgG) forms. After approximately 3 to 12 months, anti-HAV IgM disappears and anti-HAV IgG persists, thereby conferring lifelong immunity against re-infection.

Management

Supportive management is of primary importance. Potentially hepatotoxic medications must be ceased. Alcohol should not be consumed during acute episodes because of its direct nephrotoxic effects.

Prevention and immunization

General measures are imperative—safe water supplies, proper sewage disposal and careful hand washing. HAV vaccines can prevent HAV infection and, importantly, have excellent safety profiles. Persons who have been exposed to HAV and who have not been previously vaccinated should receive the vaccine within 2 weeks of exposure. Travellers to endemic areas require inactivated hepatitis vaccine, which confers long-term immunity to more than 90% of persons.

Table 9.6.1 Characteristics of the main hepatitis virusess

	HAV	*HBV*	*HCV*	*HDV*	*HEV*

HAV, Hepatitis A virus; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus; *HDV*, hepatitis D virus; *HEV*, hepatitis E virus.

Hepatitis B virus

Of the viral causes of hepatitis, few are of greater global importance than hepatitis B virus (HBV). HBV infection is endemic in certain parts of the world—Southeast Asia, China and sub-Saharan Africa. It is estimated that there are 350 million carriers worldwide. By 2020, it is estimated there will be a two- to threefold increase in the number of hepatitis B–induced liver cancer cases and a marked increase in the number of deaths attributable to hepatitis B under current treatment patterns in Australia. (See Table 9.6.1 for virology.)

Epidemiology

Transmission occurs by percutaneous and mucosal exposure to infected blood products and bodily fluids; hence unprotected sexual contact with infected individuals, the use of contaminated paraphernalia during intravenous drug use and vertical transmission from mother to infant are commonly implicated. In the last decade, several factors have changed the worldwide dynamics of hepatitis B epidemiology, including massive population migrations from highly endemic areas and the implementation of preventive strategies, screening policies and public education.

Natural history

Many acute HBV infections are asymptomatic, particularly in younger patients. The non-specific symptoms of the acute episode may be preceded by a serum-sickness syndrome with fevers, urticaria and arthralgias.

Approximately 90% of patients completely recover from an acute episode of HBV infection. Fulminant hepatic failure may develop in 1% of patients and has a mortality rate of up to 80%.

Progression to chronic HBV infection occurs in 5% to 10% of cases, with 90% of these experiencing an asymptomatic carrier state and the remaining 10% proceeding to cirrhosis and hepatocellular carcinoma. The risk of developing chronic disease is related to the age at which HBV infection is first contracted—there is a greater than 90% risk of developing chronic HBV infection in neonates and a less than 5% risk in immunocompetent adults. Although chronic HBV infection is generally a lifelong condition, a small percentage of infected individuals will experience complete viral eradication. In chronic HBV infection, the incidence of cirrhosis is about 2% to 3% per year. Variables associated with progression to cirrhosis are persistence of viral replication, older age, elevation of ALT levels and HBeAg positivity.[3]

Laboratory investigations

The diagnosis of HBV infection is currently based on the detection of serological markers, including Hepatitis B Surface Antigen (HbsAg), anti-HBs antibodies, anti-HBc antibodies (total or IgM), HBeAg, and anti-HBe antibodies, and on the detection and quantification of HBV DNA in peripheral blood. The diagnosis of acute hepatitis B is based on the concomitant presence of HBsAg and anti-HBc IgM (Table 9.6.2). In chronic HBsAg carriers, the presence or absence of HBeAg, the HBV DNA level, and the ALT level help diagnose the phase of chronic infection.[4]

Management

Supportive care is the primary aim of management. Household contacts require adequate education. In cases of chronic HBV infection, the aims are to suppress HBV replication and to reduce liver injury. Interferon alpha (IFN-α) has antiviral, antiproliferative and immunomodulatory effects and is an effective treatment option against HBV infection. Patients with normal serum ALT levels have a poor response to IFN-α because the lack of hepatic dysfunction is suggestive of low immune-mediated hepatic inflammation. The limiting factor in the use of IFN-α is the side-effect profile, which includes an influenza-like illness, gastrointestinal symptoms, psychological sequelae (particularly depression), bone marrow suppression, thyroid dysfunction and possible birth defects. Lamivudine is an oral nucleoside analogue that potently inhibits HBV DNA synthesis. New antiviral approaches that target various steps and components of the HBV life cycle, including covalently closed circular DNA (cccDNA), are currently being investigated in the hope of achieving functional cure of infection or, if possible, complete viral eradication. These approaches include HBV entry inhibitors, such as Mrycludex B, cytokines or sequence-specific nucleases that damage or destroy cccDNA and monoclonal antibodies that decrease circulating HBsAg load.

Prevention and immunization

The pre-exposure administration of HBV vaccine is fundamental to immunoprophylaxis. The vaccine is protective in over 90% of individuals. Current recommendations include all infants at birth and individuals with high exposure risk, such as health care personnel, injecting drug users and high-risk sexual workers. Antibody titres may decrease with time but the protective effects persist. The risk of HBV infection in the occupational setting is related primarily to the degree of contact with blood and to the HBeAg status of the donor. In needle-stick injuries, the risk of developing clinical hepatitis if the blood is both HBsAg- and HBeAg-positive has been estimated to be up to 30%. Post-exposure prophylaxis involves the administration of hepatitis B immunoglobulin in addition to the recombinant vaccine series.

Hepatitis C virus

International studies estimate that up to 3% of the world's population is infected with hepatitis C virus. International studies estimate that up to 3% of the world's population is infected with hepatitis C virus (HCV).[5] (See Table 9.6.1 for virology.) The identification of six major genotypes of the HCV has important clinical implications in that such genomic sequence variation makes vaccine development extremely difficult.

Epidemiology

Parenteral exposure leads to HCV infection, the use of contaminated needles and syringes being a predominant factor. Sexual and perinatal transmission of HCV is negligible. Transfusion-related HCV transmission has essentially been eradicated via donor screening. Up to 10% of HCV cases do not have an identifiable source of infection.

Natural history

A pre-icteric phase featuring non-specific symptoms develops in 15% to 20% of patients. When the icteric phase develops, it typically lasts for 1 to 2 weeks. Fulminant hepatic failure rarely results from acute HCV infection.

Following an acute episode, 75% to 85% of adults and 55% of children will enter a chronic phase. There is a high proportion of subclinical chronic HCV infection; hence patients may not manifest any pathology until incidental blood tests or end-stage liver disease many years after the initial infection. Approximately 20% to 30% of patients with chronic HCV develop cirrhosis, with subsequent hepatocellular carcinoma occurring in up to 20% of the latter group.

Laboratory investigations

A fluctuating titre of HCV RNA is detectable within days to weeks of the initial HCV infection. The rate at which HCV antibodies develop is variable. Notably, HCV antibodies are neither neutralizing nor protective. It may not be possible to distinguish between acute and chronic HCV infection given that the same laboratory markers can be present in both conditions. Further specific laboratory tests for viral hepatitis are presented in Table 9.6.2.

Management

Supportive management is fundamental in addressing HCV infection. Relevant education and counselling regarding high-risk behaviours and referrals to appropriate support networks are necessary. Avoidance of alcohol is advisable. Standard therapy for HCV infection has consisted of a combination of pegylated IFN-α and ribavirin. However, the combination therapy leads to cure in only about 50% of cases. Direct-acting antiviral agents target specific steps within the HCV life cycle and disrupt viral replication in an attempt

Table 9.6.2 Laboratory tests in viral hepatitis

Test	*Interpretation of positive test*	*Clinical significance*
Tests for HAV		
Anti-HAV IgM	Recently acquired HAV	Acute hepatic illness
Anti-HAV IgG	Previous infection/vaccination	Immunity
Tests for HBV		
HBsAg (surface Ag)	Current/chronic infection	Structural viral component
Anti-HBsAg (surface Ab)	Previous infection/vaccination	Immunity
Anti-HBclgM (core Ab)	Recently acquired HBV	Test for acute HBV
HBeAg	Marker of viral replication	High infectivity
Anti-HBeAg	No viral replication	Low infectivity
HBV DNA	Complete virus present	High infectivity
Tests for HCV		
Anti-HCV	HCV exposure	Variable infectivity
HCV RNA	Virus present	
Tests for HDV		
Anti-HDV IgG/IgM	HDV exposure	Acute or chronic HDV
Delta Ag	HDV present	Acute or chronic HDV
Tests for HEV		
Anti-HEV IgM	Recently acquired HEV	Acute hepatic illness
Anti-HEV IgG	Previous exposure	

HAV, Hepatitis A virus; *HBV,* hepatitis B virus; *HCV*, hepatitis C virus; *HDV,* hepatitis D virus; *HEV,* hepatitis E virus.
(Modified with permission from Talley N, Martin C. *Clinical Gastroenterology: A Practical Problem-based Approach.* 2nd ed. Edinburgh: Churchill Livingstone; 2006.)

to terminate that cycle before its completion.[6] Rapid development of directly acting antiviral drugs against HCV has led to the reality of interferon-free regimens being available for the treatment of HCV. These regimens have a short course, are easily tolerated and are equally successful in HIV-positive and negative individuals. Major national collaborative ventures with the ultimate aim of controlling and eliminating HCV infection in Australia by 2026 are currently in place. Programs such as Control and Elimination within AuStralia of HEpatitis C from people living with HIV (CEASE), directed toward the Australian HIV-positive population, have been developed with the specific aim of evaluating the feasibility of rapid scale-up of interferon-free direct-acting antiviral agent (DAA) treatments.[7]

Prevention and immunization

Currently no effective vaccination is available against HCV infection, nor is there any specific post-exposure prophylactic regimen. Vaccination against HAV and HBV is advisable. HCV is not transmitted efficiently through occupational exposures to blood. The average incidence of anti-HCV seroconversion after accidental exposure from an HCV-positive source is less than 2%.

Hepatitis D virus

Hepatitis D virus (HDV) infection leads to the most severe form of chronic viral hepatitis. As a defective virus, HDV requires the presence of HBV for virion assembly and viral replication. (See Table 9.6.1 for virology.)

Epidemiology

Only patients with acute or chronic HBV infection are susceptible to infection with HDV. An estimated 5% of HBV carriers are infected with HDV worldwide. Parenteral exposure is the primary transmission mode. HDV infection can occur as a co-infection with acute HBV (acquired at the same time) or as a superinfection in chronic HBV carriers.

Natural history

In cases of HDV and HBV co-infection, acute HDV infection generally presents as a benign acute hepatitis with subsequent resolution in up to 80% to 95% of patients. Chronic HDV/HBV infection may occur in 5% to 10% of patients. HDV superinfection results in progression to chronic HDV/HBV in 70% to 80% of cases. Chronic HDV/HBV infection manifests as a chronic healthy carrier state or severe liver disease. HDV superinfection may result in fulminant hepatitis in 2% to 20% of cases. Chronic HDV infection leads to more severe liver disease than HBV mono-infection and is associated with an accelerated progression of fibrosis, earlier hepatic decompensation and an increased risk for the development of hepatocellular carcinoma.

Laboratory investigations

HBsAg must be detected to diagnose acute HDV/HBV co-infection. Anti-HDV IgM is transiently present in acute infections. Anti-HDV IgG appears late in acute infections.

Management

The management of CHD has not changed in over 30 years and consists of treatment with IFNs. The only modification in therapy is the switch from conventional to pegylated IFN (peg-IFN), which probably has not led to better viral response rates but is more convenient for patients, with once-weekly dosing compared with the thrice-weekly schedule of conventional IFNs.[8] Hepatocyte entry inhibitors and prenylation inhibitors give hope to patients suffering from chronic hepatitis D.

Prevention and immunization

Currently there is no vaccine for preventing HDV infection. HBV immunization has been shown to provide protection against the development of HDV.

Hepatitis E virus

See Table 9.6.1 for virology.

Epidemiology

Hepatitis E virus (HEV) is endemic in developing countries, such as Southeast and Central Asia and the Indian subcontinent. The primary mode of transmission is via the faecal-oral route, with contaminated drinking water and food supplies being primary sources of infection. Young adults are often predominantly affected.

Natural history

The clinical course is similar to that of acute HAV infection. Full recovery from the acute HEV infection is the norm. There have not been any recorded cases of chronic HEV infection.

Overall mortality from acute HEV infection is about 5%. For reasons that remain unclear, fulminant hepatic failure with a subsequent high mortality rate occurs in 25% of women with HEV infection during the third trimester of pregnancy. Liver transplant recipients may be at a greater risk for HEV infection, which can lead to chronic hepatitis.

Laboratory investigations

Anti-HEV IgM appears between 1 week and 6 months after illness onset. Anti-HEV IgG is evident during the convalescent phase or post-exposure.

Management

Supportive management is the key.

Prevention and immunization

Disease control depends on good personal hygiene and improved environmental sanitation. There is no effective vaccine.

Hepatitis G virus

Exposure to blood products is a recognized route of acquisition of hepatitis G virus (HGV) infection in humans. Chronic viraemia results and the reported prevalence of HGV infection ranges from 1% to 3% in most populations, figures that are higher than those for either HBV or HCV in these populations. A causal relationship between the prevalence of HGV and hepatitis, however, has not been proven. HGV RNA may persist in the serum of patients acutely infected with HGV for as long as 16 years; however, in about 90% of these patients persistence is not accompanied by evidence of hepatocellular injury. Currently there should be no need to test for HGV in the emergency setting.

Non-hepatotrophic viruses

Several non-ABCDE viruses cause viral hepatitis. The cytomegalovirus (CMV) and Epstein-Barr virus (EBV) commonly contribute to abnormal LFTs, and icteric hepatitis may also occasionally be noted. In immunocompromised patients, herpes simplex may lead to a hepatitic picture. Progression to chronic hepatitis has not been demonstrated with any of these viruses.

Non-viral hepatitis

Of the causes of non-viral hepatitis, the following are important in the emergency setting: alcoholic hepatitis, non-alcoholic steatohepatitis (NASH), drug-induced hepatitis and autoimmune hepatitis.

Alcoholic hepatitis

Alcoholic hepatitis is an important clinical syndrome that is variably characterized by anorexia, nausea, jaundice, hepatomegaly and features of portal hypertension, such as ascites and encephalopathy. Cirrhosis and death are possible sequelae if the patients do not cease their alcohol consumption.

Non-alcoholic steatohepatitis

Defects in the processing of fatty acids through the liver may cause steatosis-induced inflammation (steatohepatitis). Ten to 50% of patients with this condition are at risk of developing cirrhosis.

Drug-induced hepatitis

Toxic exposure to certain medications, vitamins, herbal remedies and food supplements may result in a drug-induced hepatitis. This may occur as an expected consequence of a drug's toxicity profile or as an idiosyncratic reaction to a standard dose. Hepatotoxic agents result in variable clinicopathological patterns of liver injury via toxic and immune mechanisms. The formation of reactive hepatotoxic metabolites is often the primary underlying mechanism. Extensive lists of hepatotoxic drugs can be found in the literature. Acute liver injury may be necro-inflammatory (e.g. from paracetamol), cholestatic (e.g. from chlorpromazine) or of a mixed type. Table 9.6.3 lists drugs that may induce hepatitis and are encountered in the emergency setting.[2]

Autoimmune hepatitis

Autoimmune hepatitis is a self-perpetuating hepatocellular inflammation of unknown cause associated with hypergammaglobulinaemia and serum antibodies. Fatigue, anorexia and jaundice may progress to liver failure. Corticosteroids are the basis of treatment.[9]

Future directions

- Global emphasis on adequate public health schemes, including vaccination programmes, to control the transmission of viral hepatitis
- Emphasis on public education regarding high-risk practices
- Surveillance of the long-term immunity conferred by the hepatitis A and B vaccinations
- Development of a vaccine for hepatitis C
- Optimization of the management algorithms for chronic viral hepatitis

Table 9.6.3 Hepatitis-inducing drugs

Drug	*Pathology*
Allopurinol	Hepatic granulomas
Cloxacillin	Lobular hepatitis
Chlorpromazine	Cholestatic hepatitis
Dantrolene	Cytolytic hepatitis
Erythromycin	Cholestasis with hepatitis
Flucloxacillin	Cholestatic hepatitis
Halothane	Hepatocellular injury
Isoniazid	Cytolytic hepatitis
Non-steroidals	Primarily cholestasis
Paracetamol	Cytolytic hepatitis
Phenothiazines	Cholestatic hepatitis
Phenytoin	Non-caseating granulomas
Sulphonamides	Cytolytic hepatitis

9.7 Human immunodeficiency virus and acquired immune deficiency syndrome

Carl Luckhoff

ESSENTIALS

1 Patients with previously undiagnosed human immunodeficiency virus (HIV) infection may present to the emergency department at any time during the course of infection, from early (seroconversion) to late acquired immune deficiency syndrome ([AIDS]-defining illness) stages.

2 Patients with previously diagnosed HIV infection may present with complications of anti-retroviral therapy or, if therapy has failed or is not taken, with a range of HIV-related clinical syndromes.

3 Globally, heterosexual transmission accounts for most HIV infections; in Australia, however, HIV infection remains predominantly a disease of men who have sex with men (MSM).

4 Most AIDS-defining illnesses occur when the CD4 T-lymphocyte count is below 200/μL (bacterial pneumonia and tuberculosis are exceptions).

5 Serious non-AIDS events that are not classically associated with HIV infection—such as cardiovascular disease, bone disease, renal disease and cognitive impairment—cause significant morbidity, may occur at higher CD4 cell counts and are possibly related to chronic inflammation.

6 Combination anti-retroviral therapy with well-tolerated and potent once-daily regimens dramatically reduces HIV mortality and morbidity, reduces the risk of HIV transmission from the infected individual to his or her partner and may decrease HIV transmission at a population level (treatment as prevention).

7 Close liaison between emergency department staff and the patient's hospital or local doctor is vital for optimal management of HIV-infected patients.

Introduction

HIV medicine is a complex and specialized field and emergency physicians are not the usual primary care providers for people with HIV infection. However, the emergency department (ED) is often the first point of contact for patients presenting with acute HIV-related complications, whether or not they have already been diagnosed with HIV.

Emergency medicine physicians do not need to be HIV experts, but they should develop knowledge and skills in the following areas:

- The natural history and clinical manifestations of HIV infection
- The principles of HIV diagnosis, including the ability to engage patients in discussions about HIV testing and test results
- The principles of early management of patients with common HIV-related disease syndromes
- Knowledge of the antiretroviral agents in current use, including toxicity and drug interactions

The first cases of AIDS were recognized in the United States in 1981 and in Australia in 1982. The causative agent, human immunodeficiency virus (HIV), was discovered in 1984 and a diagnostic blood test was developed soon thereafter. In 1986, the first effective antiretroviral drug (azithromycin [AZT], later renamed zidovudine) became available. Since the late 1990s, the use of combination antiretroviral therapy (ART) has led to dramatic reductions in HIV-associated morbidity and mortality in resource-rich countries. Antiretroviral use is rapidly increasing in developing countries, with AIDS-related deaths having decreased by 43% since 2010. The world's most affected region remains eastern and southern Africa. Worldwide 2.1 million infections were reported in 2015, adding up to a total of 36.7 million people living with HIV.[1]

Epidemiology

The great majority of HIV infections globally arise as a result of heterosexual transmission. In developed countries, injecting drug use and men who have sex with men (MSM) account for a greater proportion of HIV infections, although the contribution of specific behaviours to overall transmission varies greatly within and between countries and over time.

In 2016 it was estimated that 26,444 people were living with HIV in Australia. The number of newly diagnosed cases remained stable between 2011 and 2016, with approximately 1000 new cases per year. Seventy-five percent of people infected with HIV report male-to-male sex, 20% become infected through heterosexual transmission and the rest occurred in other groups, including injecting drug users and recipients of contaminated blood or blood products. Women account for 9% of HIV-infected people and children less than 1%.[2] Compared with some other countries, the prevalence of HIV infection in injecting drug users in Australia has remained low, in the order of 1% to 2%.

In 2016, an estimated 11% of all people living with HIV in Australia were unaware of their HIV status.[2]

Pathogenesis

Once HIV infection becomes established, huge numbers of HIV virus particles are produced, chiefly in lymph nodes and other lymphoid tissue, accompanied by the daily turnover of up to 1 billion CD4 T lymphocytes. The number of CD4 cells falls secondary to mechanisms such as immune activation and direct infection of CD4 cells, resulting in reduced helper function for cell-mediated and humoral immunity.[3]

HIV replication occurs at a relatively constant rate, producing a stable level of HIV in the blood; this can be measured with quantitative HIV RNA detection tests. The HIV viral load in combination with blood cell counts is used as a prognostic marker (because it is associated with the rate at which CD4 T lymphocytes are lost) and to monitor the efficacy of anti-retroviral therapy (ART).

The peripheral blood CD4 T-lymphocyte count is an accurate indicator of the degree of immunosuppression. The normal count is 500 to 1500 cells/μL; susceptibility to opportunistic infection and to most other serious HIV-related

complications is greatest when the CD4 cell count is less than 200 cells/μL. In untreated patients the rate of decline in CD4 cells follow a skewed distribution, with progressive decline in CD4 cell count following HIV infection.[20]

A wide variety of chronic medical conditions not previously associated with HIV infection—such as cardiovascular, bone and kidney disease, mild cognitive impairment and non-HIV related cancers—are more common in HIV-infected patients.[4] Predisposition to these serious non-AIDS events results from a complex interplay between an ageing HIV-infected population, traditional risk factors, side effects of some antiretroviral agents and HIV infection itself. Chronic inflammation induced by HIV infection, which may persist despite effective ART, is thought to mediate some of the direct HIV effects.

Classification and natural history

HIV infection can be divided into the following stages:

- Viral transmission
- Acute HIV infection
  - Seroconversion
- Chronic HIV infection
  - Asymptomatic
  - Early symptomatic HIV infection
  - AIDS, characterized by a CD4 cell count below 200 cells/μL or the presence of any AIDS-defining condition
  - Advanced HIV infection characterized by a CD4 cell count below 50cells/μL

Patients are categorized as having AIDS when they develop an AIDS-defining condition regardless of the CD4 count, a CD4 cell count below 200 cells/μL , an HIV-related malignancy, a wasting syndrome or AIDS dementia complex.

Presentation

Patients with underlying HIV infection who present to the ED fall into three distinct groups. First, they may present with a manifestation of previously unrecognized HIV infection. To identify these patients, the physician must know who is potentially at risk of HIV infection (see 'Epidemiology', earlier) and be aware of the many different ways in which previously undiagnosed HIV infection may present. Prompt consideration of the possibility of HIV infection is important because the differential diagnosis of the presenting problem will broaden to encompass a variety of other conditions, some of which may be life threatening and require a different approach to initial investigation and treatment.

The second group includes those who are already known to be HIV-infected. Many of these patients will have been started on ART; serious HIV-related infections or malignancies are uncommon in this group, but ED presentations may be related to complications of therapy or to the chronic medical conditions associated with HIV infection discussed in the previous section. A smaller group of patients have developed resistance to or are intolerant of antiretroviral agents or decline to start or remain on treatment; these patients usually present with one of a limited number of classic HIV-related clinical syndromes, such as fever and cough or shortness of breath, diarrhoea, unexplained fever or neurological symptoms. The initial diagnostic and treatment approach is based on knowledge of the differential diagnosis for each of these syndromes.

Finally, there will be patients whose ED presentation is not related to an HIV complication at all but who have clinically silent, 'incidental' HIV infection. Readily identifiable groups who may be in this category are patients with a sexually transmitted infection (STI) and those with hepatitis B or hepatitis C infection. Otherwise a brief history including a sexual history is required to elicit HIV risk factors. Presentation of these patients to the ED offers an important opportunity to explore HIV risk factors and to discuss the benefits of early HIV diagnosis and the desirability of HIV testing.

Previously undiagnosed HIV infection

Acute seroconversion illness (Box 9.7.1)

The proportion of patients suffering from symptoms of acute infection varies greatly and 10% to 60% patients do not experience any symptoms at all. For those patients suffering from acute retroviral syndrome, the symptom duration and severity may vary widely. The highest frequency of symptoms and signs is observed just prior to peak viraemia, usually 2 weeks after the initial detection of viral RNA.[6] The most common features are fever, fatigue, myalgia, rash, headache, lymphadenopathy and/or diarrhoea. Prolonged duration of any of these and the presence of mucocutaneous ulcers are suggestive of acute retroviral syndrome. The diagnosis is often missed at this stage; patients may be thought to have a 'viral illness', such as infectious mononucleosis or, if a patient develops a complication, more common causes (e.g. herpes simplex virus in a patient with encephalitis) and not HIV are considered.[5]

Chronic HIV Infection

Asymptomatic infection People are generally healthy during this phase. Thrombocytopaenia may occur; therefore HIV infection should be considered in appropriate patients with idiopathic thrombocytopenia.

Early symptomatic human immunodeficiency virus infection This is a phase when previously undiagnosed HIV-infected patients often present with HIV-related conditions, but the clues may not be recognized as such and the underlying diagnosis can be missed. Manifestations that will alert the astute clinician include the following:

- Minor infections: shingles, severe or very frequent orolabial or genital herpes, oral thrush
- Skin conditions: extensive seborrhoeic dermatitis, worsening psoriasis
- Constitutional symptoms: fever, weight loss, diarrhoea
- Generalized lymphadenopathy
- More serious complications: bacterial pneumonia (especially recurrent), tuberculosis and, rarely, Kaposi sarcoma or non-Hodgkin lymphoma

AIDS characterized by a CD4 cell count below 200 cells/μL or AIDS-defining condition

It is often not appreciated that patients may remain completely well during the early and intermediate stages of HIV infection and present only when they develop a serious HIV-related complication, such as an opportunistic infection. The ED may be the first point of medical care for such patients. If the history reveals risk factors for HIV infection, HIV testing can be performed and initial investigations directed at specific HIV-related complications. However, if the patient does not volunteer this information, is not specifically asked about HIV risk factors or does not belong to a 'conventional' HIV risk group, diagnosis of the presenting illness and the underlying HIV infection is often delayed.

The following clinical situations (discussed in more detail in the following section) should

Box 9.7.1 Manifestations of primary HIV infection

Common (present in >30% of patients)	Less common	Complications
Fever	Diarrhoea	Aseptic meningitis
Rash	Generalized lymphadenopathy	Guillain-Barré syndrome
Myalgia/arthralgia	Painful swallowing	Encephalitis
Headache	Abdominal pain	Interstitial pneumonitis
Pharyngitis	Cough	Rhabdomyolysis
Cervical lymphadenopathy	Photophobia	Haemophagocytic syndrome
Mouth ulcers	Tonsillitis	

prompt consideration of the possibility of underlying HIV infection:

- Diffuse bilateral pulmonary infiltrates (as a manifestation of *Pneumocystis jiroveci* pneumonia [PJP]): This is the commonest serious opportunistic infection in patients with previously undiagnosed HIV infection. It is often misdiagnosed as atypical pneumonia, leading to incorrect initial treatment with a macrolide agent or doxycycline.
- Ring-enhancing space-occupying cerebral lesion: In non–HIV-positive patients, the usual cause is a tumour or bacterial brain abscess, and brain biopsy is required. In the setting of HIV infection, cerebral toxoplasmosis is the most likely diagnosis and brain biopsy can usually be avoided.
- Tuberculosis: Although the overlap between those at risk for HIV and tuberculosis is not as great in Australia as in resource-poor countries with a high HIV burden, all patients with tuberculosis should be encouraged to undergo HIV testing after appropriate counselling.
- Kaposi sarcoma: Well-developed lesions (purple, oval and nodular) are easy to recognize, but early lesions are often non-descript (brown or pink and flat) and biopsy may be required for diagnosis.
- Other presentations: Unexplained cytopaenias (anaemia or pancytopenia) and other AIDS-defining conditions such as non-Hodgkin lymphoma, cryptococcal meningitis, chronic cryptosporidial diarrhoea or AIDS dementia complex (manifesting as impaired cognition and motor performance) are occasionally the first manifestation of previously unsuspected HIV infection.

Previously diagnosed HIV infection[7]

Patients with known HIV infection are less likely to present with the classic AIDS-related clinical syndromes indicative of advanced immunodeficiency. However, previously diagnosed patients may fail ART or elect not to start or continue treatment and are still susceptible to AIDS-defining conditions. (Otherwise these presentations involve patients with previously unrecognized HIV infection, as discussed in the preceding section.) Patients with known HIV infection may also present with complications of ART, with chronic medical conditions not associated with HIV and of course with an acute problem not related to HIV at all.

Cough, shortness of breath, fever

Respiratory pathogens are listed in Box 9.7.2. The most important issue is to decide whether the patient has PJP or not, because this complication is common and potentially serious. Tuberculosis must also be considered because of the need to place the patient in respiratory isolation.

Box 9.7.2 Respiratory complications in HIV-infected patients

Common	Uncommon
Pneumocystis jiroveci pneumonia (PJP)	Infectious:
Bacterial pneumonia: *Streptococcus pneumoniae*	Tuberculosis
Haemophilus influenzae	Atypical mycobacteria
Bronchitis	*Aspergillus* pneumonia
	Other infectious:
	Rhodococcus equi, cytomegalovirus (CMV)
	Non-infectious:
	Pulmonary Kaposi sarcoma
	Lymphoma

- PJP (strongly suspected in patients with CD4 cell count <200 cells/μL): The presentation is subacute or chronic, with a non-productive cough, dyspnoea, fever and chest tightness. Physical examination may reveal fever, tachypnoea and reduced chest expansion, but chest auscultation is often normal. PJP is unlikely in patients taking regular co-trimoxazole (a trimethoprim/sulphamethoxazole combination).
- Bacterial pneumonia: Patients usually present with a short history, a productive cough and sometimes pleuritic chest pain. Physical examination may be normal or reveal signs of consolidation, a pleural rub or pleural effusion.
- Patients who are immunosuppressed secondary to HIV have a high incidence of invasive streptococcal infection, although the availability of multi-valent pneumococcal vaccines has helped to decrease the incidence of these infections.
- Tuberculosis: The clinical features vary according to the degree of immunosuppression. Patients with otherwise asymptomatic HIV infection usually present with typical symptoms and signs of tuberculosis (chronic cough, haemoptysis, fever and weight loss). However, in late-stage HIV infection, atypical manifestations such as disseminated disease are common and diagnosis is more difficult.

Investigations If the CD4 cell count is above 200 cells/μL, most patients can be managed as if they did not have HIV infection. Investigations required for patients with suspected bacterial pneumonia or tuberculosis include a chest x-ray, full blood examination, sputum examination and blood cultures.

If the CD4 cell count is below 200 cells/μL, investigation is almost always indicated. Its extent will be guided by the patient's condition and the likely diagnostic possibilities.

Investigations may include some or all of the following:

- Chest x-ray
- Blood cultures
- Sputum Gram stain, culture and acid-fast bacillus (AFB) smear and culture
- Induced sputum for detection (by microscopy or polymerase chain reaction [PCR]) of PJP
- Bronchoscopy, usually during inpatient admission.

A high index of suspicion for tuberculosis must be maintained; the diagnosis is generally suggested by one or more suggestive epidemiological, clinical or radiological features.

Management Any person with suspected pulmonary tuberculosis must be placed in respiratory isolation until the diagnosis is excluded. Otherwise, on the basis of the initial diagnostic evaluation, patients can be categorized and management can proceed as follows:

- Significant infection unlikely: no treatment.
- Possible PJP: empirical PJP therapy with co-trimoxazole, and corticosteroids if saturation levels are below 93% at rest on room air oxygen.
- Possible bacterial pneumonia:
  - Non-severe, outpatient—treat as for community-acquired pneumonia in immunocompetent patient.
  - Non-severe, inpatient—treat as for community-acquired pneumonia in immunocompetent patient.
  - Severe—consider community-acquired pneumonia regimens plus HIV-related opportunistic infections.
  - Possible tuberculosis—admission and respiratory isolation; treatment with isoniazid, rifampicin, pyrazinamide and ethambutol according to local guidelines if diagnosis confirmed; empirical therapy is sometimes necessary depending on clinical circumstances (e.g. suspected coexisting tuberculous meningitis).

Focal neurological signs, convulsions or altered conscious state

These features generally indicate the presence of an intracerebral space-occupying lesion, the most common causes of which are as follows:

- Cerebral toxoplasmosis: This infection occurs when the CD4 cell count is below 200cells/μL. The specific focal features depend on the site of the usually multiple lesions and may include hemiparesis, visual field defects, personality change and/or cerebellar signs.
- Primary intracerebral lymphoma: This complication occurs with advanced HIV infection (CD4 cell count usually below 500 cells/μL) and manifested in 2% to 3% of AIDS patients

prior to the development of effective ART. It is associated with Epstein-Barr virus (EBV) infection. Clinical presentation is indistinguishable from that of cerebral toxoplasmosis.
- Progressive multifocal leucoencephalopathy: Caused by JC virus (a polyomavirus). Patients present with cognitive decline or focal signs. Seizures are relatively uncommon. Differentiation from cerebral toxoplasmosis and primary cerebral lymphoma requires computed tomography (CT) or magnetic resonance imaging (MRI) (see later).

Investigations A brain CT scan (with contrast) should be done in all patients, often as a matter of some urgency and should always precede a lumbar puncture. MRI will often provide additional important information. The commonest causes of focal lesions are cerebral toxoplasmosis and primary intracerebral lymphoma. A *Toxoplasma gondii* IgG test will usually have been performed in those with previously diagnosed HIV infection; if positive, this indicates prior infection and a predisposition to the development of cerebral toxoplasmosis; if negative, toxoplasmosis is much less likely. Diagnosis of cerebral lymphoma is primarily based on non-response to empiric treatment for cerebral toxoplasmosis; cerebrospinal fluid (CSF) cytology, detection of EBV DNA in CSF by polymerase chain reaction (PCR) or, occasionally, brain biopsy will be required for a specific diagnosis. Progressive multi-focal leucoencephalopathy manifests as focal white matter lesions visible on T2-weighted MRI scans.

Management Treatment is guided by the results of the brain CT scan. If a space-occupying lesion is found, the patient is treated empirically for cerebral toxoplasmosis with sulphadiazine and pyrimethamine. The CT scan is repeated after 2 to 3 weeks; if no response is evident, a brain biopsy might be considered in selected patients to diagnose cerebral lymphoma. If the CT scan is normal or non-diagnostic, MRI scanning is usually indicated and supplemented by lumbar puncture.

Diarrhoea, with or without abdominal pain or fever

A wide range of gastrointestinal (GI) pathogens cause diarrhoea in HIV-infected patients (Box 9.7.3). Patients should be asked about recent travel or antibiotic use. Bloody, small-volume diarrhoea with cramping lower abdominal pain is suggestive of a large bowel pathogen, such as cytomegalovirus (CMV), *Entamoeba histolytica* or *Clostridium difficile*, whereas profuse watery diarrhoea suggests an infection of the small bowel, such as cryptosporidiosis. Clinical features are, however, of limited diagnostic value and the specific diagnosis rests on identification of the pathogen in a faecal or biopsy specimen. Prominent anal pain or tenesmus should alert the clinician to the possibility of proctitis due to a sexually acquired infection, such as gonorrhoea, *Chlamydia trachomatis* (including lymphogranuloma venereum) or herpes.

Box 9.7.3 Gastrointestinal pathogens in HIV-infected patients

Bacterial
Salmonella
Campylobacter
Clostridium difficile
Mycobacterium avium complex (MAC)

Viral
Cytomegalovirus (CMV)

Protozoal
Cryptosporidium
Giardia
Entamoeba histolytica
Microsporidium

Non-infectious
Lactose intolerance
Gastrointestinal Kaposi sarcoma
Lymphoma

Investigations Faecal examination (preferably two to three fresh specimens collected on different days) for the following:
- Microscopy for ova, cysts and parasites
- *Cryptosporidium* antigen test or stain, *Microsporidium* stain
- culture for *Salmonella*, *Campylobacter* and *Shigella*
- *Clostridium difficile* culture and toxin, especially if there has been recent antibiotic therapy

Selected patients with diarrhoea may require colonoscopy or upper GI endoscopy if infections such as CMV, MAC or microsporidiosis are suspected. Endoscopy is generally reserved for those in whom no specific cause is identified on initial evaluation and whose diarrhoea persists despite antimotility therapy.

Swabs for gonorrhoea, *Chlamydia* and herpes should be taken from patients with symptoms of proctitis.

Management Any infection identified on initial faecal examination is treated on its merits. Symptomatic treatment with an anti-motility agent such as loperamide is contraindicated if bloody diarrhoea and fever are present; otherwise it can be given safely to most patients.

Fever without localizing features

This is chiefly a problem in those with a CD4 cell count below 200 cells/μL.

The differential diagnosis is extensive, the major causes being as follows:
- Disseminated opportunistic infections: disseminated MAC, disseminated tuberculosis, disseminated histoplasmosis (the United States and South America), *Salmonella* bacteraemia, CMV
- Focal opportunistic infections with non-focal presentation: PJP, cryptococcal meningitis, tuberculosis
- Bacterial infections: sinusitis, bacterial pneumonia, primary bacteraemia (especially in patients with an indwelling long-term intravenous device or neutropaenia)
- Non-HIV–specific infections: right-sided endocarditis, secondary syphilis
- Non-infectious causes: non-Hodgkin lymphoma, drug fever

Investigations If the CD4 cell count is greater than 200 cells/μL, serious HIV-related causes are uncommon; therefore investigation will be guided by clinical features, severity of illness and other salient clinical findings. If the CD4 cell count is below 200 cells/μL, most patients will need investigation, beginning with the following:
- Blood cultures, including mycobacterial blood cultures if CD4 cell count <500 cells/μL
- Chest x-ray
- Serum cryptococcal antigen

Additional tests for selected patients include faecal examination, sputum examination, abdominal ultrasonography or CT scanning and, occasionally, bone marrow or liver biopsy.

Management Empirical antibacterial therapy (with an anti-pseudomonal agent such as piperacillin/tazobactam with or without an aminoglycoside or vancomycin) is indicated for patients with an absolute neutrophil count below 500 cells/μL; otherwise the need for specific treatment is guided by the condition of the patient and the results of the diagnostic workup. Any long-term intravenous access device should be removed if infection of the device is suspected on clinical or microbiological grounds or if diagnostic evaluation reveals no other focus of infection. Treatment for disseminated MAC (with clarithromycin and ethambutol with or without rifabutin) is generally given only after the organism has been isolated, although occasional patients with debilitating fevers, weight loss and no other diagnosis may be treated empirically.

Difficult or painful swallowing

This is usually due to *Candida* oesophagitis, in which case coexisting oral candidiasis is often present. Other causes include CMV oesophagitis, herpes simplex oesophagitis and idiopathic aphthous ulceration.

Investigation Oesophagoscopy and biopsy are reserved for those who fail an empiric course of antifungal therapy (see later).

Management Empirical antifungal therapy is started with an azole agent, usually oral fluconazole. Patients with resistant *Candida* infections need treatment with an alternative azole agent, such as posaconazole, or a short course of

intravenous amphotericin B. Patients undergo endoscopy if they do not respond to antifungal treatment; the results of histology and cultures determine subsequent treatment.

Headache, fever, neck stiffness

Cryptococcal meningitis is the most common cause of this syndrome, although headache may be mild and signs of meningism subtle or absent. Less common causes include tuberculous meningitis, syphilitic meningitis, HIV itself and lymphomatous meningitis.

Investigation The serum cryptococcal antigen test is a useful screening test for cryptococcal meningitis because a negative result effectively excludes the diagnosis. A lumbar puncture should be performed only after a CT brain scan and if the CT does not show a space-occupying lesion or evidence of increased intracranial pressure. CSF should be routinely sent for the following:

- Protein and glucose
- Gram stain and culture (and AFB smear and culture if tuberculosis is suspected)
- India ink stain and cryptococcal antigen
- Cytology
- Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (RPR) test –indicated only if serum syphilis serology is positive

Management Patients with confirmed cryptococcal meningitis are treated with a combination of intravenous amphotericin B and oral 5-fluorocytosine for 2 weeks; they then remain on suppressive therapy with oral fluconazole. If tuberculous meningitis is suspected, empirical therapy should be started immediately while awaiting the results of CSF cultures.

Specific treatment of other infections

- CMV infections: Intravenous ganciclovir or intravenous foscarnet
- *Salmonella* infections (non-enteric fever): Ciprofloxacin

Complications of antiretroviral therapy

Antiretroviral drugs are discussed in more detail further on and drug side effects are outlined in Table 9.7.1. Examples of more serious side effects and treatment complications that may prompt presentation to the ED include the following:

- Pancreatitis—didanosine[a]
- Hepatitis—nevirapine
- Drug rash—nevirapine, abacavir, fosamprenavir,[a] efavirenz
- Renal calculi—indinavir,[a] atazanavir
- Lactic acidosis—zidovudine
- Renal impairment—tenofovir
- Anaemia—zidovudine

[a]These agents are no longer in widespread use in Australia

Table 9.7.1 Side effects of antiretroviral agents

Agent	*Side effect*
Nucleoside/nucleotide reverse transcriptase inhibitors (NRTI)	
Zidovudine	Nausea, headache, myalgia, anaemia, neutropaenia
Lamivudine (3TC)	Abnormal liver function, neutropaenia, pancreatitis (all uncommon)
Emtricitabine (FTC)	Skin pigmentation
Abacavir	Hypersensitivity reaction (challenge contraindicated); associated with HLA-B*5701 (8% of Caucasian populations), perform HLA B locus typing pre-therapy
Tenofovir	Renal tubular dysfunction, renal impairment, reduced bone mineral density
Non-nucleoside reverse transcriptase inhibitors (NNRTI)	
Nevirapine	Rash, hepatitis, fever
Efavirenz	Neuropsychological symptoms (vivid dreams, insomnia, difficulty concentrating, light-headedness, sleeping difficulty), rash, abnormal liver function, teratogenic in animals
Etravirine	Rash, abnormal liver function
Rilpivirine	Abnormal liver function, depression and other neuropsychological effects
Protease inhibitors (PIs)	
Class effects (variable between individual agents)	Hyperglycaemia, hyperlipidaemia, redistribution of body fat, abnormal liver function, gastrointestinal symptoms
Lopinavir	Diarrhoea, nausea
Atazanavir	Hyperbilirubinaemia, renal calculi
Fosamprenavir	Rash, diarrhoea, nausea
Darunavir	Rash
Tipranavir	Rash, myalgia
Integrase inhibitors	
Raltegravir	Myalgia, abnormal liver function
Entry inhibitors	
Enfuvirtide	Injection-site reactions, hypersensitivity
Maraviroc	Gastrointestinal symptoms, myalgia, respiratory infections

Drugs that are licensed in Australia but are no longer commonly used have been omitted.

- Jaundice—atazanavir (unconjugated hyperbilirubinaemia)
- Immune reconstitution inflammatory syndrome—patients who commence ART with very low CD4 cell counts may develop an exacerbation of symptoms and signs of a recently diagnosed opportunistic infection or a previously unrecognized infection may be 'unmasked'; this occurs with mycobacterial infections (notably tuberculosis) and a range of other infections.

Other presentations

- Cutaneous manifestations: Kaposi sarcoma, infections (e.g. secondary syphilis, herpes zoster, warts, molluscum contagiosum and crusted scabies), eosinophilic folliculitis, drug rashes
- Abdominal pain: Pancreatitis due to ART, HIV cholangiopathy, intra-abdominal lymphadenopathy secondary to MAC or lymphoma, lactic acidosis and hepatic steatosis associated with ART
- Neuropsychiatric manifestations: Depression, mania, cognitive decline
- HIV-associated neurocognitive disorders (HAND): Changes in memory, concentration, attention and motor skills that are not clearly attributable to a cause other than HIV are collectively classified as HAND. These disorders broadly include three levels of neuropsychological test performance impairment and associated functional impairment including asymptomatic neurocognitive impairment (ANI), mild neurocognitive disorder (MND) and HIV-associated dementia (HAD).

- Visual complaints: CMV retinitis (when the CD4 cell count is below 500cells/μL), syphilitic uveitis or chorioretinitis and rarely toxoplasma or cryptococcal chorioretinitis.

Clinically silent HIV infection with risk factors

Sexually transmitted infections

Perianal or rectal STIs in men are obvious markers of HIV infection risk and should prompt testing for infection. However, STIs often 'hunt in packs', so any patient diagnosed with gonorrhoea, *Chlamydia*, syphilis, genital warts, genital herpes or another STI should also be investigated for HIV.

Other risk groups

Other patients who present with a problem unrelated to HIV but with whom the desirability of HIV testing should be discussed include those with the following risk factors:

- Men who have sex with men, especially if intercourse is unprotected
- Sharing of injecting equipment
- Being from a country with a high HIV prevalence
- Being the sexual partner of either an HIV-positive person or a person at risk of HIV

Investigations

Requesting an HIV test

In Australia, doctors who request an HIV test are obliged to provide patients with information about the medical, psychological and social consequences of a positive or negative HIV test (pre-test counselling) and to provide the result to the patient in person. More detailed information about HIV testing can be found in guidelines issued by Australian authorities.[8]

Unfortunately, practical issues mean that the ED is usually not an ideal setting for HIV testing. First, discussion about sensitive personal information, such as sexual history (especially if it has to be obtained via an interpreter) is difficult in an open-design, crowded, noisy ED. Second, many EDs do not have a mechanism for the follow-up of patients to provide test results. For these reasons, a more appropriate arrangement may be to refer patients who are discharged from the ED to their local doctor or local sexual health clinic for testing, whereas testing of patients admitted to hospital can be the responsibility of the admitting unit.

Widespread 'opt out' HIV testing of hospital patients is recommended in the United States but has not been adopted in Australia. However, if the 'treatment as prevention' approach is to be effective, increasing rates of testing among groups at risk of HIV will be necessary in order to reduce the number of undiagnosed HIV infections and increase the acceptance of HIV treatment. Rapid point-of-care HIV tests are now licensed in Australia and do not require a follow-up visit, but whether these tests will have a role in settings such as EDs is currently unclear.

Primary HIV infection

- Full blood examination, heterophile antibody test
- HIV antibody/p24 antigen enzyme immunoassay (EIA) test: may be negative initially, in which case it is vital to repeat the test in 2, 4 and 6 weeks. A positive EIA is confirmed with a positive Western blot test.
- HIV RNA (viral load) test: not generally recommended for diagnosis of primary HIV infection because false positives may occur (although with a low viral load, whereas true positives usually have a very high viral load).

Previously unrecognized HIV infection (not including acute HIV infection)

The HIV antibody/antigen EIA test will be positive in all infected patients; other tests are not needed for diagnosis.

Antiretrovirals in the management of HIV infection

ART aims to reduce HIV-related morbidity and mortality and to prevent transmission of HIV. It should be offered to all HIV-infected persons regardless of immune status, although evidence for ART in untreated patients with preserved CD4 cell counts and undetectable HIV RNA (non-progressors) is lacking. Combination ART has transformed the lives of people living with HIV infection by improving their quality of life and reducing the incidence of HIV-related complications and deaths by 80% or more. More than 90% of patients starting treatment with one of the currently recommended antiretroviral regimens will achieve a non-detectable plasma HIV viral load and a substantial increase in CD4 cell count. In the great majority of patients, these benefits are sustained in the long term.[9] Modern antiretroviral regimens are much more convenient, less toxic and more potent than earlier combination ART, but ART is not without its costs: difficulty in maintaining life-long adherence, short- and long-term toxicities of antiretroviral agents and the potential development of antiretroviral resistance remain challenges.

Effective treatment is also available for patients failing therapy because of drug resistance or intolerance, using antiretroviral agents that belong to the same classes of drugs used for initial therapy or that have novel mechanisms of action. Examples include 'new-generation' protease inhibitors (tipranavir and darunavir) and non-nucleoside reverse transcriptase inhibitors (etravirine), inhibitors of CCR5 (maraviroc), a host chemokine receptor involved in HIV cell entry and the fusion inhibitor enfuvirtide.[10]

The emergency physician does not require a detailed knowledge of ART but should be aware of the agents in current use, their side effects and the potential for clinically significant drug-drug interactions. More detailed information can be referenced in regularly updated antiretroviral guidelines; examples are those produced by a panel of the US Department of Health and Human Services with an added Australian commentary, accessible at http://www.ashm.org.au/aust-guidelines/ and British HIV treatment guidelines, accessible at http://www.bhiva.org/.

Indications

Advances in treatment options and improved side-effect profiles have led to a general approach of initiating ART in all HIV-infected individuals with detectable viraemia regardless of their CD4 cell count.[11–13]

Classes of drug[b]

- Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs): tenofovir, emtricitabine (FTC), abacavir, lamivudine (3TC), zidovudine (ZDV or AZT)
- Non-nucleoside reverse transcriptase inhibitors (NNRTIs): nevirapine, efavirenz, etravirine, rilpivirine
- Protease inhibitors (PIs): atazanavir, lopinavir, fosamprenavir, tipranavir, indinavir, darunavir (all co-administered with low-dose ritonavir)
- Integrase strand transfer inhibitors (INSTIs): raltegravir, dolutegravir
- Fusion inhibitors: enfuvirtide
- Entry (chemokine receptor 5 [CCR5]) antagonist: maraviroc

The first four classes of drugs mentioned in the preceding list are typically used in initial regimens. The CCR5 antagonist is also available but is generally not used in treatment-naive patients. The fusion inhibitor is generally reserved for patients with multi-drug–resistant virus.

Initial regimens—at least three drugs

- Two NRTIs plus one NNRTI: examples are tenofovir plus FTC plus efavirenz (Atripla) OR abacavir plus 3TC (Kivexa) plus efavirenz OR tenofovir plus FTC plus rilpivirine (Eviplera)
- Two NRTIs (as listed earlier) plus one PI (atazanavir) boosted with low-dose ritonavir
- Two NRTIs (as listed earlier) plus raltegravir

[b]Drugs that are licensed but are no longer in common use in Australia have been omitted.

Side effects[14] *(see Table 9.7.1)*

If an antiretroviral drug is suspected or known to be the cause of a serious side effect, the patient's treating HIV doctor or a hospital HIV doctor should be consulted. In the interim, or unless advised otherwise by the treating or hospital doctor, all antiretroviral medications and not just the incriminating drug should be withheld to reduce the risk of development of resistance on a less than fully suppressive therapy.

Drug-drug interactions

Some commonly used drugs metabolized by or that induce hepatic cytochrome P450 oxidases are contraindicated with certain PIs or NNRTIs; in addition, many other drugs will require dose modification or closer monitoring. Always check before prescribing any new drug to a patient on ART; a very useful website (from the University of Liverpool, UK) is www.hiv-druginteractions.org.

Disposition

Patients with newly diagnosed HIV infection should be referred to a specialized HIV clinic or to a doctor with expertise in HIV medicine.

HIV medicine is a complex and rapidly changing field. For this reason the management of patients with known HIV infection presenting to the ED should always involve consultation with a hospital doctor knowledgeable about HIV infection, such as an infectious diseases physician or immunologist. The patient's usual HIV doctor (a hospital specialist, sexual health physician or general practitioner with a high HIV case load) can be contacted to obtain important details such as recent CD4 cell count and current antiretroviral agents. In general, patients with a suspected or confirmed serious opportunistic infection will have to be admitted for investigation and management. Patients in the final stages of AIDS (fortunately an uncommon group in Australia) or those with less serious complications can often be managed in the community, in which case liaison with the local doctor, home-care nurses or community-care agencies is vital.

Prognosis

Prior to the widespread use of opportunistic infection prophylaxis and effective ART, 50% of patients developed AIDS 10 years after becoming HIV-infected and 75% of patients did so after 13 years. Following an AIDS-defining illness, the median survival was 12 to 24 months. Long-term non-progressors who have normal CD4 cell counts and no HIV-related complications without ART after 10 or more years of HIV infection comprise less than 5% of patient cohorts.

Most AIDS-defining infections, such as PJP, now have low mortality and high 1-year survival rates if the infection is treated appropriately and patients are started promptly on combination ART. However, survival rates following the diagnosis of disseminated MAC and CMV end-organ disease are lower because these two opportunistic infections usually occur at a very advanced stage of HIV infection. Combination ART has reduced the mortality and incidence of opportunistic infections by over 80%.

Data from several large cohort studies indicate that average life expectancy in developed countries for patients on long-term ART is close to but still lower than that of the HIV-uninfected population.[15] This difference is partly accounted for by an excess of deaths due to chronic conditions not typically associated with HIV infection, such as cardiovascular disease, non-HIV associated malignancy and renal disease (discussed earlier in the chapter); classic HIV complications, such as opportunistic infections or HIV-related malignancies, still occur but do not contribute substantially to this difference.

Prevention

Prevention of HIV transmission

- Public health and educational efforts to encourage the adoption of safer sex practices
- HIV screening of blood, blood products and tissue donors
- Non-sharing and use of clean needles and syringes by injecting drug users
- Observance of standard precautions by workers in health care settings
- Use of antiretroviral therapy and avoidance of breastfeeding to prevent transmission from an HIV-infected mother to baby
- Use of ART to prevent transmission from an infected individual to an uninfected partner[16]
- Use of anti-retroviral prophylaxis after significant occupational exposure (see Chapter 9.10) or sexual exposure to HIV (post-exposure prophylaxis)
- Use of anti-retroviral prophylaxis by an uninfected individual before HIV exposure (pre-exposure prophylaxis)[17]
- Male circumcision—shown to reduce the acquisition of HIV infection by 60% in studies in sub-Saharan Africa[18]

Prevention of HIV-related complications[19] (Table 9.7.2)

Table 9.7.2 Prevention of HIV-related complications

Infection	*Preventive measure*
Pneumococcal pneumonia	Pneumococcal vaccination
Latent tuberculous infection	Isoniazid
Pneumocystis jiroveci pneumonia	Co-trimoxazole
Toxoplasmosis	Co-trimoxazole
Mycobacterium avium complex (MAC)	Azithromycin or rifabutin

CONTROVERSIES

- Will the 'treatment as prevention' approach (broadening treatment indications for people already known to be HIV-infected and increasing testing rates in at-risk groups in order to diagnose and then treat people with unrecognized HIV) lead to a reduction in HIV transmission at the population level?
- What is the role of other preventive measures that are known to be effective, such as pre-exposure prophylaxis and male circumcision?
- What is the relative contribution of HIV infection, antiretroviral therapy and standard risk factors to the risk of developing chronic medical conditions that are responsible for most of the morbidity and mortality in patients on effective antiretroviral therapy, and what is the nature of the association?
- Can an effective HIV vaccine be developed?

9.8 Sexually transmitted infections

Jane Terris

ESSENTIALS

1 **Sexually transmitted infections (STIs) are among the commonest infections worldwide and account for a significant number of emergency department (ED) visits per year. ED staff should be competent to screen, diagnose and treat STIs and to notify and improve future sexual health through advice and referral.**

2 **Emergency physicians should aim to provide effective, confidential, non-judgemental and culturally appropriate care. The sexual history, where appropriate, should be normalized as part of the medical history.**

3 **Patients may be asymptomatic or may present at any stage of the STI and with multiple co-existent STIs; if missed or undertreated, these can result in chronic infection and infertility.**

4 **Constantly evolving antimicrobial resistance renders treatment regimens eventually ineffective; therefore knowledge of current local treatment guidelines is essential, as is effective treatment that is easily taken with a low side-effect profile.**

5 **The essentials of the sexual history can be summed up by the five Ps: Partners, Practices, Pregnancy, Protection, Past STIs.**

6 **Empirical treatment may have to be commenced in the ED, as screening results are rarely available at presentation; syndromic treatment in areas of high prevalence may also have to be commenced. Highly sensitive point-of care-testing is becoming more widespread.**

7 **Emerging behavioural and medical factors, such as social media–related sexual encounters as well as pre-exposure prophylaxis, may further alter the profile of STIs during the next decade.**

Introduction

Sexually transmitted infections (STIs) are among the commonest infections worldwide and continue to be a major public health problem. Over 340 million people per year contract an STI according to World Health Organization figures.[1] STIs account for a significant number of emergency department (ED) visits per year and notification rates in Australia,[2] the United Kingdom,[3] and the United States[4] currently show a year-on-year increase. However, the true incidence is difficult to ascertain in view of likely under-reporting.

EDs should aim to provide effective and confidential care in a sensitive and non-judgemental environment for patients who are unable to access a specialist STI clinic. This may be a challenge for a busy, noisy department with multiple simultaneous care priorities.

Patients will continue to use EDs to access help for their health care needs, therefore emergency physicians (EPs) must have a sound working knowledge of STI management, including screening, diagnosis, treatment, advice and notification to public health. This may be the only opportunity to intervene.

Patients may present at any stage of their disease and with multiple coexistent, STIs. A detailed and specific sexual history should be normalized within the context of the general medical history and with consideration of the individual's cultural background, using skilled interpreters where necessary.

STIs may be asymptomatic, missed or undertreated, leading to complications that may include ectopic pregnancy, chronic infection and infertility.

EPs should maintain a high index of suspicion, avoid stereotyping patients, and be prepared to treat empirically, especially in areas of high prevalence.

Patients should be referred for follow-up, including HIV and hepatitis screening.

ED patients may have high rates of asymptomatic STIs,[5] and around half of females presenting

with chlamydial infection or gonorrhoea are discharged without adequate treatment.[3] Conversely, most females presenting with vaginal discharge do not have STIs and are more likely to have candidiasis or bacterial vaginosis. Debates around whether to screen for STIs and HIV in EDs versus specialist clinics continue. The cost of screening—especially if adequate and accessible specialized facilities exist nearby and the potential for increasing antibiotic resistance with empiric treatment—must be weighed against the consequences of missed infections and the significant public health, social and economic burden of undiagnosed and untreated STIs. Alternative facilities may not be accessible at the time of presentation. There is, therefore, an important opportunity for the EP to intervene and capture these patients at presentation.

Epidemiology

STIs are increasing worldwide. There are several well-documented high-risk groups for STIs and some newly emerging patient groups. Those known to be high-risk include young people in the 15- to 24-year age group, individuals who exchange sex for money or drugs (also known as transactional sex), pregnant women and men who have sex with men (MSM). Users of erectile dysfunction medication and widowers may also be at risk.[6] STIs can affect any sexually active person and be transmitted in utero and at birth, therefore stereotyping should be avoided.

The commonest STI in Australia, the United Kingdom and the United States is infection with *Chlamydia trachomatis* (commonly called simply chlamydia), with an increase in Australia from 103 to 409 cases per 100,000 population between 2001 and 2016. The next commonest is gonorrhoea, with an increase from 31 to 101 cases per 100,000 in the same period.[2]

Syphilis is currently increasing overall in Australia, as in the United Kingdom[3] and the United States,[4] with 659 reported cases in Australia in 2005, which increased to 1285 cases in 2011.[2] Donovanosis is now rare in Australia following a successful eradication programme, although cases are still occasionally seen in Papua New Guinea, South Africa and India.

Prevention

Public health campaigns have been active around STI prevention, although rates of infection continue to increase. It is not clear whether this is linked to increased awareness and reporting, and possibly in some urban areas to newly emerging behaviours such as the rise of social media—facilitated sexual encounters.[7] Advice should include discussion around high-risk behaviour and safe sex practices. This should include effective barrier contraception in the form of latex condoms, the need to abstain from sex until STI treatment is complete and the need for regular STI screening, especially in high-risk groups. Pre-exposure prophylaxis (PreP) is another new field that may affect rates of STI transmission over the next decade.

History

Effective communication is especially important within the context of a sexual history, and patients are often embarrassed and anxious. The sexual history should take the form of a comprehensive and holistic risk screening. Wherever possible, a private, clean, comfortable cubicle with a door that closes should be used for taking the sexual history. Thought is required around the initial greeting, appropriate body language, eye contact, skilled interpreters where needed and non-verbal cues from the patient. Be prepared that this may take a little longer than the focused history often used in EDs. It may be necessary for the EP to reflect on his or her own personal attitudes toward sexual behaviour in order to normalize the sexual history within the overall medical history and make an objective assessment. Communication must take into account language, hearing difficulty and cultural context; these should be addressed.

Efforts should be made to reinforce the confidential nature of the interview in order to encourage candour. It may help to display local STI clinic posters and literature within the ED. Students and observers will need the consent of the patient to be present, and such consent is not always given owing to the sensitive nature of the interview and the need for confidentiality. A detailed and specific history is important to identify at-risk patients and ascertain which anatomic sites should be focus on for screening. The history may start with open statements and questions, such as telling the patient that it is important to ask questions around his or her sexual behaviour, and then progressing to closed questions around specifics of the five Ps of the history, as outlined further on. It may be necessary to explain clearly the need to ask certain questions in order to avoid offence. For example, explaining that asking about the gender of a partner and details of sexual practices is needed in order to offer appropriate screening tests, and that questions around partners are necessary to allow contact tracing and follow-up. The history often opens with the presenting symptoms, including discharge or genital ulcers. Further questions should ask about the characteristics of any discharge, abdominal and pelvic pain, dyspareunia, dysuria, joint and eye symptoms, bowel or urinary symptoms and skin rashes. The history should look for risk factors for STI in general and for specific features of STIs; it should also screen for complicated, disseminated or recurrent infection. A previous history of STI or partner infection and treatment and the possibility of pregnancy should be explored. It is important to adapt the questioning style to the cultural context, as many patients will be unfamiliar and uncomfortable with discussing the details of their sexual practices.

The sexual history can be summarized in terms of the five Ps: Partners, Practices, Pregnancy, Protection and Past STIs (Table 9.8.1). The skill of taking a focused sexual history, including the following points, in the time available in ED takes practice.

Partners

Ask how many in the past year and how many in the past 3 months, what gender, current length of relationship, risk factors of partners (e.g. intravenous drug use), seroconcordance if HIV is confirmed in the patient or partners, and other partners outside the relationship. The practice of multiple sexual partners over several days, often accompanied by recreational drug ingestion—known as 'chemsex'—is becoming recognized as a new risk factor for STIs among MSM.[7]

Practices

Number and genders of recent partners within the past 3 months, whether condoms are used (always, sometimes, never); whether sexual acts are vaginal, anal insertive, anal receptive or oral; other practices and with whom.[7] A history of recent travel may identify infections in areas where specific pathogens or antibiotic resistance are known.

Table 9.8.1 Essentials of the sexual history

The five Ps of the sexual history	*Essential points to cover*
Partners	Last 3 months who, how many, where from, risk factors in partners?
Practices	Is sexual contact vaginal, oral, anal and with whom? Are condoms used sometimes, always, never?
Protection	How is risk reduced (e.g. monogamy, condoms)?
Pregnancy	Plans around becoming or preventing pregnancy and details of contraception used
Past STIs	In patient and partners—what infections, when and how were they treated, how were they followed up? Screening since?

STIs, Sexually transmitted infections.

Pregnancy

Assess for current risk of pregnancy, which may affect treatment options and follow-up, whether contraception is used or not and what type, any pregnancy-related symptoms, including last menstrual period. All females of childbearing age should have a pregnancy test. The need for emergency contraception should be assessed and a cervical cytology history taken.

Protection

It is useful to ask what the patient does to protect himself or herself from STIs and HIV, including monogamy, condoms, safer sexual practices, PreP; also to gauge the patient's perception of his or her own and the partners' risks.

Past sexually transmitted infections

Previous STIs may indicate higher-risk behaviour and also repeat infection. Ask specifically whether the patient has ever had or been treated for gonorrhoea, chlamydia or any other STI, including HIV testing and results, and about hepatitis testing and results.

General principles of examination and screening

Following the full sexual history, a comprehensive STI check should be offered.

A chaperone should be available for all intimate examinations. Examination should be performed in a comfortable private cubicle with a door that closes and, preferably, with screens available for additional privacy. A good light source is essential and swabs and specimen pots should be readily available.

General physical examination—including the mouth, pharynx, lymph nodes and skin—should then be followed by genital examination. This should include palpation for inguinal lymph nodes, careful inspection of the genital and perianal areas for discharge, papules, ulcers, warts, lice or nits; and signs of local trauma. Examination beneath the foreskin in the male is important, as is inspection of the urethral meatus for lesions and discharge. The scrotum, testes and epididymis should be examined for lesions and tenderness and the anorectal area examined, including a digital exam and proctoscopy considered in patients at risk of rectal disease or presenting with anorectal symptoms.

Examination of the vulva, Bartholin glands, vagina, cervix and perianal area is important in the female and should include bimanual pelvic examination to assess for tenderness and masses. A pregnancy test should be performed on all women of childbearing age.

It is important to confirm with the laboratory which specimen tubes and transport media are needed for which tests and how specimens should be stored; for example gonorrhoea swabs should be kept at room temperature. A ready-made testing pack supplied by the laboratory is useful and will generally include swabs with charcoal transport medium for urethral and high vaginal smear and culture, glass slides for high vaginal or urethral smear, wire cotton-tipped swabs with a plastic shaft tube for chlamydia, gonorrhoea and herpes. The nucleic acid amplification test (NAAT) is now becoming highly accurate and may replace other testing methods in time. Clotted blood tubes are used for serological tests. Specimen collection is a specialist skill upon which the diagnosis rests, and advice from laboratory staff prior to collection is invaluable. Swabs should be taken from the appropriate areas, as detailed further on, for microscopy, culture and sensitivity (M, C and S) and NAAT for chlamydia, gonorrhoea, trichomonas and other organisms as indicated. This may include the genital area, anorectal area and pharynx. Best practice in specimen collection may require extra training and updates by genitourinary medicine clinicians. A badly collected and transported specimen is unhelpful and even harmful if treatment is incorrect as a result. Current local guidelines should be used for specimen collection, transport and storage.

Urine should be sent as first void specimen for M, C and S and NAAT testing for specific organisms and a midstream specimen for general M, C and S. Swab or lesion scrapings should be sent if ulcers are present. Blood should be taken for syphilis, HIV and hepatitis serology.

Clinical features of specific infections

STIs may be asymptomatic or may present with constitutional or focal symptoms (Table 9.8.2). Focal symptoms are commonly those of urethritis, cervicitis or genital ulcers. Disseminated infection may present with skin rash or with joint or eye symptoms. Not considering an STI in the differential diagnosis of a skin, joint, bowel or other generalized presentations will lead to missed diagnoses. One or more STIs may coexist and, as the clinical features may be indistinguishable, empirical treatment, especially in males in areas of high prevalence, is indicated. Syndromic treatment, according to symptoms, has been shown to be neither sensitive nor specific in females presenting with vaginal discharge because most cases of vaginal discharge are not caused by STIs and many STIs in females are asymptomatic. In areas of high prevalence, a judgement should be made as to whether symptoms are likely to be STI-related and whether treatment is indicated prior to results. Around one-third of cases of vaginal discharge presenting to ED remain undiagnosed pathologically,[8] which may reflect inadequate specimen sampling or possibly other non-infective physiological causes.

Infections presenting with discharge, urethritis and cervicitis

These symptoms may be caused by chlamydia, gonococcus, *Trichomonas vaginalis*, *Ureaplasma urealyticum* and *Mycoplasma genitalium* (MG). Occasionally genital herpes may cause discharge, although this is seldom the only symptom. *Candida* and bacterial vaginosis also present with discharge, although these are not classically STIs.

Chlamydia

Chlamydia is the most common STI in Australia, the United Kingdom and the United States. It is caused by the organism *Chlamydia trachomatis* and often coexists with gonorrhoea and other STIs. Chlamydia is often asymptomatic, especially in women,[3,9] and may be carried at extra-genital

Table 9.8.2 Clinical presentation of sexually transmitted infections and differential diagnosis

Symptoms	*Differential diagnosis*	
Vaginal discharge	*Candida albicans* *Trichomonas vaginalis* *Neisseria gonorrhoeae* *Chlamydia trachomatis* Herpes simplex Bacterial vaginosis	
Urethritis or cervicitis	*Neisseria gonorrhoeae* *Chlamydia trachomatis* *Mycoplasma genitalium* *Ureaplasma urealyticum* *Trichomonas vaginalis*	
Genital ulcers	Syphilis Chancroid LGV Donovanosis Herpesvirus	Primary chancre, secondary ulcers, tertiary gumma

LGV, Lymphogranuloma venereum.

sites in asymptomatic MSM.[7] This leads to under-diagnosis and under-treatment, which may result in long-term complications, including pelvic inflammatory disease (PID) and infertility. Screening in sexually active females under 25 years of age and in older females with new or multiple sexual partners as well as in other high-risk groups is advised.[7] Symptoms and signs, if present, are most commonly a mucopurulent cervical, urethral or vaginal discharge, intermenstrual bleeding and dysuria in females, or symptoms of urethritis, proctitis and epididymitis in males, including urethral discharge, itching, dysuria and sterile pyuria. Males may present with Reiter syndrome.

Diagnosis is made by NAAT and Gram stain of discharge or first voided urine for NAAT.

Treatment for uncomplicated infection is with azithromycin 1 g oral as a single dose. If PID is likely, ceftriaxone 500 mg IM once and metronidazole 400 mg oral bd for 14 days should be added. Antibiotic resistance and regional sensitivities may alter and current local guidelines should always guide treatment.

Gonorrhoea

Gonococcal infections are increasing and are the second most common STI in Australia,[2] the United Kingdom[3] and the United States.[4] Of the 24,000 new diagnoses in Australia in 2016, most were in young men in the 20- to 29-year age group. They are caused by the gram-negative intracellular diplococcus *Neisseria gonorrhoeae*, which has an incubation period of 10 to 14 days. Infection in females is often asymptomatic and may coexist with chlamydia. Untreated gonococcal infection may lead to PID and ectopic pregnancy in females and epididymitis and prostatitis in males. Symptomatic presentation is usually with purulent penile discharge in males and pelvic discomfort and mucopurulent cervicitis in females. Rectal infection is seen in up to 50% of females and is more common in MSM,[7] as is pharyngeal gonorrhoea, which is often asymptomatic. Gonococcal infections may disseminate to cause constitutional symptoms of fever and malaise as well as focal signs of septic arthritis, tenosynovitis and a distinctive skin rash of pustular lesions on an erythematous base on the palms and fingers.

Diagnosis is by NAAT testing of swabs and urine, with swabs taken also at extra-genital sites according to the history. A suggested treatment regimen may be found in Table 9.8.3, although local sensitivities and antibiotic resistance mandates current local knowledge and microbiology advice. Gonococcal antibiotic sensitivities change rapidly, with fluoroquinolone resistance widely documented, and some regions, for example the Northern Territory of Australia and Southeast Asia, have penicillin-sensitive strains.

Table 9.8.3 Treatment guideline summary

Clinical diagnosis and pathogen	*Recommended treatment*	*Alternative choice treatment*
Chlamydia **(uncomplicated)**	Azithromycin 1 g PO once	Doxycycline 100 mg bd oral 7 days
Gonorrhoea Genital, pharyngeal, rectal	Ceftriaxone 500 mg IM once plus azithromycin 1 g PO once	If acquired from Top End or Central Australia, amoxicillin 3 g plus probenecid 1 g PO once
Trichomoniasis	Metronidazole 2 g PO once OR tinidazole (not in pregnancy) 2 g PO once	
Pelvic inflammatory disease	Ceftriaxone 500 mg IM once PLUS Azithromycin 1 g PO once PLUS Metronidazole 400 mg PO, bd for 14 days PLUS Doxycycline 100 mg oral bd for 14 days	
Bacterial vaginosis	Metronidazole 400 mg PO bd for 7 days	
Urethritis, dysuria, urethral discharge	Ceftriaxone 500 mg IM once PLUS Azithromycin 1 g PO once OR Doxycycline 100 mg PO bd for 7 days	Erythromycin 500 mg PO qds for 7 days
Chancroid	Azithromycin 1 g PO once OR Ceftriaxone 500 mg IM once	Ciprofloxacin 500 mg PO, bd for 3 days
Lymphogranuloma venereum	Doxycycline (not in pregnancy) 100 mg PO, bd for 21 days	Erythromycin 500 mg oral qid for 21 days OR Azithromycin 1 g PO 1 dose weekly for 3 weeks
Donovanosis	Azithromycin 1 g PO once weekly or 500 mg qd for 3 weeks or until lesions have healed	Co-trimoxazole 160/800 mg bd PO 3 weeks
Mycobacterium G	Doxyclcline, azithromycin and moxifloxacin	
Herpes Anogenital, primary episode	Valacyclovir 500 mg PO, bd for 7–10 days	
Anogenital, recurrent episode	Valacyclovir 500 mg PO, bd for 3 days	
Severe, disseminated infection	Acyclovir 5–10 mg/kg IV q 8 h for 5–10 days	
Genital warts		
External genital and perianal	Podophyllin 0.5% lotion topical tds for 3 days, then no treatment for 4 days, repeat 4 cycles or until resolution	
Mucosal warts	Cryotherapy or trichloroacetic acid 80% topical weekly for 2 weeks	Podophyllin resin 25% in benzoin topical for urethral meatus warts once weekly for 2 weeks
Syphilis		
Primary, secondary, early latent, late latent or >2 years' duration	Benzathine penicillin G 2.4 million U IM, with 2 mL 1% lignocaine once	

Trichomoniasis

This infection occurs mainly in females and is caused by the protozoan *Trichomonas vaginalis*. The incubation period is up to 1 month. Infection may be asymptomatic or may present with genital irritation and vaginal discharge or urethritis in males. The discharge is rarely frothy and green-coloured but, more commonly, clear and offensive. Other symptoms may include dysuria, dyspareunia and pelvic pain. Untreated trichomoniasis may cause PID. Diagnosis is by visualization of the protozoa within 20 minutes if a wet mount is readily available, but more accurate diagnostic methods include high vaginal or urethral swabs for NAAT. Treatment is with metronidazole 2 g PO as a single dose or tinidazole 2 g PO if the patient is female and not pregnant. PID should be treated with combination antibiotics, as described previously. Antibiotic resistance and regional sensitivities may alter and current local guidelines should always be consulted.

Mycoplasma genitalium

This organism was identified in the 1980s; it is slow-growing and difficult to culture. MG is thought to account for up to 30% of persistent urethritis in men and PID in women. NAAT testing of urine, urethral and vaginal swabs is currently preferred for MG. In view of the difficulty isolating and diagnosing MG, treatment may have to be syndromic as part of urethritis or PID treatment. Treatment with azithromycin 1g as a single dose may be effective, although resistance is high and moxifloxacin and doxycycline may be used as second-line therapy. Current local treatment guidelines should always be considered.

Urethritis or urethral discharge in males

This is usually caused by gonorrhoea or chlamydia but may also be due to *U. urealyticum*, MG, *T. vaginalis* or herpesvirus. Diagnosis is made by the clinical history (although this will not indicate the causative organism) plus urethral swab and first void urine specimen for NAAT, culture and cell count. Midstream urine should be sent for general M, C and S, as UTI, especially in older males, may be the cause. Consider swabbing extra-genital sites also, depending on the history. Treat empirically if the STI is likely to be gonorrhoea and/or chlamydia, as per current local guidelines.

Candidiasis

Vaginal candidiasis may feature in the differential diagnosis of STIs causing irritation and discharge but it is generally not a STI. It is caused by the fungus *Candida albicans* in most cases and characterized by an itchy white, curd-like discharge. Swabs for Gram stain or wet mount specimens may confirm the diagnosis by visible yeasts and pseudohyphae. Treat with clotrimazole 500 mg as a single-dose vaginal pessary or fluconazole 150 mg PO single dose.

Bacterial vaginosis

Bacterial vaginosis is not caused by any one specific organism and may occur in women who are not sexually active. It is associated with having multiple sexual partners and is a differential diagnosis of STI-related vaginal discharge. It is characterized by an overgrowth of normal vaginal flora by anaerobic bacteria and may be asymptomatic or present with discharge. Diagnosis is by Gram stain, combined with the characteristic thin, offensive discharge and clue cells on microscopy. Treat with metronidazole 400 mg bd PO for 7 days.

Infections presenting with genital ulcers

Genital ulceration may be caused by the herpesvirus, syphilis and, rarely, chancroid, lymphogranuloma venereum (LGV) and lymphogranuloma inguinale (Donovanosis). These infections have higher rates of HIV co-transmission. Genital ulceration may rarely be caused by malignancy and referral should be made for any lesion that does not respond to treatment. There are reports of an increase in vulval cancer in young indigenous Australian females.[10]

Herpes simplex (e-Fig. 9.8.1)

The widespread introduction of the herpes simplex virus (HSV) vaccination programme for schoolgirls in 2007 and schoolboys in 2013 has seen a 90% reduction in HSV-related genital lesion presentations from 2007 to 2016 in Australia and the United Kingdom, with similar programmes internationally.[2,3]

HSV infections are still common worldwide, although most are asymptomatic. Genital ulceration is more commonly caused by HSV type 2 and occurs in up to one-quarter of patients who are seropositive for the virus. HSV type 1 generally causes oro-labial blisters but may also cause genital ulceration identical to HSV-2. Subclinical infections may spread by viral shedding during sex. The primary outbreak of genital ulceration is usually accompanied by constitutional symptoms of fever, malaise, headache and painful bilateral regional lymphadenopathy, which may precede the ulceration by 1 or 2 days. Prodromal tingling or paresthesia in the affected dermatomes may occur. The lesions are initially vesicular with an itchy, erythematous base; they then become ulcerated before forming a scab. They may occur around the vulva, anus, thighs or buttocks in women and on or around the penis, perianal area, thighs and buttocks in males. They are usually very painful, and adequate analgesia is important. Females may experience urinary retention due to the pain of voiding and sacral radiculopathy and may require admission for catheterization and intravenous anti-viral treatment. The virus is shed for up to 2 weeks after the rash appears and lesions usually heal within 3 weeks. Recurrent episodes are generally less severe. Genital herpes is diagnosed by the characteristic clinical features and confirmation may be possible from viral swabs of lesion fluid, although treatment should be commenced empirically. Severe or disseminated infection should be treated by high-dose intravenous anti-virals with a duration adequate to ensure lesion healing. The patient should be informed that treatment does not cure and that there may be recurrent episodes. Future episodes can be attenuated if treatment is commenced at the onset of symptoms. Frequent recurrences (more than six per year) may indicate the need for prophylactic antiviral therapy. Diagnosis is clinical and confirmation is by dry swab of the ulcer base or blister fluid for NAAT. Treatment is with valacyclovir 500 mg bd for 7 to 10 days for the primary episode or 3 days for recurrent episodes. Local guidelines should be followed for current drug regimens.

Chancroid

Chancroid is a disease seen mainly in Asia, Africa and the Caribbean, with few cases reported in the developed world. There have been very few reports in Australia for the decade up to 2016. It is caused by the gram negative bacillus *Haemophilus ducreyi* and presents with painful genital ulcers up to 2 cm diameter. Painful inguinal lymph nodes may go on to suppurate if the infection is untreated. Chancroid may coexist with other genital ulcerating infections including syphilis and HSV. Unlike herpes, chancroid is rarely accompanied by constitutional symptoms and is rarely recurrent. Diagnosis is generally clinical, although lesion swabs for culture and NAAT may confirm the diagnosis. Treatment may be with azithromycin 1 g PO single dose or cefrtiaxone 500 mg IM single dose and should follow current local guidelines.

Lymphogranuloma venereum

LGV is caused by *Chlamydia trachomatis* and is endemic in parts of Africa, South America, India, Southeast Asia and the Caribbean. It is rarely seen in the developed world with the exception of sporadic outbreaks since 2003, predominantly among MSM who are HIV-positive. It presents either with proctitis or may be asymptomatic. There are three clinical stages. The initial presentation with a painless ulcer or papule may be missed. The second stage involves painful inguinal lymphadenopathy, which is commonly unilateral. The third stage involves strictures, fistulae and scarring around the perianal area. Diagnosis is clinical and by NAAT of vulvovaginal swabs in females or urethral swabs in males or NAAT of first-catch early morning urine in both.

Treatment is according to current local guidelines, with a suggested regimen of doxycycline 100 mg PO bid for 21 days or erythromycin 500 mg qid for 21 days.

Donovanosis

This is now a rare infection, although there are pockets of increased prevalence in desert areas of central Australia and in rural tropical and subtropical areas including Southeast India, South Africa, Papua New Guinea and the Caribbean. Only two cases have been reported in Australia since 2011.[2] It is caused by *Klebsiella granulomatis* and is seen more commonly in males. The incubation period is up to 12 weeks. Red papules in the genital and perianal areas evolve into nodules of friable granulation tissue that bleed easily. The initial lesions may resemble chancroid and progress to spread and necrose; if untreated, there may be loss of genital tissue and depigmentation. Diagnosis is generally clinical and may be confirmed by lesion swab or scraping for NAAT, although specialized laboratory services may be required for testing. Treat according to current local guidelines, which may include azithromycin 1 g PO weekly for at least 4 weeks or until the lesions are fully healed.

Syphilis (e-Figs. 9.8.2-9.8.4)

Syphilis is currently increasing worldwide in Australia, the United Kingdom and the United States, especially among MSM. The causative organism is the spirochaete *Treponema pallidum*. Patients may present with symptoms in any of the three stages of primary, secondary or tertiary infection or may present in the latent phase. Primary syphilis has an incubation period of up to 90 days, which is thought to be dose dependent, with larger inoculations presenting sooner.[7] It classically presents with a painless genital ulcer known as the primary chancre. This may last for up to 6 weeks and is not accompanied by constitutional symptoms. If untreated, the primary stage may evolve into the secondary stage within 6 weeks, characterized by the distinctive macular pink rash that may resemble pityriasis rosea. It may be present on the flexor surfaces, trunk, palms and soles. The secondary stage is often accompanied by constitutional symptoms of fever, malaise and headache. Tertiary syphilis occurs up to 20 years after the primary infection in around one-third of patients with untreated secondary syphilis. The presentation includes widespread granulomas, known as gummas, or may present with meningitis, dementia, thoracic aneurysm or neuropathy, known as tabes dorsalis. There may be extensive involvement of the cardiovascular and nervous systems.

Diagnosis depends on serological confirmation of treponemal or non-treponemal tests. Treponemal tests remain positive for life. Non-treponemal tests respond to treatment. An NAAT for syphilis may be requested from swabs or scrapings from rash or ulcers. Treatment is according to current local guidelines, typically including benzathine penicillin 2.4 million units IM as a single dose if the infection is under 2 years in duration or three doses at weekly intervals if over 2 years in duration. There is no documented treponemal resistance as yet to penicillin, although treatment failures have occurred occasionally and are thought to be either re-infection or individual variation in decline of the non-treponemal test titres in response to treatment.

Notification of cases should be sent to the regional syphilis register.

Genital warts

Genital warts are caused by the human papillomavirus. Since 2003, new diagnoses have fallen by over 90% among the immunized population of young adults. Up to three-quarters of non-immunized sexually active adults are infected, although most infections are subclinical. Multiple warts, which may cluster, are seen over the vulva and penis. Internal warts may be seen in the rectum and around the cervix. Diagnosis is clinical and the differential diagnosis of molluscum contagiosum, secondary syphilis (condylomata) and carcinoma must be considered. Treatment is with podophllin 0.5% lotion applied twice daily to lesions for 3 days, then no treatment for 4 days, and repeat until lesions resolve. This may take four or more cycles of treatment.

Principles of clinical investigations

Diagnosis is initially clinical and treatment may need to be empirical. Attempts should be made to confirm the diagnosis by laboratory analysis of swabs and urine, and it is important to communicate with laboratory staff to discuss the collection, transport and testing of specimens and the specific type of swab, transport medium and temperature for each organism. All specimens should be correctly labeled with patients' details in leakproof containers. NAAT is now seen as the gold standard for confirmation of many STIs and has the advantage of first-voided early-morning urine collection. Swabs from possible affected areas for M, C and S and swabs and urine for NAAT should be taken. Serum for syphilis, HIV and hepatitis serology should be sent and referral should be considered for cervical cytology in females.

If lesions are suggestive, scraping the lesion for syphilis microscopy and specialist swabs for HSV and *H. ducreyi* may be helpful.

Overall, it is unlikely that most emergency medicine clinicians will become expert STI specimen collectors without additional training; either modular training delivered in the ED or specialist clinic rotation may increase the yield of diagnostically useful ED specimens.

Treatment

See Table 9.8.3 for an example summary guideline.

Treatment is subject to current local guidelines and sensitivities and may vary according to regional strains and sensitivities. Where the infection likely originated is an important part of the history. Always refer to current local guidelines.

Follow-up

Referral to a local STI clinic for follow-up, contact tracing and treatment of partners is essential to stop the spread of STIs.

The patient should be advised of the need for partner treatment and abstinence from sex until the infection has been treated adequately. The opportunity for health education around safer sexual practices and STI prevention should be taken. Notifiable diseases include chlamydia, gonorrhoea, syphilis, chancroid, LGV and Donovanosis.

CONTROVERSIES AND FUTURE DIRECTIONS

- There are conflicting views over whether the ED is the right place to screen for STIs including HIV, although in some cases an ED visit may offer the only opportunity for diagnosis and treatment.
- Debate continues over whether to treat infections empirically and the potential for increasing antibiotic resistance versus the burden of untreated disease. Syndromic treatment in areas of low prevalence may be more effective in males, as most cases of vaginal discharge in females are not STI-related.
- Highly sensitive point-of-care testing is becoming more readily available and will shorten time to diagnosis and treatment.
- The rise of social media–facilitated sexual encounters, mainly in major cities among MSM over the past few years, is a new high-risk sexual behaviour for STI transmission[7]
- Pre-exposure prophylaxis for HIV and STIs is gaining momentum and is likely to alter the landscape of STI transmission and sexual habits over the next decade.
- Constantly changing antibiotic sensitivities mandate the consideration of current local treatment guidelines and close liaison with colleagues in sexual health, infectious disease, microbiology and virology.

9.9 Antibiotics in the emergency department

John Vinen

ESSENTIALS

1 **Patients with infections and infectious diseases commonly present to emergency departments.**

2 **There are also changing patterns of infectious disease, largely due to immunosuppression from chemotherapy, continuing development of bacterial resistance, HIV-associated infections and new and emerging infections.**

3 **Many bacteria are becoming increasingly resistant to available antimicrobials, with some resistant to multiple agents including many community-acquired infections.**

4 **The growing world trade in wildlife, factory farming, increasing air travel and increased population density increases the risk of infectious disease transmission.**

5 **There are relatively few new antimicrobials to counter these changing patterns of resistance.**

6 **Antimicrobial prescribing should follow evidence-based guidelines or infectious disease consultant advice.**

7 **Some patients with infection can be treated wholly as outpatients using parenteral therapy or after early discharge once the acute toxic phase is over.**

8 **Early administration of guideline-based antibiotics combined with supportive therapy is the key to a good outcome in patients with serious infections.**

9 **The increasing incidence of terrorism may result in patients presenting with novel, unusual or clusters of infections caused by biological agents.**

Principles of antimicrobial therapy

Antibiotic stewardship

The first decision to be made regarding antimicrobial therapy is whether the administration of these agents is truly indicated. The growing incidence of antibiotic resistance is rapidly increasing. In many cases, antibiotics are administered without clear indications. This practice is potentially dangerous, as some agents can cause serious toxicity or allergic reactions, diagnoses may be masked if appropriate cultures are not taken prior to therapy, serious adverse events can result and microorganism resistance may emerge.

Ideally, antibiotic therapy is determined by the isolation of the organism(s) involved and determination of the antibiotic susceptibility pattern. As this information is rarely available, it is necessary to make treatment decisions without precise knowledge of the infectious source or microbial species, in which case empiric treatment is commenced based on the type of infection (if known) and the likely organisms involved utilizing recognized guidelines.

In specific situations (e.g. suspected meningitis, meningococcal infection, necrotizing fasciitis, sepsis, peritonitis, febrile neutropaenia and pneumonia), early empiric therapy can be lifesaving.

The choice of an appropriate antimicrobial agent requires consideration of the following factors.

The microorganism

The identity of the infecting organism(s) needs to be identified or suspected. In the emergency department (ED) setting, almost all antimicrobial decisions will be made without the benefit of cultures, with treatment commencing based on the most likely to cause infection in a given clinical setting.[1] However, certain 'rapid methods' of microbial identification may be employed. These include Gram-stain preparations (bacterial, some fungal and leucocyte identification) and immunological methods for antigen detection (enzyme-linked immunoabsorbent assay, latex agglutination, polymerase chain reactions).

Another way of guiding appropriate use and prescription of antibiotics is to use defined criteria, examples are shown in Box 9.9.1.

Other examples include:

- Systemic inflammatory response syndrome (SIRS), Sepsis and Septic Shock Criteria
- Renal, age, purulence, infection source, and dietary factors (RAPID) for pleural infection

Microorganism susceptibility

This information is unlikely to be available and therapeutic decisions will generally be based on evidence-based guidelines and a knowledge of likely susceptibilities.[1] For example, group A streptococci remain susceptible to the penicillins

and cephalosporins, and virtually all anaerobes (except *Bacteroides* spp.) are susceptible to penicillin G. However, when the identity or susceptibility of the infecting organism is sufficiently in doubt, the patient's clinical condition is atypical, serious or potentially serious or where antimicrobial resistance is suspected, it is good practice to obtain appropriate specimens for culture and susceptibility testing prior to empirical broad-spectrum antimicrobial therapy (Table 9.9.1).

Host factors

An adequate history of drug allergies must be obtained to prevent the administration of an antimicrobial that may have serious or fatal consequences. Where this is not possible, avoid the administration of penicillin and associated antimicrobials. The age of the patient may have clinically significant effects on drug absorption (e.g. penicillin absorption is increased in the young and the elderly),[2] metabolism (e.g. reduced chloramphenicol metabolism in the neonate)[2] and excretion (e.g. declining renal function with age[3] may reduce the excretion of penicillins, cephalosporins and aminoglycosides). Furthermore, tetracyclines bind and discolour the developing bone and tooth structures in children aged 8 years or less.[2] Pregnant women and nursing mothers may pose certain problems in the selection of appropriate

Table 9.9.1 Antimicrobial agents of choice in selected infections

Microorganism	*Diseases*	*First choice*	*Second choice*
Gram positive cocci			
Staphylococcus aureus[a]	Abscesses penicillinase-negative: Osteomyelitis	Benzylpenicillin (penicillin G), phenoxymethyl penicillin (penicillin V)	Cephalosporin (G1), clindamycin
	Bacteraemia penicillinase-positive:	Nafcillin, oxacillin	Cephalosporin (G1)
	Endocarditis		Vancomycin, clindamycin
	Pneumonia methicillin-resistant:	Vancomycin ± rifampicin	Co-trimoxazole + rifampicin
	Cellulitis		Ciprofloxacin + rifampicin
Streptococcus (A, B, C, G and *bovis*)	Pharyngitis, scarlet fever, otitis media, cellulitis, erysipelas, pneumonia, bacteraemia, endocarditis, meningitis	Benzylpenicillin (penicillin G), phenoxymethylpenicillin (penicillin V), ampicillin	Erythromycin Cephalosporin (G1) Vancomycin
Streptococcus pneumonia[a]	Pneumonia, arthritis, sinusitis, otitis media, meningitis, endocarditis	Benzylpenicillin (penicillin G), phenoxymethylpenicillin (penicillin V), ampicillin, penicillin G	Erythromycin, cephalosporin (G1–3) Vancomycin + rifampicin Ceftriaxone
Streptococcus viridians[a]	Bacteraemia, endocarditis	Benzylpenicillin (penicillin G) ± gentamicin	Ceftriaxone, vancomycin ± gentamicin
Enterococcus	Bacteraemia, endocarditis, urinary tract infection	Ampicillin + gentamicin, benzylpenicillin (penicillin G) + gentamicin	Vancomycin + gentamicin, nitrofurantoin Fluoroquinolone, ampicillin + clavulanic acid
Gram negative cocci			
Moraxella catarrhalis	Otitis, sinusitis, pneumonia	Co-trimoxazole	Cephalosporin (G2,3)
		Amoxicillin + clavulanic acid	Erythromycin, tetracycline
Neisseria gonorrhoeae	Gonorrhoea, disseminated disease	Ceftriaxone, ampicillin + probenecid	Ciprofloxacin, doxycycline spectinomycin
Neisseria meningitides	Meningitis, carrier state	Benzylpenicillin (penicillin G) rifampicin	Cephalosporin (G3), chloramphenicol
Gram positive bacilli			
Clostridium perfringens[a]	Gas gangrene Tetanus	Benzylpenicillin (penicillin G)	Clindamycin, metronidazole, cephalosporin
Clostridium tetani	Tetanus	Benzylpenicillin (penicillin G), vancomycin	Doxycycline, clindamycin
Clostridium difficile	Antimicrobial-associated colitis	Metronidazole (oral)	Vancomycin (oral)
Corynebacterium diphtheriae	Pharyngitis, tracheitis, pneumonia	Erythromycin	Benzylpenicillin (penicillin G), clindamycin
Listeria monocytogenes	Meningitis, bacteraemia	Ampicillin ± gentamicin	Co-trimoxazole, erythromycin

Table 9.9.1 Antimicrobial agents of choice in selected infections—cont'd

Microorganism	*Diseases*	*First choice*	*Second choice*
Gram negative bacilli			
Brucella	Brucellosis	Doxycycline + gentamicin	Co-trimoxazole + gentamicin/ rifampicin
Campylobacter jejuni[a]	Enteritis	Fluoroquinolone	Erythromycin, azithromycin
Escherichia coli[a]	Urinary tract infection, bacteraemia	Ampicillin, co-trimoxazole,	Ampicillin + gentamicin
		cephalosporin (G_1)	Fluoroquinolone, nitrofurantoin
Enterobacter species	Urinary tract and other infections	Fluoroquinolone imipenem	Gentamicin + broad-spectrum penicillin, co-trimoxazole
Haemophilus influenza[a]	Otitis, sinusitis, pneumonia	Co-trimoxazole, ampicillin, amoxicillin	Amoxicillin + clavulanic acid, azithromycin, Cefuroxime
	Epiglottitis, meningitis	Cephalosporin (G_3)	Chloramphenicol
Klebsiella pneumonia[a]	Urinary tract infection, pneumonia	Cephalosporin ± gentamicin	Co-trimoxazole, fluoroquinolone
Legionella pneumophila	Legionnaires disease	Erythromycin ± rifampicin	Ciprofloxacin, azithromycin, co-trimoxazole
Pasteurella multocida	Animal bite infections, abscesses, bacteraemia, meningitis	Benzylpenicillin (penicillin G) amoxicillin + clavulanic acid	Doxycycline, cephalosporin
Proteus mirabilis[a]	Urinary tract and other infections	Ampicillin, amoxicillin	Cephalosporin, co-trimoxazole, gentamicin
Proteus (other species)[a]	Urinary tract and other infections	Cephalosporin (G_3), gentamicin	Co-trimoxazole, fluoroquinolone
Pseudomonas aeruginosa[a]	Urinary tract infection, pneumonia, bacteraemia	Broad-spectrum penicillin ± gentamicin	Ceftazidime ± gentamicin Fluoroquinolone ± gentamicin
Salmonella species[a]	Typhoid fever, paratyphoid fever, bacteraemia, gastroenteritis	Fluoroquinolone, ceftriaxone	Ampicillin, co-trimoxazole, chloramphenicol
Shigella[a]	Acute gastroenteritis	Fluoroquinolone	Ampicillin, co-trimoxazole
Vibrio cholera	Cholera	Doxycycline, fluoroquinolone	Co-trimoxazole
Miscellaneous agents			
Chlamydia species	Pneumonia, trachoma, urethritis, cervicitis	Doxycycline	Azithromycin, erythromycin
Mycoplasma pneumonia	Atypical pneumonia	Erythromycin, doxycycline	Azithromycin
Pneumocystis carinii	Pneumonia in impaired host	Co-trimoxazole	Trimethoprim + dapsone, pentamidine
Rickettsia	Typhus fever, Q fever,	Doxycycline	Chloramphenicol
	Rocky Mountain spotted fever		
Treponema pallidum	Syphilis	Benzylpenicillin (penicillin G)	Ceftriaxone, doxycycline

[a] G_1, First-generation cephalosporin; G_2, second-generation cephalosporin; G_3, third-generation cephalosporin. All strains should be examined *in vitro* for sensitivity to various antimicrobial agents.

antimicrobial agents, as all of these agents cross the placenta to varying degrees. The administration of antibiotics to pregnant patients must be based on guidelines.[4] Whether or not antibiotic use has an effect on the efficacy of combined oral contraceptive pills (OCPs) has been a matter of controversy. A significant pharmacokinetic interaction between combined OCPs and antibiotics, apart from rifampicin and griseofulvin, has not been proven. It has been suggested that if an interaction does exist, it is likely that it occurs in a small number of predisposed individuals. It is not possible at this time to predict who is at risk for potential interaction.[5] Other host factors that may require consideration include the patient's renal and hepatic function, their genetic (e.g. liver acetylation rate) or metabolic abnormalities (e.g. diabetes mellitus) and the site of the infection.[6]

Route of administration

In general, the oral route is chosen for infections that are mild and can be managed on an outpatient basis. In this situation, consideration needs to be given to compliance with treatment, the variability of absorption with food in the stomach and interaction of the agent with concomitant medications.[7] The parenteral route is used for agents that are inefficiently absorbed from the gastrointestinal tract and for the treatment of patients with serious infections in whom high concentrations of antimicrobial agents are required.[7] Intramuscular administration (not in patients on anticoagulants or who are coagulopathic) will provide adequate serum concentrations for most infections and may be appropriate where antimicrobial depots are desirable; for example, procaine penicillin injections where patient compliance with oral medication is doubtful. Intravenous administration allows

large doses of drugs to be given with a minimal amount of discomfort to the patient; for example, infection prophylaxis in compound fractures, life-threatening infections and shock. For intravenous administration, large veins should be used followed by saline flushing of the veins to help to minimize the incidence of venous irritation and phlebitis.

Supportive care

Supportive care in association with antimicrobial therapy is essential in many infections, fluid resuscitation, vasopressors and compliance with sepsis guidelines being essential for a good outcome in suspected sepsis/sepsis.[8]

Adverse drug events involving antibiotics

Antibiotics are one of the top medication classes resulting in ED visits for adverse drug events.

There is a 1:1000 risk that an individual prescribed an antibiotic will require a visit to the ED because of an antibiotic side effect.

Antibiotics are responsible for 19% of ED visits for adverse drug events:

- in children (<18 years), antibiotics are the most common cause of ED visits for adverse drug events
- 79% of ED visits for documented antibiotic-associated adverse drug events are due to allergic reactions.[9]

Antibiotic resistance

Bacteria can be resistant to an antimicrobial agent because the drug fails to reach the target or is inactivated or because the target is altered.[10–12] Bacteria may produce enzymes that inactivate the drug or have cell membranes impermeable to the drug. Having gained entry into the microorganism, the drug must exert a deleterious effect. Natural variation or acquired changes at the target site that prevent drug binding or action can lead to resistance.

Resistance is most commonly acquired by the horizontal transfer of resistance determinants from a donor cell, often of another bacterial species, by transformation, transduction or conjugation. Resistance also may be acquired by mutation and passed vertically by selection to daughter cells. Antimicrobial agents can affect the emergence of resistance by exerting strong selective pressures on bacterial populations favouring those organisms capable of resisting them.[13]

The increasing emergence of antibiotic resistance is a very serious development that threatens the end of the antibiotic era. Penicillin-resistant strains of pneumococci account for >50% of isolates in some European countries. The worldwide emergence of *Haemophilus* and gonococci that produce β-lactamase is a major therapeutic problem.[14] Methicillin-resistant strains of *Staphylococcus aureus* (MRSA) are widely distributed among hospitals and are increasingly being isolated from community-acquired infections.[15] There are now strains of enterococci (vancomycin-resistant Enterococcus), *Pseudomonas* and enterobacters that are resistant to all known drugs.[16] Epidemics of multiple drug-resistant strains of *Mycobacterium tuberculosis* are increasingly being reported.[16]

A more responsible approach to the use of antimicrobial agents is essential to slow the development of multidrug-resistant organisms. Their use is unnecessary in viral infections; their use in prophylaxis and in established bacterial infections must be on evidence-based guideines.[1] The use of narrow-spectrum antimicrobial agents to which the organism is susceptible is encouraged and, in certain circumstances, the use of combinations of agents may prevent the emergence of resistant mutants during therapy.

Prophylactic use of antibiotics

Antimicrobial prophylaxis is the use of antimicrobial agents in order to prevent infection developing. It is indicated in many circumstances, including the prevention of recurrent rheumatic fever, endocarditis, meningitis, tuberculosis and urinary tract and surgical infections.[1] Antimicrobial prophylaxis in the ED is usually indicated to prevent trauma-related infection following contamination of soft tissue, crush injuries, bites, clenched fist injuries and compound fractures. Other risk factors for wound infection include 'old' wounds (>18 hours),[17] penetrating injuries, contaminated wounds, co-morbid illness, shock, colon injury and massive haemorrhage.[18]

Antimicrobial prophylaxis should be considered where there is a significant risk of infection, but cannot be relied upon to overcome excessive soiling, damage to tissues, inadequate debridement or poor surgical technique. Adequate wound care, with splinting and elevation of the affected area as indicated, will continue to be important factors in trauma-related infection prophylaxis.

Antimicrobial prophylaxis should be directed against the likely causative organism(s). However, an effective regimen need not necessarily include antimicrobials that are active against every potential pathogen. Regimens that only reduce the total number of organisms may assist host defences and prevent infection.[1] The type, dose, duration and route of administration of antimicrobial therapy will vary according to the nature, site and aetiology of the injury, as well as host factors, and should be based on established guidelines. In all cases of open traumatic injury, no matter how trivial, tetanus prophylaxis must be considered.

Penicillins

Chemistry and mechanism of action

The penicillins constitute one of the most important groups of antimicrobial agents and remain the drugs of choice for a large number of infectious diseases. The basic structure of the penicillins consists of a thiazolidine ring connected to a β-lactam ring, and a side chain. The penicillin nucleus is the chief structural requirement for biological activity, whereas the side chain determines many of the antibacterial and pharmacological characteristics of the particular type of penicillin.

Peptidoglycan is an essential component of the bacterial cell wall and provides mechanical stability by virtue of its highly cross-linked latticework structure. Penicillin is thought to acetylate and inhibit a transpeptidase enzyme responsible for the final cross-linking of peptidoglycan layers. Penicillin also binds to penicillin-binding proteins (PBPs), causing further interference with cell wall synthesis and cell morphology. The lysis of bacteria is ultimately dependent on the activity of cell wall autolytic enzymes: autolyses and murein hydrolases. Although the relationship between the inhibition of PBP activity and the activation of autolysins is unclear, the interference with peptidoglycan assembly in the face of ongoing autolysis activity might well lead to cell lysis and death.

Bacterial resistance to penicillins

Microorganisms may be intrinsically resistant to the penicillins because of structural differences in PBPs. Resistance may be acquired by the development of high molecular weight PBPs that have reduced affinity for the antibiotic.[12] Bacterial resistance also can be caused by the inability of the agent to penetrate to its site of action. Unlike gram positive bacteria, gram negative bacteria have an outer membrane of lipopolysaccharide which functions as an impenetrable barrier to some antibiotics. However, some broader-spectrum penicillins, such as ampicillin and amoxicillin, can diffuse through aqueous channels (porins) of this outer membrane to reach their sites of action.

Bacteria can destroy penicillins enzymatically. Different bacteria elaborate a number of different β-lactamases and individual penicillins vary in their susceptibility to these enzymes. In general, gram positive bacteria produce a large amount of β-lactamase, which is secreted extracellularly. Most of these enzymes are penicillinases, which disrupt the β-lactam ring and inactivate the drug. In gram negative bacteria, β-lactamases are found in relatively small amounts strategically located between the inner and outer bacterial membranes for maximal protection.

Classification of penicillins

Benzylpenicillin (penicillin G) and phenoxymethyl penicillin (penicillin V)

These drugs are the so-called 'natural penicillins'. The antimicrobial spectra of benzyl penicillin (penicillin G) and phenoxymethyl penicillin (penicillin V) are very similar for aerobic gram positive microorganisms. Benzyl penicillin is the drug of choice against many gram positive cocci (streptococci, penicillin-sensitive staphylococci), gram negative cocci (*Neisseria meningitidis* and *Neisseria gonorrhoeae*), gram positive bacilli (*Bacillus anthracis*, *Corynebacterium diphtheriae*), anaerobes (peptostreptococcus, *Actinomyces israelii*, *Clostridium* and some *Bacteroides*), *Pasteurella multocida* and *Treponema pallidum*. Phenoxymethyl penicillin is an acceptable alternative for *Streptococcus pneumoniae*, *Streptococcus pyogenes* (A) and *Actinomyces israelii*.

The sole virtue of benzylpenicillin compared to phenoxymethyl penicillin is that it is more stable in an acid medium and therefore much better absorbed from the gastrointestinal tract. Benzylpenicillin is administered parenterally but has a half-life of only 30 minutes. Accordingly, repository preparations (penicillin G procaine, penicillin G benzathine) are often used, and probenecid may be administered concurrently to block the renal tubular secretion of the drug. Once absorbed, both penicillins are distributed widely throughout the body. Significant amounts appear in the liver, bile, kidney, semen, joint fluid, lymph and intestine. Importantly, penicillin does not readily enter the cerebrospinal fluid (CSF) when the meninges are normal. However, when the meninges are acutely inflamed, penicillin penetrates into the CSF more easily. Under normal circumstances, penicillin is eliminated unchanged by the kidney, mainly by tubular secretion.

The penicillinase-resistant penicillins

These drugs remain the agents of choice for most staphylococcal disease. Methicillin is a penicillin resistant to staphylococcal β-lactamase, although the increasing incidence of isolates of methicillin-resistant microorganisms is cause for concern. MRSA contain a high molecular weight PBP with a very low affinity for β-lactam antibiotics.[12] From 40% to 60% of strains of *Staphylococcus epidermidis* are also resistant to penicillinase-resistant penicillins by the same mechanism. As bacterial sensitivities are usually not known in the ED, methicillin is rarely administered in this setting.

The isoxazolyl penicillins (oxacillin, cloxacillin, dicloxacillin and flucloxacillin) are congeneric semisynthetic penicillins that are pharmacologically similar. All are relatively stable in an acid medium and are adequately absorbed after oral administration. These penicillins undergo some metabolism but are excreted primarily by the kidney with some biliary excretion. All are remarkably resistant to cleavage by penicillinase and inhibit both penicillin-sensitive and some penicillin-resistant staphylococci. Methicillin-resistant staphylococci are resistant to these penicillins. Isoxazolyl penicillins inhibit streptococci and pneumococci but are virtually inactive against gram negative bacilli.

The aminopenicillins

Ampicillin is the prototypical agent in this group. It is stable in acid medium and, although well absorbed orally, is often administered parenterally. Amoxicillin is a close chemical and pharmacological relative of ampicillin. The drug is stable in acid and was designed for oral use. It is more rapidly and completely absorbed from the gastrointestinal tract than is ampicillin. The antimicrobial spectra of these agents are essentially identical, with the important exception that amoxicillin appears to be less effective for shigellosis. Ampicillin is the penicillin of choice for many gram negative bacilli (*Haemophilus influenzae*, *Escherichia coli*, *Proteus mirabilis*, *Salmonella typhi* and *Salmonella* spp.), some gram positive bacilli *(Listeria monocytogenes)* and some gram positive cocci *(Enterococcus faecalis)*. It also has activity against *Pneumococcus* spp., *Neisseria* spp., *Peptostreptococcus*, *Fusobacterium*, *Clostridium* and *Erysipelothrix*.

Bacterial resistance to these drugs is becoming an increasing problem. Many pneumococcal isolates have varying levels of resistance to ampicillin. *H. influenzae* and the viridans group of streptococci are usually inhibited by very low concentrations of ampicillin. However, strains of *H. influenzae* (type b) that are highly resistant to ampicillin have been recovered from children with meningitis. It is estimated that 30% or more cases of *H. influenzae* meningitis are now caused by ampicillin-resistant strains. Similarly, ampicillin-resistant strains of *H. influenzae* have been increasingly isolated from cases of acute otitis media. An increasing percentage of *N. gonorrhoeae*, *E. coli*, *P. mirabilis*, *Salmonella* and *Shigella* are now resistant to ampicillin and practically all species of *Enterobacter* are now insensitive.

β-Lactamase inhibitors have been introduced to combat many penicillin-resistant microorganisms. These molecules bind to β-lactamases and inactivate them, thereby preventing the destruction of β-lactamase antibiotics. Clavulanic acid binds to the β-lactamases produced by a wide range of gram positive and gram negative microorganisms. It is well absorbed orally and can be given parenterally. It has been combined with amoxicillin as an oral preparation (Augmentin) and with ticarcillin (a carboxypenicillin) as a parenteral preparation (Timentin). Augmentin is effective for β-lactamase-producing strains of staphylococci, *H. influenzae*, gonococci and *E. coli*. Sulbactam is another β-lactamase inhibitor, which also can be administered orally or parenterally. In combination with ampicillin (Unasyn), good coverage is provided for gram positive cocci (including β-lactamase-producing strains of *Staph. aureus*), gram negative anaerobes (but not *Pseudomonas*) and anaerobes.

Adverse reactions to penicillin

Hypersensitivity reactions are the major adverse effects of penicillins. Penicillins are capable of acting as haptens to combine with proteins contaminating the solution or with human protein after the penicillin has been administered. Penicilloyl and penicillanic derivatives are the major determinants of penicillin allergy. All acute hypersensitivity reactions to penicillin are mediated by the immunoglobulin (Ig)E antibody and range in severity from rash to anaphylaxis. Anaphylactic reactions are uncommon, occurring in only 0.2% of 1000 courses of treatment, with 0.001% out of 100,000 courses resulting in death.[19] Morbilliform eruptions that develop after penicillin therapy are likely to be mediated by IgM antibodies and the uncommon serum sickness is likely to be mediated by IgG antibodies. All forms of penicillin are best avoided in patients with a history of penicillin allergy.

Otherwise, the penicillins are generally well tolerated. Central nervous system (CNS) toxicity, in the form of myoclonic seizures, can follow the administration of massive doses of benzylpenicillin (penicillin G), ampicillin or methicillin. Massive doses have also been associated with hypokalaemia. Haematological toxicity—usually neutropaenia—and nephrotoxicity have also been reported. Gastrointestinal disturbances have followed the use of all oral penicillins, but have been most pronounced with ampicillin. Enterocolitis due to the overgrowth of *Clostridium difficile* is well documented, and abnormalities in liver function have been reported, especially with flucloxacillin.[20]

Cephalosporins

The antimicrobial activity of cephalosporins, like that of other β-lactam antibiotics, results at least in part from their ability to interfere with the synthesis of the peptidoglycan component of the bacterial cell wall. However, the exact bactericidal and lytic effects of cephalosporins are not completely understood.

Classification and uses

The first-generation compounds (cephalothin, cefazolin, cefalexin) have a relatively narrow spectrum of activity focused primarily on the gram positive cocci, especially penicillin-sensitive

streptococci and methicillin-sensitive *Staph. aureus*. These compounds have modest activity against gram negative organisms, including *E. coli* and *Klebsiella* spp. Cefaclor has extended gram negative activity and is active against *H. influenzae* and *M. catarrhalis*.

The second generation of cephalosporins (cefuroxime, cefamandole) are more stable against gram negative β-lactamases. They have variable activity against gram positive cocci, but have increased activity against gram negative bacteria (*E. coli*, *Proteus*, *Klebsiella*). In spite of relatively increased potency against gram negative aerobic and anaerobic bacilli *(Bacteroides fragilis)*, the cephamycins (cefoxitin, cefotetan) are included in this generation.

The third-generation cephalosporins (cefotaxime, ceftriaxone, ceftazidime, cefpirome) have very marked activity against gram negative bacteria. Most are useful against *Ps. aeruginosa*, *Serratia* and *Neisseria* species and some Enterobacteriaceae. Some of these compounds have limited activity against gram positive cocci, particularly methicillin-sensitive *Staph. aureus*. This generation of cephalosporins is particularly effective in meningitis because of their better penetration into the CSF and higher intrinsic activity. However, as these third-generation drugs are more expensive and have a wide antimicrobial spectrum, their use should be based on established guidelines.

Recently, several compounds have been considered as possibly meriting classification as a fourth generation. Cefepime has activity against gram positive cocci and a broad array of gram negative bacteria, including *Ps. aeruginosa* and many of the Enterobacteriaceae with inducible chromosomal β-lactamases.

Adverse reactions

Hypersensitivity reactions are the most common side effects of the cephalosporins and all compounds have been implicated. The reactions appear to be identical to those caused by the penicillins. Immediate reactions, such as anaphylaxis, bronchospasm, angio-oedema and urticaria, have been reported. More commonly, a maculopapular rash develops, usually after several days of therapy. Because of the similarity in structure between the penicillins and the cephalosporins, patients allergic to one class of agents may manifest cross-reactivity when a member of the other class is administered. Studies indicate that about 0.5% of patients allergic to penicillin will demonstrate a clinically apparent reaction when a first-generation cephalosporin is administered (0% for second- and third-generation cephalosporins).[21] Patients with a mild or temporarily distant reaction to penicillin appear to be at low risk of rash or other allergic reactions following the administration of a cephalosporin. However, subjects with a recent history of an immediate reaction to penicillin should not be given a cephalosporin. Other reactions to cephalosporins are uncommon and include diarrhoea, nephrotoxicity, intolerance of alcohol and bleeding disorders.

Penicillin allergy cross-reactivity with cephalosporins is significantly overstated. Cross-reactivity between penicillins and cephalosporins is much less than the 10% commonly cited. Cephalothin, cephalexin, cefadroxil and cefazolin confer an increased risk of allergic reaction among patients with penicillin allergy.

Cefuroxime, cefpodoxime, ceftazidime and ceftriaxone do not increase risk of an allergic reaction.

No cross-reactivity exists between penicillins and third-generation cephalosporins. However, if a patient has known anaphylaxis to penicillin, caution with cephalosporin use is still warranted.

Bacterial resistance

The most prevalent mechanism for resistance to cephalosporins is their destruction by β-lactamase hydrolysis. The cephalosporins have variable susceptibility to β-lactamase, with the later-generation compounds being more resistant to the β-lactamases produced by gram negative bacteria. However, third-generation cephalosporins are susceptible to hydrolysis by inducible, chromosomally encoded (type 1) β-lactamases. The induction of type 1 β-lactamases by treatment of infections due to many aerobic gram negative bacilli with second- or third-generation cephalosporins may result in resistance to all third-generation cephalosporins.

Macrolides

Erythromycin was originally isolated from soil bacteria and contains a many-membered lactone ring to which are attached one or more deoxy sugars. Clarithromycin, azithromycin and roxithromycin are new semisynthetic derivatives of erythromycin. Clarithromycin differs only by methylation of a hydroxyl group and azithromycin contains a methyl-substituted nitrogen atom in the lactone ring. Roxithromycin is a good alternative to oral erythromycin and has good oral bioavailability, but is more expensive. The macrolides are usually bacteriostatic and inhibit protein synthesis by binding reversibly to 50S ribosomal subunits of sensitive microorganisms. They are thought to inhibit the translocation step wherein a newly synthesized peptidyl tRNA molecule moves from the acceptor site on the ribosome to the peptidyl (donor) site.

Clinical uses

Erythromycin is most effective against aerobic gram positive cocci and bacilli. It is active against *Strep. pyogenes*, *Strep. pneumoniae*, *Clostridium perfringens*, *C. diphtheriae*, *L. monocytogenes* and some staphylococci. Useful activity has also been seen with *P. multocida*, *Borrelia* spp., B. *pertussis*, *Campylobacter jejuni*, *Legionella pneumophila*, *M. pneumoniae*, *C. trachomatis* and some atypical mycobacteria. It has modest activity *in vitro* against some gram negative organisms, including *H. influenzae* and *N. meningitidis* and excellent activity against most strains of *N. gonorrhoeae*.

Clarithromycin is more potent against erythromycin-sensitive strains of streptococci and staphylococci, but has only modest activity against *H. influenzae* and *N. gonorrhoeae*. However, it has good activity against *M. catarrhalis*, *Chlamydia* spp., *L. pneumophila* and *Mycoplasma pneumoniae*. Azithromycin is generally less active than erythromycin against the gram positive organisms and is more active than the other two macrolides against *H. influenzae* and *Campylobacter* spp. Azithromycin is very active against *M. catarrhalis*, *P. multocida*, *Chlamydia* spp., *M. pneumoniae*, *L. pneumophila* and *N. gonorrhoeae*.

Adverse reactions

Erythromycin is one of the safest antibiotics and causes serious adverse effects only rarely. Dose-related abdominal cramps, nausea, vomiting, diarrhoea and flatulence occur, but are uncommon in children and young adults. Allergic reactions observed include fever, eosinophilia and skin eruptions. Cholestatic hepatitis, transient hearing loss, polymorphic ventricular tachycardia, superinfection of the gastrointestinal tract and pseudomembranous colitis have been reported. Intravenous use of erythromycin is often associated with thrombophlebitis, but the incidence of this complication can be reduced with appropriate dilution of the dose. Adverse reactions to the other macrolides, at the usual dose, are rare and usually confined to the gastrointestinal tract. For this reason, roxithromycin is often prescribed instead of erythromycin.

Erythromycin and, to a lesser extent, the other macrolides, has been reported to cause clinically significant drug interactions.[22] Erythromycin has been reported to potentiate astemizole, terfenadine, carbamazepine, corticosteroids, digoxin, theophylline, valproate and warfarin, probably by interfering with cytochrome P450-mediated drug metabolism. Care should be used in the concurrent administration of the macrolides with these drugs.

Bacterial resistance

Resistance to erythromycin may be the result of reduced permeability through the cell envelope. This form of resistance is exhibited by the Enterobacteriaceae and *Pseudomonas* spp.

Alteration of ribosomal proteins, especially the 50S protein, often affects binding of the drug and has led to the emergence of resistant strains of *B. subtilis*, *Strep. pyogenes* and *Strep. pneumoniae*, *Campylobacter* spp., *E. coli*, *Staph. aureus*, *Cl. perfringens*, *Listeria* spp. and *Legionella* spp. Finally, enzymatic degradation of the drug has conferred high-level resistance among strains of Enterobacteriaceae.

Tetracycline

Tetracyclines are generally bacteriostatic and are thought to inhibit bacterial protein synthesis by binding to the 30S bacterial ribosome and preventing access of aminoacyl tRNA to its acceptor site.

Clinical uses

The antimicrobial spectra of all the tetracyclines are almost identical. They possess a wide range of antimicrobial activity against aerobic and anaerobic gram positive and gram negative bacteria. Clinically, the tetracyclines are useful against *Strep. pneumoniae*, *H. influenzae*, *Neisseria* spp., *E. coli*, *Brucella* spp., *H. ducreyi*, *Vibrio cholerae*, *Campylobacter* spp. and some *Shigella* and *Mycobacterium* spp. Many pathogenic spirochaetes are susceptible, including *Borrelia burgdorferi*. They are also effective against some microorganisms that are resistant to cell-wall active antimicrobial agents, such as *Rickettsia*, *Coxiella burnetii*, *Mycoplasma pneumoniae*, *Chlamydia* spp., *Legionella* spp. and *Plasmodium* spp.

Adverse reactions

The tetracyclines all produce gastrointestinal irritation in some individuals, although doxycycline is usually well tolerated. Epigastric discomfort, nausea, vomiting and diarrhoea are commonly reported. Renal and liver toxicity and photosensitivity may occur. Tetracyclines are deposited in the skeleton and teeth during gestation and childhood and can cause abnormalities of bone growth and discoloration of the teeth. It is therefore essential not to administer these agents to pregnant women or children under 8 years of age. Hypersensitivity reactions, including skin reactions, burning of the eyes, pruritus ani, vaginitis, angio-oedema and anaphylaxis, are rarely seen.

Bacterial resistance

Bacteria develop resistance to the tetracyclines mainly by preventing the accumulation of the drug within the cell. This is accomplished by reducing the influx or increasing the ability of the cell to export the antibiotic. Rarely, the tetracyclines are inactivated biologically or inhibited in their ribosomal attachment.[23] Resistance to one tetracycline usually means resistance to all. Clinically, most strains of enterococci are now resistant to tetracycline; group B streptococci are 50% susceptible and only 65% of *Staph. aureus* remain susceptible. Resistant pneumococci are now found in many geographical areas and many strains of *Neisseria* spp. are now resistant.

Aminoglycosides

Each aminoglycoside demonstrates concentration-dependent bactericidal activity against susceptible microorganisms. Gentamicin is the most commonly administered aminoglycoside in the ED and is a mixture of three closely related constituents. It binds to a specific area on the interface between the smaller (30S) and the larger (50S) bacterial ribosomal subunits, causing an increase in the misreading of messenger RNA and a measurable decrease in protein synthesis. However, these effects do not provide a complete explanation for the rapidly lethal effect of gentamicin on bacteria.

Clinical uses

The antibacterial activity of gentamicin is directed primarily against aerobic and facultative gram negative bacilli. It has little activity against anaerobic microorganisms and facultative bacteria under anaerobic conditions and its activity against most gram positive bacteria is very limited. Gentamicin is clinically effective against *Pseudomonas aeruginosa*, *P. mirabilis*, *Klebsiella pneumoniae*, *E. coli*, *Enterobacter* spp. and *Serratia* spp. It is particularly effective when used in combination with cell-wall active antimicrobial agents (e.g. penicillin, cephalosporin). Interactions between these agents result in synergistic effects on bacterial death and may be useful against enterococci, *Strep. pyogenes*, some staphylococci, Enterobacteriaceae and *Pseudomonas aeruginosa*.

Adverse reactions

Like most other aminoglycosides, gentamicin has the potential to cause injury to the renal proximal convoluted tubules, damage to the cochlear and/or vestibular apparatus and neuromuscular blockade. As the drug is eliminated almost entirely by glomerular filtration, gentamicin dosing in renal failure must be undertaken with care and drug-level monitoring is recommended. Gentamicin has little allergenic potential. Anaphylaxis, rash and other hypersensitivity reactions are unusual.

Bacterial resistance

Bacteria defend themselves against the aminoglycosides by a combination of alteration of uptake, synthesis of modifying enzymes and a change of ribosomal binding sites.

In several centres, a significant percentage of clinical isolates are highly resistant to all aminoglycosides. At present, other widespread bacterial resistance to the aminoglycosides remains limited. However, there are reports of resistance emerging among some strains of *Ps. aeruginosa*, Enterobacteriaceae, *E. coli*, *Serratia* spp. and *Staph. aureus*.

Metronidazole

The toxicity of metronidazole is due to short-lived intermediate compounds or free radicals that produce damage by interaction with DNA and possibly other macromolecules.

Clinical uses

Metronidazole is active against a wide variety of anaerobic protozoal parasites. It is directly trichomonicidal. Sensitive strains of *Trichomonas vaginalis* are killed by very low concentrations of the drug under anaerobic conditions. The drug also has potent amoebicidal activity against *Entamoeba histolytica*, even in mixed culture, and substantial activity against the trophozoites of *Giardia lamblia*. Metronidazole manifests antibacterial activity against all anaerobic cocci and both anaerobic gram negative bacilli and anaerobic spore-forming gram positive bacilli. *Bacteroides*, *Clostridium*, *Helicobacter*, *Fusobacterium*, *Peptococcus* and *Peptostreptococcus* spp. are all susceptible.

Adverse reactions

In general, metronidazole is well tolerated. The most common side effects are headache, nausea, dry mouth and a metallic taste. Vomiting, diarrhoea and abdominal distress are occasionally experienced.[24] Furry tongue, glossitis and stomatitis may occur during therapy and are associated with a sudden intensification of moniliasis. Of clinical importance is metronidazole's well-documented disulfiram-like effect (Antabuse). Some patients experience abdominal distress, vomiting, flushing or headache if they drink alcohol during therapy with this drug.

Bacterial resistance

Fortunately, very few strains of *Bacteroides* spp. have demonstrated resistance. Some resistant strains of *T. vaginalis* have been isolated from patients with refractory cases of trichomoniasis, but these patients have usually responded to higher doses of metronidazole and prolonged courses of therapy.[25]

Co-trimoxazole

Co-trimoxazole is a combination of sulphamethoxazole, a sulphonamide antibiotic, and trimethoprim, a diaminopyrimidine. The antimicrobial activity of this combination results from actions on two steps of the enzymatic

pathway for the synthesis of tetrahydrofolic acid. Sulphamethoxazole inhibits the incorporation of Para-aminobenzoic acid (PABA) into folic acid and trimethoprim prevents the reduction of dihydrofolate to tetrahydrofolate. The latter is the form of folate essential to bacteria for one-carbon transfer reactions. Mammalian cells utilize preformed folate from the diet and do not synthesize this compound. This combination has been associated with serious sulphonamide-induced side effects. It has been recommended that the combination product be restricted to the few situations where combined use is the treatment of choice.[1]

Clinical uses

Trimethoprim is effective in the treatment of most urinary tract infections and should be used alone for this indication. However, co-trimoxazole is active against a wide range of gram positive and gram negative microorganisms. *C. diphtheriae* and *N. meningitidis* are susceptible, as are most strains of *Strep. pneumoniae*. From 50% to 95% of strains of *H. influenzae*, *Staph. aureus* and *epidermidis*, *Strep. pyogenes* and *viridans*, *E. coli*, *Proteus mirabilis*, *Enterobacter* spp., *Salmonella*, *Shigella* and *Serratia* are inhibited. Also sensitive are *Klebsiella* spp., *Brucella abortis*, *Pasteurella haemolytica* and *Yersinia* spp. Co-trimoxazole has an important place in the treatment and prophylaxis *of P. carinii* infection and the treatment of *L. monocytogenes* and *Nocardia* infection.

Adverse reactions

In routine use, the combination appears to produce little toxicity. About 75% of adverse reactions involve the skin. These reactions are typical of those produced by sulphonamides and include a wide variety of rashes, erythema nodosum, erythema multiforme and Stevens–Johnson syndrome, exfoliative dermatitis and photosensitivity. Severe reactions tend to be more common among the elderly and HIV-infected patients. Gastrointestinal reactions include nausea and vomiting, but rarely diarrhoea. Glossitis and stomatitis are relatively common. CNS reactions (headache, depression and hallucinations) and haematologic disorders (anaemias, coagulation disorders and granulocytopaenia) have been reported.

Bacterial resistance

The frequency of development of bacterial resistance to co-trimoxazole is lower than it is to either of the constituent compounds alone. Resistance to sulphamethoxazole is presumed to originate by random mutation and selection or by transfer of resistance by plasmids. Such resistance is usually persistent and irreversible. Resistance to all sulphonamides is now becoming widespread in both community and nosocomial strains of bacteria, including streptococci, staphylococci, Enterobacteriaceae, *Neisseria* spp. and *Pseudomonas* spp. Trimethoprim-resistant microorganisms may arise by mutation, but resistance in gram negative bacteria is often associated with the acquisition of a plasmid that codes for an altered dihydrofolate reductase. Increasing incidences of resistance have been found in Enterobacteriaceae, *Ps. aeruginosa*, *Staph. aureus*, *E. coli*, *Salmonella* and *Shigella*.

Quinolones

The 4-quinolones, including nalidixic acid, are a family of compounds that contain a carboxylic acid moiety attached to a basic ring structure. The newer fluoroquinolones also contain a fluorine substituent, for example, ciprofloxacin, and ofloxacin. Some may also contain a piperazine moiety. Bacterial DNA gyrase is an essential enzyme involved in DNA function. The quinolones inhibit the enzymatic activities of DNA gyrase and promote the cleavage of DNA within the enzyme–DNA complex.

Clinical uses

The early quinolones are most active against aerobic gram negative bacilli, particularly Enterobacteriaceae and *Haemophilus* spp. and against gram negative cocci, such as *Neisseria* spp. and *M. catarrhalis*. The fluoroquinolones are significantly more potent and have a much broader spectrum of antimicrobial activity. Relative to nalidixic acid, the fluoroquinolones also have additional activity against *Ps. aeruginosa* and some staphylococci. Ciprofloxacin remains the most potent fluoroquinolone against gram negative bacteria. Several intracellular bacteria are inhibited by the fluoroquinolones, including *Chlamydia*, *Mycoplasma*, *Legionella*, *Brucella* and some mycobacteria. Recently, a new drug, moxifloxacin, has been released, which is useful for sinusitis, community-acquired pneumonia and acute bronchitis.

Adverse reactions

Generally, these drugs are well tolerated. Gastrointestinal symptoms of anorexia, nausea, vomiting, diarrhoea and abdominal discomfort are commonly seen, particularly with the older quinolones. Headache, dizziness, insomnia and alteration in mood are the next most commonly reported symptoms. Allergic and skin reactions, including phototoxicity, may occur. Rarely, arthralgias and joint swelling, leucopaenia, eosinophilia, thrombocytopaenia and haemolysis are reported.

Bacterial resistance

Resistance patterns over time have indicated that resistance increased following the introduction of fluoroquinolones and occurred most often with *Pseudomonas* spp. and staphylococci, and in soft-tissue infections and infections associated with foreign bodies. Possibly reflecting the pressures of extensive use, increasing fluoroquinolone resistance has been reported among strains of *Cl. jejuni* and *E. coli*. Focused quinolone use should be considered to avoid compromising the utility of the fluoroquinolones.

Nitrofurantoin

The mechanism of action is poorly understood, but activity in many cases appears to require enzymatic reduction within the bacterial cell.[26] The reduced derivatives are thought to bind to and damage intracellular proteins, including DNA, and inhibit bacterial respiration, pyruvate metabolism and the synthesis of inducible enzymes.

Clinical uses

Nitrofurantoin is active against over 90% of clinical strains of *E. coli*, *Citrobacter* spp., *Staph. saprophyticus* and *E. faecalis*. However, most species of *Proteus*, *Pseudomonas*, *Serratia*, *Providencia*, *Morganella* and many *Enterobacter* and *Klebsiella* spp. are resistant. Given its spectrum of activity and concentration in the urine, nitrofurantoin is usually administered for the treatment of urinary tract infections or for urinary antisepsis. However, it may have activity against bacteria not usually associated with urinary tract infections, including *Salmonella*, *Shigella*, *Staph. aureus*, *Strep. pneumoniae* and *pyogenes* and *Bacteroides*. Fortunately, bacteria that are susceptible to nitrofurantoin rarely become resistant during therapy.

Adverse reactions

Gastrointestinal upsets, particularly nausea, vomiting and diarrhoea, are the commonest side effects of nitrofurantoin. The frequency of these symptoms may be reduced if the macrocrystalline formulation is administered. Rashes, presumably allergic in nature, have been seen quite commonly. Cholestatic jaundice, acute and chronic hepatitis, pulmonary and haematologic reactions and peripheral neuropathies have all been reported.

Colistin Link Parenteral

Colistin Link Parenteral has activity against gram negative bacilli: *Enterobacter aerogenes*, *E. coli*, *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*.

Serious infection due to strains of *Pseudomonas aeruginosa* that exhibit resistance to all common antipseudomonal antimicrobials is an increasingly serious problem.

Pseudomonas aeruginosa is the gram negative pathogen that most commonly causes nosocomial pneumonia and is associated with the

highest rates of crude and attributable mortality, even among patients who receive appropriate antimicrobial therapy.

Colistin Link Parenteral is eliminated mainly by renal excretion; it should be used with caution when the possibility of impaired renal function exists. The decline in renal function with advanced age should be taken into consideration; it can also cause nephrotoxicity. The maximum daily dose should not exceed 5 mg/kg/day with normal renal function.[27]

Antiviral drugs

Several antiviral drugs are available, although famciclovir, acyclovir and valacyclovir (prodrug of acyclovir that requires a lower dosage frequency) are the most frequently prescribed. Their mechanism of action is similar. Each drug targets virus-infected cells and inhibits viral DNA polymerase. Consequently, viral DNA synthesis and therefore viral replication are inhibited.

Clinical uses

These drugs are primarily used for the management of herpes zoster (within 72 hours of rash onset), treatment and suppression of genital herpes and the management of patients with advanced symptomatic HIV disease. Famciclovir is well absorbed in the gut and has the advantage of a three times daily dosage compared to five times daily for acyclovir.

Acyclovir is also used to treat herpes simplex encephalitis (HSE).

HSE needs to be distinguished from herpes simplex meningitis, which is more commonly caused by the herpes simplex virus (HSV)-2 than by HSV-1 and which often occurs in association with a concurrent herpetic genital infection.

Empiric treatment with acyclovir is essential in patients with suspected HSE pending confirmation of the diagnosis because acyclovir is the drug of choice and is relatively non-toxic and, if commencement of treatment is delayed, the prognosis for untreated HSE is poor.

Adverse reactions

These drugs are generally well tolerated. However, headache, gastrointestinal disturbance, dizziness and fatigue have been reported. Adverse effects are generally mild.

Antiviral agents for influenza

Zanamivir and oseltamivir are related antiviral medications known as neuraminidase inhibitors. These two medications are active against both influenza A and B viruses. They differ in pharmacokinetics, safety profiles, route of administration, approved age groups and recommended dosages.

The two other drugs used to treat influenza, amantadine and rimantadine are related antiviral drugs classified as adamantanes. These medications are active against influenza A viruses but not influenza B viruses. Widespread adamantane resistance among influenza A (H_3N_2) virus strains has made this class of medications less useful clinically.

Early antiviral treatment can shorten the duration of fever and symptoms and may reduce the risk of complications from influenza (e.g. otitis media in young children, pneumonia, respiratory failure) and death, and shorten the duration of hospitalization. Clinical benefit is greatest when antiviral treatment is administered early, especially within 48 hours of influenza illness onset.

Antiretroviral drugs

Emergency physicians are unlikely to initiate these drugs as they form the basis of HIV treatment.

The only exception is prophylaxis following needle stick injury or body fluid exposure where close adherence to the hospital's policy is essential.

However, an appreciation of their uses and side effects is useful. Furthermore, the management of patients with HIV disease can be difficult, and advice from an appropriate specialist source is essential.

Standard antiretroviral therapy consists of the combination of at least three antiretroviral (ARV) drugs to suppress maximally the HIV virus and to stop the progression of HIV disease.

Clinical uses

The ARVs are used in the treatment of established HIV infection. This includes patients with HIV-associated illnesses (e.g. CNS disease, malignancies, opportunistic diseases) and asymptomatic patients with low CD4 cell counts and/or high HIV viral loads. The drugs are also of use in the prevention of maternofoetal transmission and as post-exposure prophylaxis for significant exposure from a known HIV-infected source.

Three major classes of ARV drugs are available. For initial therapy, two to three drugs are generally used in combination (see Chapter 9.2).

Post-exposure prophylaxis [PEP] has been recently introduced. PEP is a 4-week course of anti-HIV medication effective in preventing HIV infection if commenced within 72 hours of exposure. Jurisdictional guidelines are available.[28]

Antifungal agents

Systemic fungal infections are becoming more and more common. Candidiasis and aspergillosis are the most common infections; other systemic fungal infections include histoplasmosis, blastomycosis, coccidioidomycosis.

Severe systemic fungal infection in hospitals are commonly seen in:

- neutropenic patients following chemotherapy and other oncology patients with immune suppression
- persons that are immune compromised due to acquired immune deficiency syndrome caused by HIV infection
- patients in intensive care (ICU), who are not necessarily neutropenic but are compromised due to the presence of long-term intravascular lines or other breaches in their integument, severe systemic illness or burns and prolonged broad-spectrum antibiotic therapy.

Other predisposing factors include:

- Acute physiology and chronic health evaluation (APACHE) score >10
- renal dysfunction
- haemodialysis
- surgery for acute pancreatitis, splenectomy
- recurrent gastrointestinal perforation
- Hickmann catheters.

Systemic fungal infections cause ≈25% of infection-related deaths in patients with leukaemia. Infections due to *Candida* species are the fourth most important cause of nosocomial bloodstream infection.

The mainstay of antifungal therapy for severe systemic mycoses is amphotericin B.

Cryptococcal meningitis

Cryptococcus neoformans is an encapsulated yeast. The most serious infections usually develop in patients with defective cell-mediated immunity including, patients with:

- AIDS
- organ transplantation
- reticuloendothelial malignancy
- corticosteroid treatment
- sarcoidosis.

The incidence of cryptococcosis is increasing and now represents a major life-threatening fungal infection in AIDS patients.

Occupational risk factors for the infection include arborists and those exposed to bird droppings.

The initial site or sites of infection (pulmonary, CNS, and disseminated disease) determine the medical history of patients with symptomatic cryptococcal disease.

Patients with CNS infections, which are usually subacute or chronic in nature, present with headaches, neck pain, confusion, lethargy, malaise, and then – as the untreated infection progresses – focal neurological defects and decreased Loss of consciousness (LOC). Fever, nausea and vomiting are not uncommon.

Treatment

Amphotericin B at 0.7 to 1 mg/kg/day for 2 weeks, with or without 2 weeks of flucytosine at 100 mg/kg/day in four divided doses, followed by

fluconazole at 400 mg/day for a minimum of 8 to 10 weeks.

Initial therapy should be considered successful only after CSF culture is negative for cryptococcal organisms and the patient has had significant clinical improvement.

Initial therapy of fluconazole 400 to 800 mg followed by maintenance therapy using fluconazole at 200 mg/day for life.

Amphotericin B

Amphotericin B is useful in the treatment of infection with *Blastomyces*, *Coccidioides*, *Histoplasma*, *Paracoccidioides*, *Candida* and *Cryptococcus*, but does have substantial risk of toxicity. It is a 'polyene' and works on fungi by binding to ergosterol in the fungal cell membrane, disrupting the membrane and killing the fungus.

Other antifungal agents include fluconazole, which is mainly used for *C. albicans* infection (and some other susceptible *Candida* spp. but not *C. krusei*, and has variable activity against *C. glabrata*). *C. albicans* may acquire resistance, especially with chronic or recurrent treatment in AIDS patients. Fluconazole may be effective against *Cryptococcus neoformans* meningitis and coccidioidomycosis.

Outpatient parenteral antibiotic therapy

Outpatient parenteral antibiotic therapy (OPAT) has been widely used for the treatment of moderate to serious infections, either as an alternative to hospitalization or following initial hospitalization and early discharge once the patient is over the toxic phase of the infection. A wide range of infections are suitable for OPAT therapy (Box 9.9.2).

Significant savings, both in terms of direct and indirect costs, are possible utilizing OPAT. Appropriate patient selection is essential for safe and effective outpatient parenteral therapy (Boxes 9.9.3 and 9.9.4). Patients should be clinically stable, be willing to participate and be physically and mentally capable of being treated at home (see Box 9.9.4).

Some patients require initial hospitalization (Box 9.9.5), following which they may be suitable for early discharge to continue treatment at home.

Once patients comply with predefined discharge criteria (Box 9.9.6), they may be able to be discharged into an outpatient parenteral therapy programme.

Close patient monitoring is essential, with daily reviews by a nurse either by telephone or face to face while patients are in the programme. Patients should be reviewed at least weekly by a physician.

The benefits of OPAT include a reduction in the overall costs of patient care through avoidance or reduction in hospitalization, reduction of the costs associated with the hazards of hospitalization and increased patient satisfaction.[29,30]

Box 9.9.2 Conditions that can be treated on an outpatient basis with parenteral antibiotic therapy

AIDS
Associated infections

Cardiac
Endocarditis
Prosthetic-valve infections

Genitourinary
Pyelonephritis
Complicated urinary tract infections
Prostatitis
Pelvic inflammatory disease

Respiratory
Pneumonia
Lung abscess

Soft-tissue infections
Cellulitis
Wound infections/abscesses

Bone and joint infections
Osteomyelitis
Septic arthritis
Prosthetic infections
Neurological infections
Meningitis

Other infections
Bacteraemia
Mastoiditis

Box 9.9.3 Patient selection process

Condition suitable for outpatient therapy
Patient does not fulfil need to admit criteria (see Box 9.9.5)
OR
Patient meets discharge criteria (see Box 9.9.6)
Home environment suitable
Patient/family consent

Box 9.9.4 Patient selection criteria

Able to give consent
Adequate social support at home
The antibiotic(s) chosen is/are appropriate for OPAT use
Patient's condition is stable
Concurrent illness does not require hospital care
Adequate venous access can be maintained; patient is mobile
The infection is amenable to outpatient parenteral therapy
Adequate monitoring by the treating medical team is possible

OPAT, Outpatient parenteral antibiotic therapy.

Other issues

The risks associated with bioterrorism need to be taken into account with every patient presenting with a febrile illness or signs and symptoms of infection.

Box 9.9.5 Criteria for admission to hospital

Confused
Persistent high fever
Systolic blood pressure <100 mm Hg
Respiratory rate >30/min
Pulse rate >100/min
Requires specialized nursing care assistance with activities of daily living
Hypoxic on room air (PaO_2 <80 mm Hg)
Concurrent illness requiring inpatient care
Personal or social reasons
Pneumonic consolidation in more than one lobe

Box 9.9.6 Discharge criteria

Medical
Afebrile
Clinical improvement
No specialized nursing care required
Stable
Bacterial pathogens identified
Response to inpatient therapy
Complications unlikely

Social
Parents interested and motivated
Parents capable
Home environment acceptable
Telephone and transport access

Numerous bacterial agents and bacterial toxins have been identified as potential biological agents. Patients presenting in clusters or with unusual or uncommon infections—particularly those that can be used as biological agents—should be quarantined, with staff utilizing post-exposure prophylaxis and strict infection control procedures. It may be necessary to activate the hospital's Mass Casualty Incident Plan when biological agents are suspected.[31]

Recent updates from the medical literature

In August 2012, the Centers for Disease Control and Prevention (CDC) announced changes to the 2010 sexually transmitted disease guidelines for gonorrhoea treatment. The Gonococcal Isolate Surveillance Project (GISP) described a decline in cefixime susceptibility among urethral *N. gonorrhoeae* isolates in the United States from 2006 to 2011. Because of cefixime's lower susceptibility, new guidelines were issued that no longer recommend oral cephalosporins for first-line gonococcal infection treatment.[32]

The incidence of untreatable gonorrhoea is increasing.

Likely developments over the next 5 to 10 years

The most important challenge regarding infectious disease in the future will be:

- The containment of and management of antimicrobial resistance patterns. In part, these patterns have emerged as a result of poor prescribing habits.[33]
- Fewer new antimicrobial drugs are being developed, with the result that with developing resistance patterns there will be very few effective antibiotics available for use against infection.[9]
- The implementation of prescribing guidelines based on scientific evidence will form the basis of all antibiotic prescribing.
- Human behaviour, wildlife trade, factory farming, poor hygiene, global warming and increasing travel will increase the risk of pandemics, evolution and the spread of new and old infections.[34,35]

Detailed descriptions of the drugs described above are available on the Internet by accessing MIMS Online and Antibiotic Guidelines.[1]

9.10 Needlestick injuries and related blood and body fluid exposures

Sean Arendse

ESSENTIALS

1 **Avoiding blood and other body fluid exposure remains the primary means of preventing occupationally acquired blood-borne virus infections.**

2 **The risks of acquiring infection after occupational exposure to blood-borne viruses are human immunodeficiency virus (HIV) 0.3%, hepatitis B virus (HBV) 12% to 30%, hepatitis C virus (HCV) 1.8%.**

3 **HBV immunization is an integral part of workplace safety.**

4 **Effective post-exposure prophylaxis (PEP) is available for both HBV and HIV, but not HCV.**

5 **Significant emotional distress often complicates needlestick and related occupational injuries.**

Introduction

Management of the health care worker who sustains an occupational exposure to blood or other potentially infectious body fluids (e.g. semen, vaginal secretions, cerebrospinal fluid [CSF] and fluids containing visible blood) is an important issue for the emergency department (ED) doctor. Overall, 16,000 hepatitis C virus (HCV), 66,000 hepatitis B virus (HBV), and 1000 human immunodeficiency virus (HIV) infections may have occurred in the year 2000 worldwide among Health Care Workers (HCWs) due to their occupational exposure to percutaneous injuries. The fraction of infections with HCV, HBV and HIV in HCWs attributable to occupational exposure to percutaneous injuries fraction reaches 39%, 37%, and 4.4%, respectively.[1] This figure is a conservative estimate as many needlestick injuries go unreported. HBV, HCV and HIV are the most important occupationally acquired blood-borne pathogens; however, many other organisms, including malaria, syphilis, cytomegalovirus and possibly the prion diseases (e.g. Creutzfeldt–Jakob disease) also may be transmissible via this route.

When evaluating health care providers (HCPs) at risk for occupational infection with HIV, 'exposure' is defined as contact with potentially infectious blood, tissue or body fluids in a manner that allows for possible transmission of HIV, and therefore requires consideration of post-exposure prophylaxis (PEP).

Such potentially infectious contacts are:

- a percutaneous injury (e.g. a needlestick or cut with a sharp object)
- contact of mucous membrane or non-intact skin (e.g. exposed skin that is chapped, abraded or afflicted with dermatitis).

Body fluids of concern include:

- body fluids implicated in the transmission of HIV: blood, semen, vaginal secretions, other body fluids contaminated with visible blood
- potentially infectious body fluids (undetermined risk for transmitting HIV): cerebrospinal, synovial, pleural, peritoneal, pericardial and amniotic fluids.

Fluids that are not considered infectious unless they contain blood include faeces, nasal secretions, saliva, gastric secretions, sputum, sweat, tears, urine and vomitus.

In addition, any direct contact (i.e. without barrier protection) to concentrated HIV in a research laboratory or production facility is considered an 'exposure' that requires clinical evaluation and consideration of PEP.

Intact skin is an effective barrier against HIV infection. Contamination of intact skin with blood or other potentially contaminated fluids is not considered an exposure and does not require PEP.

Most exposures do not result in infection and the risk of infection following significant exposure varies with factors such as:

- the pathogen involved (hepatitis B, hepatitis C or HIV)
- the fluid involved—blood is generally the most infectious body fluid
- the type of exposure—percutaneous or mucous membrane/non-intact skin
- the amount of blood or other infectious body fluid involved in the exposure
- the amount of virus in the patient's blood at the time of exposure.

General issues

Prevention of needlestick injuries

The old adage 'prevention is better than cure' certainly rings true when considering needlestick

injuries, as the cost of managing one needlestick injury exposure can range from 376 USD to 2456 USD.[2]

The potentially infectious nature of all blood and bodily fluids necessitates the implementation of infection control practices. The universal application of standard precautions should be the minimum level of infection control when treating patients to prevent blood-borne virus transmission. The important elements of standard precautions are:

- the use of gloves when contact with blood, body fluids or secretions is anticipated
- the use of masks and protective eyewear during procedures that have the potential to generate splashes or sprays of blood or bodily fluids
- the use of gowns to protect skin and clothing from soiling by blood and other bodily fluids
- correct handling and disposal of needles and other sharp instruments:
  - disposal of sharps directly from patient immediately into sharps bins
  - locating sharps bins conveniently to reduce the unnecessary transportation of uncapped devices
  - avoiding overfilling sharps containers
  - never re-sheathing or re-capping needles
  - 100% attention when handling sharps.

More than 50 products with features designed to prevent needlestick injuries are currently available and fall broadly into two categories: those providing 'passive' or automatic protection, and those with a safety mechanism that the user must activate.

It has been demonstrated that most needlestick injuries are preventable[3] and that the use of safety-engineered devices reduces needlestick injuries.[3,4] The passive devices are most effective in preventing needlestick injuries.[5]

Hospital systems

Hospitals need to have appropriate policies and procedures to deal with occupational exposures to blood and body fluids; these are best implemented through a comprehensive and coordinated occupational exposure programme. Depending on the individual institution, such a programme is usually managed by infection control personnel and involves staff health, occupational health, laboratory services, the ED and the infectious diseases service.

Staff needs to be aware of the appropriate steps to take in the event that they sustain an exposure, such as who to notify, incident reporting requirements, and where and how to seek medical evaluation. The programme should develop processes for consent and testing of the source individual (including situations where the individual refuses or is unable to give consent), prompt blood-borne virus testing and communication of results to the exposed person. Clear written guidelines and clinical pathways should be accessible to medical staff involved in managing these exposures (including specific recommendations for exposures involving a blood-borne virus positive source and antiretroviral PEP).

Management

The initial management of all needlestick injuries is the same: first aid measures, documentation of the event, determining the status of the source and counselling of the exposed worker.

Initial management

Occupational exposure to blood or other potentially infectious body fluids should be considered a medical emergency to ensure timely management. Following exposure, the exposed person should be removed from the area and general first aid measures applied:

- for skin exposures: wash the exposed area well with soap and water; if no water is available, use an alcohol-based antiseptic. Other antiseptics, such as iodophors, chloroxylenol (PCMX) and chlorhexidine (CHG) also inactivate HIV. (Do not squeeze the needle stick injury site.)
- for eye exposures: remove contact lenses if present and irrigate eyes with copious amounts of water or saline.
- for oral mucous membrane exposures: spit out contaminating material and rinse the mouth with water several times.

Documentation

Clinical information on the source patient for the exposure and the recipient HCP should be documented. This includes risk factors and serological tests for HIV and hepatitis B and C. The nature and time of the exposure should also be described. The exposure should be evaluated and documented on the basis of the definition of exposure given above. All potential exposures to blood or contaminated body fluids as defined above should be promptly evaluated. The following information should be obtained by trained medical personnel:

- name and identification of the source
- time and date of the exposure
- nature of the exposure (i.e. non-intact skin, mucosal, or percutaneous exposure, human bite); type of fluid (i.e. blood, blood-contaminated fluid or other contaminated fluid)
- body location of the exposure and contact time with the contaminated fluid
- infective status of the source (i.e. HIV, HCV, hepatitis B surface antigen [HBsAg]), if known, including date of test
- when the source is HIV positive, selection of the PEP regimen should consider the comparative risk represented by the exposure and information about the exposure source, including the history of and the response to antiretroviral therapy based on clinical response, CD4 cell counts, viral load measurements and current disease stage
- for percutaneous injuries, a description of the injury (depth of wound, solid vs hollow needle, sharp use in source patient).

The injured HCP should be questioned about the circumstances of the exposure (activity, time, device type, availability of Personal protective equipment [PPE]). The following information should be obtained from the injured person and verified from their medical/occupational health record:

- dates of hepatitis B immunizations
- post-immunization titre, if known
- previous testing (if available) for HIV, HBV and HCV
- tetanus immunization status
- current medications
- current or underlying medical conditions that might influence drug selection (e.g. pregnancy, breastfeeding, renal or hepatic disease).

Determining status of the source

All source cases should be tested for HBsAg, HCV and HIV, unless the source is known to be infectious. If feasible, a system should be devised to allow HIV test results to be obtained as soon as possible (i.e. within 24 hours). The rapid HIV test should be used to make an initial determination of the source patient's HIV status and has the advantage that results are available in less than 60 minutes.[6] All positive tests should be confirmed by Western blot. Negative tests do not require confirmation. Determination of HBsAg status should be obtained as soon as possible, but not later than 7 days. Local and state laws regarding consent and counselling prior to HIV testing should be followed.

Clinicians should also be aware of rare case reports where the source patient tested HIV seronegative and was later found to have primary HIV infection[7]; these rare events do not alter guidelines for routine antibody testing but do highlight the importance of testing for HIV RNA if clinically indicated.

Counselling of exposed worker

Risk assessment is particularly important for the HCP to make educated decisions about PEP since the consequences are huge and the stress is extraordinary. They should also be well informed of the benefits and risks of PEP and of the importance of close follow-up. Specifically, the following issues should be discussed with the exposed HCP:

- The HCP should be informed of the risk associated with the specific exposure experienced.
- The efficacy and side effects of PEP should be discussed.
- Risk reduction strategies should be employed to prevent transmission of HIV should the HCP acquire infection. In the event of HIV infection post-exposure, the greatest risk of transmission to other individuals is in the first 6 to 12 weeks. The exposed HCP should be instructed on condom use or abstinence from sex and refraining from blood, plasma, organ, tissue and semen donation until the 6-month serological test is negative. There is no need to modify an HCP's patient-care responsibilities after an exposure.
- Follow-up is important to identify HIV infection or adverse effects of the PEP regimen, if administered.
- Specific counselling is warranted for women of childbearing age. Data from an HIV pregnancy registry suggest overall safety of antiretroviral drugs.[8] Temporary discontinuation of breastfeeding following exposure until the 6-month serological test is negative should be considered.

Hepatitis B

Hepatitis B vaccination is recommended for all health care workers who are involved in direct patient care or who handle human blood or tissues,[9] and is an important infection control and occupational health strategy. Health care workers should be aware of their HBV immunization status and should undergo antibody testing 4 to 8 weeks after the last dose of the HBV vaccine to ascertain their immune status.

The risk of acquiring HBV from occupational blood/body fluid exposure from a patient positive for HBsAg is well recognized and related primarily to the degree of contact with blood and the hepatitis B e-antigen (HBeAg) status of the source. Following contact with a source positive for HBeAg, the risk of clinical hepatitis is 22% to 31% and serological evidence of HBV infection develops in 37% to 62% of exposed, non-immune individuals. In contrast, after exposure to HBeAg-negative blood, there is a 1% to 6% risk of clinical hepatitis and a 23% to 37% risk of serological evidence of HBV infection.[10] The average time from exposure to the development of symptoms is 10 weeks (range 4 to 26 weeks). Routine vaccination against HBV has been recommended for health care workers since the early 1980s,[11] with a consequent marked reduction in the incidence of infection in this population.

Post-exposure management following an occupational blood/body fluid exposure to HBV requires evaluation of the source's HBsAg status and the HBV vaccination and vaccine response status of the exposed person.[12,13] HB immunoglobulin (HBIG) is indicated for people who are non-immune (either because of no prior vaccination or because of vaccine non-responsiveness) and are exposed to blood or other infectious body fluids from an HBsAg-positive source. HBIG is prepared from human plasma (screened for blood-borne viruses) known to contain a high titre of antibody to HBsAg (antiHBs). The dose of HBIG is 400 IU, given intramuscularly. Concomitantly, the HBV vaccination should be injected at a separate site and a full course completed. Table 9.10.1 provides more detailed information about specific indications for HBIG and hepatitis B vaccination following occupational exposures. The exposed person does not need to take any special precautions to prevent secondary transmission.[14]

There are no apparent risks for adverse effects to developing foetuses when hepatitis B vaccine is administered to pregnant women.[15] The vaccine contains non-infectious HBsAg particles, which should pose no risk to the foetus. HBV infection during pregnancy might result in severe disease for the mother and chronic infection for the newborn.

Therefore neither pregnancy nor lactation should be considered a contraindication to the vaccination of women. HBIG is also not contraindicated for pregnant or lactating women.[16]

Hepatitis C

The risk associated with occupational exposure to hepatitis C following a parenteral injury is estimated to range between 1.8% and 10%.

Transmission to health care workers has never been documented from skin contamination and rarely from mucous membrane exposure. In contrast to HBV, environmental contamination is not significant.[17]

If the source HCV antibody test is positive, then polymerase chain reaction (PCR) testing for HCV RNA should be performed. Transmission is much less likely to occur from a source who is PCR negative, and the exposed individual can be reassured that the transmission of HCV in this case is negligible. If the source is positive for HCV RNA, a baseline serum from the exposed person is tested for HCV RNA by PCR, anti-HCV antibody testing by enzyme-linked immunosorbent assay (ELISA) and alanine aminotransferase (ALT) with follow-up testing as shown in Table 9.10.2. HCV viraemia can be detected by PCR between 10 days and 6 weeks after infection.[18,19] Since 2016 in Australia, direct-acting antivirals have been available on the Pharmaceutical Benefits Scheme (PBS), which are over 90% effective in curing HCV. The standard treatment time is

Table 9.10.1 Hepatitis B virus post exposure prophylaxis following occupational exposure

Vaccination and antibody response status of exposed	*Treatment when source*		
	HBsAg positive	*HBsAg negative*	*Unknown status*
Unvaccinated	HBIG, initiate HB vaccine series	HB vaccine series	Vaccine series, consider HBIG
Vaccinated and known responder[a]	Reassure	Reassure	Reassure
Vaccinated and known non-responder[a]	HBIG, initiate HB vaccine series	Reassure, consider revaccine	If high-risk source, treat as HBsAg positive
Vaccinated and unknown response[a]	Test exposed person for anti-HBs	Reassure	Test exposed person for anti-HBs
	If adequate[a], reassure		If adequate[a], reassure
	If inadequate[a], HBIG and course of vaccination		If inadequate[a], HBIG and course of vaccination

[a]A responder is a person with adequate levels of serum antibody to HBsAg (i.e., anti HB_s equal to/o mkl/ml).

(From US Public Health Service. Updated U.S. Public Health Service guidelines for the management of occupational exposures to HBV, HCV, and HIV and recommendations for postexposure prophylaxis. *MMWR Recomm Rep.* 29 June 2001;50:(RR-11):1–452; and Centers for Disease Control and Prevention (CDC). Testing for HCV infection: an update of guidance for clinicians and laboratorians. *MMWR.* 2013;62(18):362–365.)

8 to 12 weeks, but this can be extended to 24 weeks and may also involve the addition of older medications such as interferon in resistant cases. Usually the exact drug regimen prescribed will be decided in consultation with the infectious disease consultant and is dependent on the genotype of HCV, whether the patient has sustained or has any pre-existing liver damage, and other co-morbidities. Examples of these drugs include daclatasvir and sofosbuvir.

Currently, no recommendations exist to restrict professional activities of health care workers with HCV infection. As recommended for all health care workers, those who are HCV-positive should follow strict aseptic techniques and standard precautions, including the appropriate use of hand washing, protective barriers and care in the use and disposal of needles and other sharp instruments.[14]

Human immunodeficiency virus

The average risk of acquiring HIV infection from all types of reported percutaneous exposure to HIV-infected blood is 0.3%.[20] This is increased for exposures considered as high risk involving:

- a deep injury
- visible blood on the device causing the injury
- a device previously placed in the artery or vein of the source patient
- a source with terminal AIDS or who has died as a result of AIDS within 60 days of the exposure and thus is presumed to have a high titre of HIV.[21]

These factors are also probably significant for mucous membrane and skin exposures to HIV-infected blood, where the average risk of HIV transmission is approximately 0.09% and <0.09%, respectively.[22] Prolonged or extensive skin contact or visibly compromised skin integrity would also suggest a higher risk.

Recommendations for PEP with antiretroviral agents have been guided by a better understanding of the pathogenesis of primary HIV infection, which indicates that HIV infection does not become established immediately; this leaves a brief window of opportunity during which post-exposure antiretroviral intervention might modify or prevent viral replication. An early case-control study demonstrated that use of zidovudine decreased the risk of occupational HIV seroconversion by 81%,[23] and it is likely (but not proven) that combination antiretroviral therapy provides even greater protection. Animal data also support the use of antiretroviral prophylaxis after exposure to HIV, provided prophylaxis is administered promptly and for an adequate period. Failures of HIV PEP are well documented with both single drug and combination drug regimens.[24]

HIV PEP should be initiated promptly, preferably within 2 hours of the exposure, although it may still be effective for up to 72 hours. Given the complexity of choosing and administering HIV PEP, whenever possible, consultation with an infectious diseases consultant or another physician who has experience with antiretroviral agents is recommended, but it should not delay timely initiation of PEP. There is a slight variability in the selection of drugs by different authorities. For the sake of simplicity and ease of understanding, a three-drug regimen is generally recommended for all high-risk injuries, as shown in Table 9.10.3. The preferred PEP regimen is tenofovir + emtricitabine (lamivudine may be used in place of emtricitabine) plus dolutegravir. Zidovudine is no longer recommended in the preferred PEP regimen. The recommended duration of PEP is 28 days. A 3- to 5-day supply of PEP antiretroviral agents (a 'starter pack') should be kept in the ED.

This regimen is now the preferred combination because of its excellent tolerability, proven efficacy, fewer side effects and drug–drug interactions, and ease of administration. Studies have shown increased rates of adherence

Table 9.10.2 Serology testing for needle stick injury exposed person

		Time			
		At exposure	*4–6 weeks*	*3 months*	*6 months*
Low-risk source and negative serology		Anti-HBsAg antigen antibody		HIV and HCV antibodies testing may be offered

and regimen completion when tenofovir plus either emtricitabine or lamivudine have been used as components of the PEP regimen.[25–31] Zidovudine is not a 'must' inclusion in the newer regimens, as it has no clear advantages in efficacy over tenofovir and it has significant treatment-limiting side effects. Efavirenz should not be used in pregnant women or women of childbearing age. Nevirapine, abacavir and didanosine should not be used as PEP because of significant side effects.

Most occupational exposures do not result in the transmission of HIV and the potential benefits of PEP need to be carefully weighed against the toxicity of the drugs involved. Nearly 50% of health care workers taking HIV PEP experience adverse symptoms (e.g. nausea, malaise, headache, diarrhoea and anorexia) and approximately 33% cease taking drugs because of side effects.[32,33] In some other studies, adherence to PEP has been estimated to be around 40% to 60%.[33–35] The importance of completing the prescribed regimen needs to be stressed and measures taken to minimize side effects.

The emotional effect of an occupational HIV exposure is substantial[36] and often underestimated. The exposed person may need time off work, short-term use of a night-time sedative or even referral for formal psychological or psychiatric counselling. Patients should be advised of measures to prevent secondary transmission (e.g. safer sexual practices) during the follow-up period, especially the first 6 to 12 weeks.

Maintaining confidentiality for the staff member sustaining exposure is a priority, as it may have lasting implications both personally and professionally.

The circumstances surrounding the exposure should be reviewed as part of the hospital's occupational exposure policy and appropriate preventive and educational measures taken if indicated.

Exposures that occur in the community

Blood or body fluid exposures may be sustained in the community, as well as in health care settings; examples include needlestick injuries from improperly discarded needles and syringes or blood splashes to the eye or mouth in the course of an altercation. The exposed person may be a member of the public or of an emergency service, such as a policemen or ambulance officer. These exposures are usually managed in the ED.

Although the principles of management are broadly similar to those for occupational exposures, there are some important differences. First, the source is almost never available for testing. (If the source syringe has been retrieved by the exposed person, this should *not* be tested for blood-borne viruses because such testing is only validated on serum.) Second, needlestick exposures almost always involve old dried blood; this is much less infectious than fresh blood because the viral titre falls with time and dried blood does not pass easily from the lumen of the needle into the exposed person's subcutaneous tissue. Third, these exposures often provoke a considerable degree of distress in the affected person and there may be considerable pressure from the exposed person, a family member or a colleague to 'do something'. Some of these incidents even attract media attention.

In Australia, only 1% to 2% of injecting drug users are HIV infected, so the risk of HIV transmission from a discarded needlestick injury is negligible, for example, 1:100 (risk source is HIV positive) times 1:300 (risk of HIV transmission after needlestick) times undefined factor to account for old dried blood (say 1:5)—or approximately 1 in 150,000. Similar calculations show a potentially higher risk of HBV and HCV transmission but, in reality, documented instances of blood-borne virus infection resulting from these community exposures are extremely rare and people should be reassured about this.

In Australia, antiretroviral prophylaxis is not recommended for these exposures unless there are particularly compelling epidemiological circumstances to indicate a high HIV risk in the source.

People not previously vaccinated against HBV should be given HBIG and the first dose of a hepatitis B vaccination course. Despite the low risk of blood-borne virus transmission, many patients feel more reassured if they are offered baseline and follow-up testing. As with exposures in the hospital setting, the attending doctor needs to provide the affected person with information, support and a sympathetic ear!

Pre-exposure prophylaxis

PrEP is where anti-retroviral agents are prescribed to uninfected individuals who are at high risk for contracting the HIV virus, such as those whose condom use is inconsistent and who engage in high-risk sexual activities. PrEP may be taken orally (tenofovir and emtricitabine) or topically as a vaginal gel (tenofovir).

The efficacy of oral tenofovir bases PrEP regimens has been well established by randomized control trials involving both heterosexual and homosexual individuals, as well as intravenous drug users, and in 2015 the World Health Organization recommended that those at substantial risk should be offered PrEP as part of a comprehensive prevention program.[37,38]

Provision of antiretroviral prophylaxis following sexual exposures in the community is a highly specialized field and is outside the scope of this chapter; advice should be sought from a doctor with HIV expertise. Interested readers are referred to guidelines produced by the Australian Department of Health and Ageing, available at http://www.ashm.org.au/pep-guidelines/.

9.11 Tropical infectious diseases

Sander Manders

ESSENTIALS

1 **Tropical diseases are a major cause of morbidity and mortality worldwide.**

2 **Due to climate change and increasing population mobility (migration and travel), health practitioners in non-tropical areas will increasingly have to diagnose and treat tropical diseases.**

3 **A significant proportion of northern Australia has a tropical climate and several tropical diseases occur in this area. Vigilant public health surveillance, case tracking and vector control are instrumental in controlling incursions of non-endemic tropical diseases into Australia.**

4 **Indigenous Australians are disproportionally affected by infections in tropical Australia.**

5 **Within tropical areas, the aetiological spectrum of common diseases is different from that in temperate areas. This is due to different local prevalences of common pathogens, as well as the existence of specific tropical agents. Knowledge of local protocols is important in choosing appropriate antibiotic cover for the treatment of common diseases in the tropics.**

6 **In travellers who have returned from the tropics and present to the emergency department, common infections not specific to the tropics should not be forgotten as likely causes. A good history and systematic approach may aid in the correct identification of tropical diseases. Expert consultation may be of great benefit and public health notification is essential.**

Introduction

Tropical diseases cause an enormous burden of disease worldwide, and many other diseases that are not specific to the tropics disproportionately affect people in developing countries.

Returned travellers or migrants may present to health practitioners with signs and symptoms of tropical diseases. Due to climate change and increasing population mobility (travel and migration), health practitioners in non-tropical areas will increasingly need to diagnose and treat tropical diseases. A high index of suspicion, a systematic approach and expert consultation contribute to the appropriate investigation and management of these cases.

Significant areas of northern Australia have a tropical climate, including the Top End (around Darwin), Far North Queensland (north of Cairns) and the Kimberley (in Western Australia). Several tropical diseases are endemic there, with others occurring only infrequently. Indigenous Australians are disproportionally affected by both tropical and non-tropical disease.

Diseases common to temperate climates also occur in the tropics, and it is important to recognize that these may have different aetiologies there. Community-acquired pneumonia in tropical Australia, for instance, is most commonly caused by *Streptococcus pneumoniae*; but in severe cases, organisms such as *Burkholderia pseudomallei* and *Acinetobacter baumannii* should also be covered. *Cryptococcus gattii* should be considered in meningitis or subacute pneumonia. In undifferentiated sepsis, melioidosis is an important differential diagnosis. Knowledge of protocols based on specific local circumstances is important.

Vigilant public health systems are in place to help prevent the spread of disease from endemic areas into non-endemic areas. Many of the diseases discussed in this chapter are notifiable in both Australia and New Zealand. An appropriate public health response may include case surveillance, contact tracing and vector control.

Parasitic tropical diseases

Malaria

Introduction and epidemiology

Malaria is often considered the most important tropical disease worldwide. Half of the world's population is at risk, with over 200 million cases annually. An estimated 429,000 deaths occurred in 2015, of which 92% were in sub-Saharan Africa.[1] A substantial number of malaria infections occur in South America, Southeast Asia and the Pacific.

In Australia, malaria was officially considered eradicated only in 1981, and there are ongoing concerns regarding the potential re-establishment of the disease due to the widespread presence of appropriate vectors and geographic proximity to endemic areas (particularly Indonesia and Papua New Guinea). Around 400 to 500 cases are reported in Australia each year in travellers and migrants.

Malaria is caused by the protozoan parasite *Plasmodium*, of which six species are currently known to infect humans (Table 9.11.1). They have a complex life cycle and are transmitted by *Anopheles* mosquitoes, which bite from dusk to dawn. Less commonly, malaria can also be transmitted vertically. The parasites enter the blood and spread to the liver, where they replicate and are periodically released back into the bloodstream and then invade red blood cells.

The majority of malaria cases are caused by *P. falciparum*, which is the most severe and lethal form. Groups at particular risk include young children, pregnant women, immunocompromised patients (including those with HIV/AIDS) and travellers (due to a lack of immunity). Conversely, some genetic red blood cell variations—including sickle cell trait, thalassaemia trait, G6PD deficiency[3] and Melanesian ovalocytosis—provide some resistance against malaria.

Prevention

A large number of national and international organizations are involved in malaria prevention. Measures include vector control programmes, indoor residual spraying, insecticide-treated nets and intermittent preventative treatment for pregnant women. Travellers to endemic areas should use appropriate chemoprophylaxis tailored to the locally occurring *Plasmodium* species and drug resistance patterns and avoid mosquito exposure. Efforts to develop a malaria vaccine are ongoing.

Clinical features

The incubation period is typically 10 days to 4 weeks, but it can be longer. Mild cases of acute malaria are characterized by paroxysmal fevers caused by periodic parasitaemia. Rigors herald 6 to 10 hours of high fever (>40°C), after which a relatively asymptomatic period follows. The rigors recur after approximately 40 hours ('tertian'

fever) with *P. vivax* and *P. ovale* or approximately 64 hours ('quartan fever') with *P. malariae*. In *P. falciparum* malaria, fevers are less predictable and may be continuous. Additionally, there may be flu-like symptoms, diarrhoea and mild jaundice.

Chronic malaria occurs when low-level parasitaemia persists, causing recurrent attacks and anaemia, hepatosplenomegaly and increased susceptibility to other infections. Secondary complications include massive splenomegaly, malarial nephropathy and Burkitt lymphoma.

Severe malaria is almost exclusively caused by *P. falciparum*. Important features are summarized in Table 9.11.2. The World Health Organisation (WHO) has published case definitions for severe malaria.[4] The prognosis is poor, especially in children. Non-falciparum malaria is usually more benign, but death due to splenic rupture can occur.

Diagnosis

Clinical findings are of limited utility in diagnosing malaria[5]; microscopic examination of thick and thin blood smears[6] remains essential. A thick smear (drop of blood on a slide) is used to detect the presence of parasites and a thin smear (drop of blood spread thin on a slide) may help to identify the *Plasmodium* species. One negative smear does not exclude malaria; usually three sets are obtained at 12- to 24-hour intervals. Rapid dipstick immunoassay tests exist but can be falsely negative with low or very high levels of parasitaemia. *Plasmodium*-specific polymerase chain reaction (PCR) tests are sensitive and specific but not widely available in endemic areas. Many other laboratory abnormalities, such as thrombocytopaenia and hyperbilirubinaemia, can be seen in malaria, but these are not specific enough to make the diagnosis. Before the diagnosis of cerebral malaria can be made, bacterial meningitis should be ruled out by lumbar puncture.

Table 9.11.1 *Plasmodium* species that cause malaria in humans

Plasmodium species	*Area*	*Notes*
P. falciparum (±75%)	Africa, South America, Southeast Asia	Responsible for most severe cases and deaths
P. malariae (±20%)	Africa, Southeast Asia, Pacific, South America	Quartan malaria
P. ovale curtisi *P. ovale wallikeri*	West Africa, Southeast Asia	Two subspecies of *P. ovale* have been described[2]
P. vivax	United States, South America, Asia, Africa	Relatively benign
P. knowlesi	Southeast Asia (Malaysia)	Can cause severe cases; macaques are a reservoir

Table 9.11.2 Features of severe malaria

Feature	*Causes*	*Signs and symptoms*
Cerebral malaria	Microvascular obstruction with parasite-containing red blood cells	Drowsiness, confusion, coma Delirium, transient psychosis Seizures Focal neurological signs (rare) Usually absent meningeal signs
Respiratory distress	Direct capillary damage (ARDS) Respiratory compensation of metabolic acidosis Intercurrent chest infection Anaemia	Increased work of breathing Kussmaul breathing pattern
Severe anaemia	Increased RBC clearance (both infected and non-infected RBCs) Hypersplenism and immunological causes Haemolysis Failing bone marrow erythropoiesis	Pallor Fatigue, prostration Failure to thrive Jaundice Haemoglobinuria ('blackwater fever')
Acute renal failure	Pre-renal (dehydration, hypovolaemia) Renal (microvascular obstruction, glomerulonephritis)	Oliguria, anuria
Acidosis	Lactic acidosis	Hyperpnoea (respiratory compensation)
Hypoglycaemia	Abnormal liver function Hyperinsulinaemia from quinine/quinidine administration	Anxiety, diaphoresis Drowsiness, coma Hypothermia
Disseminated intravascular coagulation (DIC)	Inappropriate coagulation cascade activation	Bleeding complications Relatively rare (<10% of severe malaria)

ARDS, Acute respiratory distress syndrome; *RBC*, red blood cell
(From Trampuz A, Jereb M, Muzlovic I, Prabhu RM. Clinical review: severe malaria. *Critical Care*. 2003;7:315–323.)

Treatment

Early treatment reduces morbidity, mortality and malaria transmission. Emerging resistance to antimalarial drugs (chloroquine and sulfadoxine-pyrimethamine) is a recurring problem worldwide. Artemisinin, a compound derived from wormwood, combined with another agent (artemisinin combination therapy) is the best currently available treatment for *P. falciparum* malaria.[7,8] It is given orally for uncomplicated cases and intravenously for severe cases. Various regimens are available to treat other *Plasmodium* species. For travellers diagnosed with malaria, different drugs should be used for treatment than were taken for prophylaxis. Initial hospitalization with the consultation of an infectious disease specialist is recommended for all cases.

Schistosomiasis (bilharzia)

This parasitic disease affects more than 200 million people worldwide, with more than 90% of infections occurring in Africa. Its global impact is second only to malaria, with an estimated 200,000 deaths per year and significant chronic morbidity in survivors.

Infected freshwater snails release free-swimming larvae (cercariae) into surface waters, which can penetrate the skin of humans who come into contact with the water. Schistosomula then circulate in the blood and replicate in the portal vessels. Subsequently they migrate to blood vessels in other parts of the body and release their eggs, some of which are shed in human faeces and end up back in the surface waters. The eggs hatch in the water and produce miracidia, which enter suitable freshwater snails. After multiplying inside the snail, cercariae are released into the water, awaiting a new human host. The species of *Schistosoma* responsible for human infections are listed in Table 9.11.3; mixed infections also occur.

Acute infections are more likely to cause symptoms among non-residents of endemic areas. A pruritic rash in response to cercariae entering the skin (swimmers' itch) can occur within a day, usually subsiding within 10 days. Acute toxaemic

schistosomiasis (Katayama fever) is an uncommon but often severe seroconversion illness that may occur 1 to 3 months after the primary infection. Symptoms include fever, malaise, urticaria, cough, diarrhoea, hepatosplenomegaly and lymphadenopathy. It may last several weeks.

In chronic infection, the parasites migrate to species-specific areas in the host body, where their eggs induce a localized inflammatory response with fibrosis. This causes a high burden of disease[9,10]; common symptoms are listed in Box 9.11.1.

Prevention includes improving sewage management and using personal protection, such as rubber boots. Freshwater exposure should be avoided where possible. Vaccine development has proved challenging.

The diagnosis is made by a history of freshwater exposure and the demonstration of eggs in the urine or faeces. During Katayama fever, no eggs may be seen. Serological tests are available. Abdominal x-rays may show bladder calcification in chronic genitourinary schistosomiasis.

Praziquantel (40 to 60 mg/kg in two divided doses) is an effective treatment but, due to the high rate of re-infection, it may be difficult to achieve a cure in endemic areas. During Katayama fever, prednisone may be given to suppress the acute reaction and a repeat dose of praziquantel is recommended after 1 to 2 months. Community treatment programmes exist in endemic areas.

Table 9.11.3 *Schistosoma* species that infect humans

Schistosoma mansoni	Latin America, Africa, Middle East
S. haematobium	Africa, Middle East, Turkey, India
S. japonicum	East Asia, Pacific
S. intercalatum (±1%)	Sub-Saharan Africa
S. mekongi (<1%)	Cambodia, Laos (Mekong river basin)

Leishmaniasis

Various species of *Leishmania* protozoa occur in South America, Africa, the Middle East and India as well as in southern Europe.[11] They are transmitted by sandflies from human and canine reservoirs. Preventative measures include diethyltoluamide (DEET)-containing insect repellents, covering exposed skin and insecticide spraying inside houses. Sandflies are so small that they will pass through the mazes of bed nets that have not been treated with insecticide.

Leishmania infections can have cutaneous or systemic manifestations depending on parasite species and host factors, and they can remain asymptomatic. HIV co-infection predisposes to severe or recurrent disease. The incubation period is usually 1 to 2 weeks to 6 months, but there can be a latent period of up to 3 years.

Cutaneous leishmaniasis manifests with skin ulcers, which are usually painless unless a secondary bacterial infection occurs. Most lesions heal spontaneously over a few months, leaving a scar. A mucocutaneous form of the disease causes destruction of the mucous membranes of the nose, mouth, throat and surrounding tissues and can occasionally be fatal.

Visceral leishmaniasis (also known as kala-azar) manifests as fever with rigors, malaise, anorexia, lymphadenopathy and non-tender hepatosplenomegaly. Malnutrition and anaemia occur as the disease becomes chronic. The mortality is very high within 2 years if the disease remains untreated, although milder chronic forms also occur.

The diagnosis can be confirmed by microscopy, culture or PCR. Treatment of leishmaniasis varies by clinical manifestation and geographic region; pentavalent antimony-containing preparations are often the most effective drugs.

Post–kala-azar dermal leishmaniasis (PKDL) can occur several months to years after recovery from visceral leishmaniasis and consists of maculopapular lesions that spread from around the mouth. It typically disappears within a year without treatment but may require several months of treatment in some regions. PKDL patients can be long-term reservoirs of infection.

Trypanosomiasis

American trypanosomiasis (Chagas disease)

A major public health concern in Latin and South America, Chagas disease is caused by the flagellate protozoan *Trypanosoma cruzi*. It is spread to humans and other mammals by the faeces of insects of the Triatominae subfamily ('kissing bugs'). Additionally, it can be spread vertically or by the administration of blood products. Prevention focuses on vector control, including the improvement of housing conditions and the use of insecticides and mosquito nets. Blood products and organ donors in the Americas are screened for *T. cruzi*.

The acute phase of the infection may cause no or non-specific flu-like symptoms, but it can be fatal in children. Swelling around the site of inoculation in the face or around the eye (Romaña sign) is well described. The infection becomes asymptomatic within approximately 2 months. In the chronic phase, the parasites invade the myocardium and intestinal smooth muscle. The development of cardiomyopathy leads to congestive heart failure and arrhythmias and is fatal in 30% of patients. Dilation of the oesophagus and colon (10%) and neurological involvement may also occur.

The diagnosis can be made by direct visualization of the parasites in blood smears or by serological testing. Benznidazole and nifurtimox are effective treatments if given soon after the infection occurs. Treatment for chronic infections is difficult and side effects are common. Supportive treatment for cardiac and gastrointestinal complications is important.

African trypanosomiasis (sleeping sickness)

This disease of sub-Saharan Africa is caused by *Trypanosoma brucei*, which is spread by bites of the tsetse fly. Several major epidemics have occurred in the last century and vector control programmes have been successful in reducing the number of cases reported.

Approximately 95% of cases are caused by *Trypanosoma brucei gambiense* (West and Central Africa). A chancre may develop at the site of inoculation, followed by an asymptomatic stage which can last months to years. Symptomatic infection then begins with the haemolymphatic stage, characterized by fever, arthralgias and pruritus. Posterior cervical lymphadenopathy (Winterbottom sign) is common. The neurological stage begins when the trypanosomes invade

Box 9.11.1 Symptoms of chronic schistosomiasis

Schistosoma mansoni
S. *japonicum*
S. *intercalatum*
S. *mekongi*

Hepatosplenic schistosomiasis (hepatic periportal fibrosis)
Hepatomegaly
Portal hypertension
Splenomegaly
Pancytopaenia

Intermittent bloody diarrhoea
Tenesmus
Anaemia
Hypoalbuminaemia
Intussusception

S. *haematobium*

Genitourinary schistosomiasis
Microscopic haematuria
Bladder fibrosis and calcification
Ureteric obstruction, hydronephrosis, reflux
Squamous cell carcinoma of the bladder

Neuroschistosomiasis
S. *japonicum*
Meningoencephalitis
Focal seizures

S. *mansoni*, S. *haematobium*
Cauda equina syndrome, paraplegia, bladder dysfunction

Pulmonary schistosomiasis
S. *haematobium*
Pulmonary hypertension
Right heart failure, tricuspid incompetence

the central nervous system, causing headaches, personality changes, psychosis and focal motor, extrapyramidal and/or cerebellar signs. The final stages of the disease are characterized by daytime somnolence, seizures, coma and death.

A second type of the disease is caused by *Trypanosoma brucei rhodesiense* (5%), which occurs in southeastern Africa. Its course is more fulminant, with early multiple organ failure and death.

The diagnosis can be made by direct microscopic observation of the trypanosomes. Several serological screening tests (card agglutination trypanosoma test) exist for Gambian trypanosomiasis. The treatment is complex and depends on parasite subtype, regional drug resistance and the stage of the disease.

Filariasis

This variable disease is caused by a number of helminth species (worms) that occur throughout the (sub)tropics and are spread by mosquitoes and black flies. Lymphatic filariasis is the most common form; the worms develop in the lymphatic system and cause lymphoedema. Elephantiasis is the most extreme manifestation of this disease. Subcutaneous filariasis is caused by different species of helminths, producing a rash and arthritis. *Onchocerca volvulus* inhabits the eyes and is the world's second cause of blindness ('river blindness'). The diagnosis can be made with thick and thin blood smears obtained on a species-specific time of the day or by PCR. Treatment is with diethyl-carbamazine or ivermectin and albendazole; sequelae often remain chronic.

Gastrointestinal parasites

A variety of gastrointestinal infections are prevalent throughout the tropics (Box 9.11.2); they represent a major cause of morbidity and childhood mortality. Most are transmitted by the faecal-oral route; prevention therefore includes improving sanitation and access to safe drinking water. The most important feature of management is appropriate oral or intravenous rehydration; specific antimicrobial therapy is secondary.

Protozoa

Giardia lamblia is a protozoan parasite with worldwide distribution, including Australia and New Zealand. It can survive for a long time in freshwater lakes and streams contaminated with animal or human faeces. Mild infections can be asymptomatic, but it often causes foul-smelling, loose stools that may become fatty and float on water. It is usually self-limiting (7 to 10 days) but can become more chronic and contribute to malnutrition. The diagnosis is made by microscopy and treatment is with oral metronidazole (30 mg/kg up to 2 g qd for 3 days) or tinidazole (50 mg/kg up to 2 g as a single dose).

Entamoeba histolytica infection is often asymptomatic or causes only mild diarrhoea, but it may lead to severe diarrhoea with mucus, pus and blood in the stools (dysentery). Complications include peritonitis from intestinal perforation and amoebal liver abscesses. Microscopy must often be repeated to make the diagnosis. Supportive treatment is important; the specific treatment is oral metronidazole (15 mg/kg up to 600 mg q8h for 7 to 10 days) or tinidazole (50 mg/kg up to 2 g qd for 3 days).

Several species of *Cryptosporidium* occur worldwide (including in Australia and New Zealand), causing self-limiting watery diarrhoea. Special microscopic techniques are required to make the diagnosis. Specific treatment is required only in immunocompromised patients (particularly those with AIDS), as this illness may become severe, even life-threatening in this group.

Helminths (worms)

Soil-transmitted helminths infect humans when their eggs are ingested (*Ascaris*, *Trichuris*) or by active penetration of the skin by larvae (hookworms, *Strongyloides*). Most helminthic infections cause chronic abdominal discomfort without significant diarrhoea. Complications include intestinal obstruction *(Ascaris)*, chronic diarrhoea *(Trichuris)* and iron deficiency anaemia (hookworms). The eggs and larvae of these species can be distinguished by microscopy. Benzimidazoles (albendazole, mebendazole) as a single dose or short course are effective treatment.

Strongyloides occurs worldwide but it is hyper-endemic in rural and remote indigenous communities in northern Australia with a reported prevalence of up to 60%. Due to a cycle of auto-infection, *Strongyloides* infection can be lifelong if untreated.[12,13] Clinical features of strongyloidiasis are summarized in Box 9.11.3. Immunocompromised patients, including those given corticosteroids, may develop disseminated strongyloidiasis, which carries a high mortality. The diagnosis can be made by the detection of larvae in stool or serology in specialized laboratories. Treatment is with ivermectin (200 µg/kg as a single dose) or albendazole (400 mg qd for 3 days); some authors advocate repeat treatments.

Box 9.11.2 Common gastrointestinal pathogens in tropical areas

Parasites	Bacteria	Viruses
Protozoa		
Giardia lamblia	*Salmonella*	Rotavirus
Entamoeba histolytica	*Shigella*	Norovirus
Cryptosporidium parvum, Cryptosporidium hominis	*Yersinia enterocolitica*	Adenovirus
	Campylobacter jejuni	Astrovirus
	Escherichia coli (enterotoxigenic)	
	Staphylococcus aureus	
	Clostridium difficile	
	Clostridium botulinum	
	Vibrio cholerae	
Helminths		
Ascaris lumbricoides (roundworm)		
Hookworms		
Ancylostoma duodenale		
Necator americanus		
Trichuris trichuria (whipworm)		
Enterobius vermicularis (threadworm)		
Strongyloides stercoralis (pinworm)		

In Australia, *Strongyloides* is sometimes called 'roundworm'; In American English, 'pinworm' refers to *Enterobius* and 'threadworm' to *Strongyloides*.

Box 9.11.3 Clinical features of strongyloidiasis

Acute strongyloidiasis
- Diarrhoea
- Hypoproteinaemia
- Hypokalaemia

Chronic uncomplicated strongyloidiasis
- Recurrent diarrhoea
- Epigastric pain
- Cutaneous manifestations
- Urticaria
- Transient, migratory, linear erythema (larva currens)
- Respiratory symptoms
- Cough, haemoptysis
- Pneumonia, pulmonary abscess

Disseminated strongyloidiasis (hyperinfective syndrome)
- Sepsis (from enteric bacteria spread by migrating larvae)
- Severe diarrhoea
- Paralytic ileus
- Pneumonia, pulmonary haemorrhage

See references 12 and 13.

Viral tropical diseases

Many tropical viral infections are arthropod-borne (arboviruses), with flaviviruses being the most important subgroup (Table 9.11.4). Alphaviruses also cause some important infections in tropical and temperate areas.

Yellow fever

In acute yellow fever, a flu-like syndrome develops after 3 to 6 days' incubation and improves after another 3 to 4 days. In 15% of cases, a 'toxic phase' then develops, with high fever and liver dysfunction causing jaundice and haemorrhage; there may also be renal impairment. Mortality in this group is approximately 50%; survivors recover without significant sequelae. There is no specific treatment, but an effective vaccine exists. Evidence of vaccination is required by health authorities in many countries for travellers returning from endemic areas.

Dengue

Four distinct serotypes of the dengue virus occur in most tropical areas of the world; most cases occur in Southeast Asia. In Australia, occasional outbreaks occur, mostly in Far North Queensland. Most cases remain asymptomatic. Dengue fever may develop after 3 to 14 days' incubation; it lasts for 2 to 7 days. Arthralgias are often severe. The rash resembles that of measles. The most feared complication is dengue haemorrhagic fever (DHF), which may develop if a subsequent infection with another dengue serotype occurs. Features are summarized in Box 9.11.4. Laboratory diagnosis can be made with PCR testing. Supportive management with adequate hydration and analgesia is important; no specific therapy exists. A vaccine against all four serotypes is in an advanced stage of development.[14]

Arboviral encephalitis

Various arboviruses cause encephalitis and, although the vast majority of infections remain asymptomatic, potentially devastating sequelae occur in symptomatic patients. Clinical symptoms do not reliably differentiate between various arboviral causes of encephalitis; a definitive diagnosis can be obtained by serological testing.

In recent years, the West Nile virus (WNV) has been successful in extending its range into temperate areas including North America, Europe and Australia. Kunjin virus is a subtype of WNV endemic to Australia and Papua New Guinea.[15] The Murray Valley encephalitis virus is also endemic to northern Australia and Papua New Guinea and epidemics in the southern states of Australia have been well described.[16] Japanese encephalitis virus sporadically occurs on the Torres Strait Islands and the northernmost tip of Queensland.

In the presence of symptoms, these viruses may cause fever with a flu-like syndrome, rash, meningeal signs, convulsions and decreased level of consciousness. Encephalitis, meningitis or a poliomyelitis-like illness with flaccid paralysis have all been described. Disease progression is variable, ranging from full recovery to death. Long-term neuropsychiatric sequelae occur in a large proportion of survivors. Treatment is supportive. A vaccine exists for the Japanese encephalitis virus.

Alphaviruses

Several thousand cases of Ross River virus (RRV) and Barmah Forest virus (BFV) infections are seen annually in Australia. They cause flu-like symptoms with arthralgia and a widespread maculopapular rash in 50% of cases. Arthritis, myalgia and fatigue can last for 6 months or longer. IgM serological tests for RRV or BFV may be false positive in patients with other infections such as malaria and dengue. The closely related chikungunya virus occurs in Africa and Southeast Asia and causes similar symptoms. There is no specific treatment.

Viral haemorrhagic fevers

Several families of viruses can cause fever with a haemorrhagic diathesis (Table 9.11.5). They are carried by vectors, but person-to-person spread is mostly responsible for outbreaks. Dengue, yellow fever and certain other flaviviruses occasionally cause haemorrhagic fever as well.

The clinical presentation of viral haemorrhagic fevers is variable but usually includes a flu-like prodrome with respiratory and sometimes central nervous system symptoms. The disease progresses to multiple organ failure with disseminated intravascular coagulopathy. Case fatality rates are high, up to 90%. Treatment is supportive; no specific antiviral agents are available.

A large outbreak of Ebola virus disease[17] in West Africa (Liberia, Sierra Leone and Guinea) between 2013 and 2016 caused immense global

Table 9.11.4 Major viral tropical diseases

Disease and virus[a]	*Areas of common occurrence*	*Vector*
Flaviviruses		Mosquitoes *(Aedes aegypti)*
• Yellow fever (YFV)	South America, Africa	
• Dengue (DENV)	Latin and South America, Africa, South and Southeast Asia	
• Zika virus disease (ZIKV)	Equatorial Africa and Asia[b]	
• West Nile encephalitis (WNV)	Africa, Middle East, Central Asia, North America, Europe, Australia	Mosquitoes (*Culex* spp.)
• Kunjin (KUNV)	Australia, Pacific	
• Japanese encephalitis (JEV)	Southeast and Far East Asia	
• Murray Valley encephalitis (MVEV)	Northern Australia, PNG	
Alphaviruses		Mosquitoes (*Aedes* spp.)
• Ross River fever (RRV)	Australia, PNG, South Pacific	
• Barmah Forest fever (BFV)	Australia	
• Chikungunya (CHIKV)	Africa, South and Southeast Asia	

[a]Commonly used abbreviation to indicate the causative virus.
[b]The 2015 to 2016 Zika virus epidemic spread the virus to parts of the Pacific and much of the Americas and the Caribbean.
PNG, Papua New Guinea.

Box 9.11.4 World Health Organization case definitions for dengue

Dengue fever (DF)
Acute febrile illness with ≥2 of:
- Headache
- Retro-orbital pain
- Myalgia
- Arthralgia
- Rash
- Haemorrhagic manifestations (not meeting DHF criteria)
- Leukopaenia *and*
- Supportive serology

Dengue haemorrhagic fever (DHF)
ALL of the following:
- Febrile illness lasting 2–7 days
- Haemorrhagic tendencies
- Positive tourniquet test
- Petechiae, ecchymoses or purpura
- Bleeding from the mucosa, Gastro-intestinal (GI) tract, injection sites or other
- Haematemesis or melaena
- Thrombocytopaenia (≤100,000/mm^3)
- Evidence of increased vascular permeability
- Rise in haematocrit ≥20%
- Drop in haematocrit ≥20% after rehydration
- Signs of plasma leakage (pleural effusion, ascites, hypoproteinaemia)

Dengue shock syndrome (DSS)
All criteria for DHF *plus* evidence of circulatory failure:
- Rapid, weak pulse
- Narrow pulse pressure (≤20 mm Hg)
- Hypotension
- Cold, clammy skin and restlessness

Note: The World Health Organisation is currently re-evaluating these clinical case definitions.

Table 9.11.5 Important viral haemorrhagic fevers

Virus	*Areas of common occurrence*	*Vector*
Arenaviridae		
• Lassavirus	West Africa	Rats
Bunyaviridae		
• Hantaviruses	South and North America, South Asia, Europe	Rodents (rats, mice)
• Crimean–Congo haemorrhagic fever virus	Africa	Ticks (*Hyalomma*)
• Rift Valley fever virus	Africa	Mosquitoes (*Aedes* and *Culex* spp.)
Filoviridae		
• Ebola virus	Central Africa	Bats
• Marburg virus	Equatorial Africa	Bats

concern. The international response was slow initially, but eventually plans were deployed to fight the outbreak locally and limit its spread internationally. Screening systems were set up at international borders and at points of entry into health services (e.g. ambulance services and emergency departments). Persons who had arrived from affected areas within the preceding 21 days with fever, flu-like symptoms or gastroenteritis, were isolated and screened for Ebola. Rigorous protocols were set up for handling patients and contaminated materials. Ultimately over 28,000 people were infected, of whom 11,000 died; only 7 patients were identified outside of West Africa. A newly developed vaccine was reported to be highly effective.[18]

Viral hepatitis

A high incidence of hepatitis A and B (HAV, HBV) occurs in developing countries. HAV is spread via the faecal-oral route, whereas HBV is spread via contaminated blood and other bodily fluids. Vaccinations are recommended for travellers to endemic areas.

The hepatitis C virus (HCV) is a non–arthropod-borne flavivirus. Transmission via non-sterilized medical equipment is a concern in certain countries and recommendations for travellers may include carrying their own needles; no vaccine is available.

Hepatitis E (HEV) causes a self-limiting disease similar to hepatitis A except during pregnancy, when fatal hepatitis has been well documented.

Bacterial tropical diseases

Tuberculosis

Introduction

Approximately one-third of the world's human population is infected by *Mycobacterium tuberculosis*, making it a major worldwide public health concern. Tuberculosis is by no means exclusively a tropical disease but it disproportionally affects people in developing countries. Risk factors include HIV infection and other causes of immune suppression, diabetes, pulmonary disease and malnutrition. It is transmitted via the inhalation of droplets produced by a person with tuberculosis when he or she coughs. Mortality if untreated is around 50%.

Screening and prevention

For screening purposes, the Mantoux (tuberculin) skin test and interferon-gamma release assays (IGRAs) are commonly used. When positive, these tests indicate prior exposure to tuberculosis but do not prove active disease. False-negative and false-positive test results are a concern. The Bacillus Calmette-Guérin (BCG) vaccination offers some protection to people at high risk of contracting tuberculosis; it may cause a false-positive Mantoux test.

Symptoms

Tuberculosis can be asymptomatic but may also produce non-specific symptoms including fever, night sweats, anorexia and cachexia.

The most common presentation is pulmonary tuberculosis, which causes a productive cough, haemoptysis, chest pain and dyspnoea. An exudative pleural effusion may occur. Chronic complications include bronchiectasis and pulmonary fibrosis.

Non-pulmonary tuberculosis can occur in virtually any part of the body, including lymph nodes, bones, meninges, pericardium, abdomen and genitourinary tract. Miliary tuberculosis is an aggressive form of haematogenously disseminated tuberculosis that occurs in infants and immunocompromised patients.

Latent tuberculosis occurs when mycobacteria persist intracellularly; patients are asymptomatic and not infectious. The disease can reactivate later—for example, when the patient becomes immunocompromised.

Box 9.11.5 Chest x-ray findings associated with pulmonary tuberculosis

Consolidation
Hilar lymphadenopathy
Ghon focus (calcified nodule that remains after resolution of initial consolidation)
Cavitating lesions
Fibrosis (dominant in upper lobes)
Calcifications
Miliary pattern (small nodules throughout lungs)
Tuberculoma (well-defined tuberculosis mass)

Diagnosis

Pulmonary tuberculosis may be suggested by chest x-ray appearance (Box 9.11.5). Mycobacteria can be demonstrated on acid-fast (Ziehl-Neelsen) staining of sputum or broncho-alveolar lavage fluid. Culture confirms the diagnosis by identifying the species of mycobacteria; it also enables drug susceptibility testing. For non-pulmonary tuberculosis, samples appropriate to the site should be obtained and tested.[19]

Management

Within an emergency department or other hospital setting, patients suspected to have infective tuberculosis should be held in a negative-pressure room; staff and visitors should wear appropriate N95 face masks (aerosol precautions).

Treatment of any form of tuberculosis requires expert consultation. Public health reporting with appropriate contact tracing is essential. A 6-month treatment regimen with four drugs initially ('HRZE', i.e. isoniazid, rifampicin, pyrazinamide, ethambutol) is often used to treat uncomplicated tuberculosis. Emerging multi-drug resistance is of increasing concern worldwide.[20,21]

Melioidosis

Introduction

The gram negative bacterium *Burkholderia pseudomallei* is the cause of melioidosis.[22] It is found throughout Southeast Asia and India and is highly endemic in northeast Thailand, Malaysia, Singapore and northern Australia (with sporadic cases seen further south). The bacteria live in the soil during the dry season but can be found in surface water and mud after a heavy rainfall; they may also become airborne. Transmission occurs through the skin (cuts and sores), inhaled airborne dust or droplets and, rarely, through the ingestion of contaminated water. Person-to-person transmission is extremely rare.

The most important risk factors are diabetes, renal disease, alcohol excess and chronic lung disease. Indigenous Australians are disproportionally affected. Healthy people can become infected while working in wet, muddy conditions without adequate hand and foot protection.

Symptoms

The most common presentation of melioidosis is pneumonia, which may be severe.[23] It can also cause multiple abscesses in the skin, prostate, spleen, kidney and liver. Septic arthritis, osteomyelitis and neurological disease also occur. In endemic areas, melioidosis is an important differential diagnostic consideration in community-acquired sepsis. Septic shock develops in approximately 20% of patients and carries a high mortality. Unusual features of melioidosis include the development of sepsis after a long initial period of subclinical infection and its potential for recurrence after apparently appropriate antibiotic treatment.

Diagnosis and management

Melioidosis should be treated empirically when the diagnosis is suspected in endemic areas. Serological tests are of limited utility in populations with high background rates of infection. Cultures of blood, sputum, urine or swabs from an abscess or skin ulcer (in Ashdown selective medium) can confirm the diagnosis. A chest x-ray should be obtained in all suspected cases and a computed tomography scan of the abdomen and pelvis is recommended to seek abscesses in any culture-positive case.

B. pseudomallei is resistant to penicillins, most cephalosporins and aminoglycosides. It has some susceptibility to ceftriaxone (2 g IV is recommended initially for adults). However, to treat melioidosis definitively, meropenem (25 mg/kg up to 1 g, q8h), imipenem (25 mg/kg up to 1 g q6h) or ceftazidime (50 mg/kg up to 2 g q6h) must be given. Intravenous antibiotic therapy should be continued for at least 14 days and be followed by oral therapy (usually with sulfamethoxazole/trimethoprim) for 3 to 6 months. Abscesses should be drained and septic joints washed out. Expert consultation is recommended.

Leptospirosis

The zoonotic spirochaete bacteria of the *Leptospira* genus have a worldwide distribution (including Australia and New Zealand), with a higher prevalence in wet and humid tropical areas. Transmission occurs via the urine of infected animals; people with occupational or recreational exposure to animals or their urine are at particular risk.

Leptospira organisms enter the body through damaged skin or mucous membranes, circulate in the blood and then invade the kidneys, lungs and liver. The incubation period is 2 to 20 days. The initial (spiraemic) phase produces non-specific flu-like symptoms with conjunctivitis and occasional jaundice and hepatosplenomegaly. This is followed by a second (immune) phase that may include renal and hepatic failure, aseptic meningitis and pulmonary haemorrhage. Multi-organ failure can lead to death.

The diagnosis is usually made by leptospirosis serology (micro-agglutination test). However, initial serology is often negative, necessitating a convalescent serum sample for diagnosis. PCR tests are also available. Cultures may become positive only after several weeks of incubation. Members of the *Leptospira* genus are sensitive to a wide variety of antibiotics, including doxycycline (100 mg PO q12h for 5 to 7 days). For more severe disease, intravenous benzylpenicillin (30 mg/kg up to 1.2 g IV q6h for 5 to 7 days) or ceftriaxone (25 mg/kg up to 1 g qd for 5 to 7 days) are recommended.

Rickettsia

The rickettsiae comprise a group of pleomorphic, gram negative, obligate intracellular bacteria, with various species occurring in different areas throughout the world. They are spread by ticks and several other vectors.

Spotted fever

This group of rickettsial diseases includes Rocky Mountain spotted fever (RMSF), African tick bite fever, Mediterranean spotted fever, Australian tick typhus and others. The disease typically begins with fever, nausea and vomiting, myalgia and headaches. After a few days, a maculopapular rash appears in the majority of cases. RMSF in particular can progress to severe disease with vasculitis involving the lungs, intra-abdominal organs, central nervous system and skin (petechial rash). Treatment with oral or intravenous doxycycline (100 mg q12h for 7 to 10 days) should be commenced when there is sufficient clinical suspicion; confirmation from serological tests should not be awaited.

Typhus

Caused by rickettsia that are spread by lice and fleas, epidemics occur after natural or human-made disasters. Symptoms include a high fever with rigors, cough, myalgias and delirium. After a few days, a centrifugal rash may be seen. Treatment with doxycycline (dosing as earlier) or azithromycin (500 mg PO on day 1, then 250 mg qd for a further 4 days) may be lifesaving.

Scrub typhus

This disease is caused by *Orientia* species, which are bacteria similar to rickettsiae. It is endemic to East and Southeast Asia and northern Australia and is spread by larval stages of mites that occur in dense scrub vegetation. Symptoms include fever with chills, headache, cough, lymphadenopathy and sometimes a rash. An eschar (macule with black scab) often develops when the bite site ulcerates, usually in the groin, on the buttocks or in the axillae. Multi-organ failure can develop and fatal cases within Australia have been described. It is treated with doxycycline or azithromycin (dosing as earlier).

Enteric fever

Salmonella enterica, serovar Typhi causes a severe, acute febrile illness known as typhoid fever. Paratyphoid fever is a similar but usually less severe disease caused by serovar Paratyphi. Together these entities are referred to as enteric fever. The causative bacteria occur throughout tropical areas of the world, with the majority of cases occurring in South Asia (India, Pakistan, Bangladesh). They are spread via the faecal-oral route, often via contaminated food or water. Oral and intramuscular vaccines are available but are not completely effective.

Enteric fever is a systemic illness, different from the 'simple' gastroenteritis caused by non-typhoid *Salmonella* serovars. Initial symptoms include high fever for more than 2 days with malaise, headache, cough and constipation. After a week, prostration and high fevers with relative bradycardia become prominent. A rash (rose spots) and hepatosplenomegaly can occur. Delirium and profuse diarrhoea often develop in the third week. Most mortality is caused by complications, including intestinal haemorrhage or perforation, septicaemia, encephalitis and the formation of secondary abscesses. Survivors slowly improve over another week or so.

The diagnosis can be made from blood or stool cultures. Management is complicated by increasing rates of antibiotic resistance, with multi-drug resistance particularly problematic in Southeast Asia. Fluoroquinolones or third-generation cephalosporins are still largely effective treatments; azithromycin is recommended for Southeast Asia. For infections acquired in areas with less antibiotic resistance, other options may include chloramphenicol, amoxicillin and co-trimoxazole; expert consultation is recommended. Dexamethasone may reduce mortality in septic shock from enteric fever, and good supportive management is essential.

Cholera

The flagellated gram negative bacterium *Vibrio cholerae* secretes a toxin that causes profuse, watery diarrhoea.[24] It is transmitted via the faecal-oral route and occurs throughout sub-Saharan Africa, South Asia and South America. Oral vaccines are available.

Cholera causes high-volume watery diarrhoea ('rice water'), leading to dehydration with electrolyte loss, metabolic acidosis and hypoglycaemia. Vomiting occurs in the majority of cases. Shock, renal failure and cardiac arrhythmias are the main causes of mortality.

In the event of an outbreak, the diagnosis is often made on clinical grounds alone. *V.*

cholerae may be demonstrated on microscopy, and cultures in selective media can confirm the diagnosis.

The cornerstone of management is rehydration (oral or intravenous fluids) with electrolyte replacement. In severe cases, antibiotics reduce the duration and severity of diarrhoea. Doxycycline and azithromycin (20 mg/kg up to 1 g PO as a single dose) are most commonly used; other antibiotics may also be effective, such as ciprofloxacin (25 mg/kg up to 1 g PO as a single dose).

Approach to the returned traveller

People returning from tropical areas may present to health care providers with a variety of symptoms. A systematic approach is important to appropriately investigate and manage these patients. Ordered lists of common presenting symptoms, incubation times and geographical distributions can be found widely on the internet[25]. Up-to-date information on endemic tropical diseases in the area of the patient's travel should be sought, including any current outbreaks of tropical or non-tropical diseases. Recent outbreaks have included novel influenza viruses, severe acute respiratory syndrome (SARS), Middle Eastern respiratory syndrome (MERS), and Zika virus. It is essential that common non-tropical diseases, such as influenza or meningococcal meningitis, be included in the differential diagnosis.

History

Obtain a detailed previous medical history, including any predisposing factors such as immune compromise, splenectomy and pregnancy as well as a list of medications and known adverse drug reactions.

The travel history should include the following:

- The exact locations, duration and dates of stay, including any stopovers
- The nature of the accommodation (e.g. air-conditioned hotel or camping), use of bed nets and insect repellents
- Vaccination history (routine and travel-related) and adherence to preventative medication (such as antimalarial drugs)
- Any behaviour that may have led to disease exposure: known insect or tick bites, contact with sick people, animals, fresh water (including leisure activities), potentially unsafe food or water and sexual or needle exposures

The history of the presenting complaint should include fever patterns (including rigors) and associated symptoms (e.g. respiratory, cutaneous, gastrointestinal and other symptoms). Ask about the appearance and frequency of stools and whether they contained blood or mucus (dysentery).

Examination

The physical examination is often non-specific but can sometimes provide important clues to the diagnosis. Careful examination of the respiratory system, lymph nodes and skin is important (Table 9.11.6). Look for hepatosplenomegaly, jaundice and bleeding.

Investigations

Potential non-tropical causes for the patient's condition should be investigated as usual (e.g. chest x-ray for respiratory infections or a lumbar puncture for meningitis).

If the history and examination have raised suspicion for conditions for which specific tests (such as serology or cultures) are available, these should be sent off. Keep in mind that many of these will take days or longer to come back. Stool samples for culture, ova and parasites may be helpful. Specific tests for *Giardia*, *Cryptosporidium* and *Entamoeba histolytica* can be requested.

Routine blood tests may provide support for certain conditions, but they are rarely diagnostic. There should be a low threshold for obtaining three sets of thick and thin smears for malaria. Malaria rapid antigen detection tests are also very helpful, although because of the relatively low sensitivity of these kits, three blood films are still required to rule out malaria in any traveller with persisting fever who has returned from a malaria-endemic location. Eosinophilia is usually associated with parasitic (helminth) infection but also with several other infections including HIV, Human T-cell lymphotropic virus (HTLV) and tuberculosis. Evidence of haemolysis or coagulopathy may correlate with worse outcome.

Table 9.11.6 Common differential diagnoses of fever in the returned traveller

Fever plus:	*Non-specific systemic symptoms*	*Respiratory symptoms*	*CNS involvement*	*Cutaneous involvement*
Tropical or travel-related causes (consider dependent on travel history):	• Malaria • Arboviral infections (e.g. dengue, chikungunya, Zika) • Enteric fever • Infectious hepatitis (HAV) • Rickettsial diseases • Tuberculosis • Trypanosomiasis • Leptospirosis • Viral haemorrhagic fevers	• Epidemic respiratory viruses (e.g. influenza, SARS, MERS) • Pneumonia from tropical pathogen (e.g. *Burkholderia pseudomallei, Cryptococcus gattii*) • Q fever • Pertussis • Malaria • Tularaemia • Pneumonic plague	• Arboviral encephalitis (e.g. WNV, JEV) • Cerebral malaria • Meningitis/ encephalitis from other tropical cause (e.g. *Cryptococcus gattii*) • Trypanosomiasis • Rabies	• Arboviral infections (e.g. dengue, chikungunya, Zika) • Alphaviral infections (BFV, RRV) • Measles • Rickettsial diseases • Enteric fever • Rheumatic fever • Lyme disease • Scabies • Diphtheria • Leishmaniasis • Schistosomiasis • Cutaneous larva migrans (hookworms) • Filariasis
Non-tropical causes (do not forget):	• Seasonal influenza • Atypical pneumonia (e.g. *Legionella pneumophila*) • Bacterial sepsis (e.g. *Neisseria meningitidis*) • Urinary tract infection • Intra-abdominal infections • Acute HIV infection • Osteomyelitis • Endocarditis • Auto-immune diseases	• Seasonal influenza • Bacterial pneumonia from non-tropical pathogens (typical, atypical, hospital-acquired) • Pulmonary embolism	• Bacterial meningitis/ encephalitis from non-tropical pathogens (e.g. *Neisseria meningitidis*) • Viral meningitis/ encephalitis • Intracranial haemorrhage • Seizures	• Infectious mononucleosis • Varicella • Viral myocarditis • Endocarditis • Acute HIV infection • Syphilis • Childhood viral infections (e.g. parvovirus B19) • Henoch-Schönlein purpura (HSP) • Allergic reaction or drug rash

(Modified from Fairley JK. General Approach to the Returned Traveler. Centers for Disease Control; 2017. https://wwwnc.cdc.gov/travel/yellowbook/2018/post-travel-evaluation/general-approach-to-the-returned-traveler. Accessed December 24, 2017 and other sources.)

BFV, Barmah Forest virus; *HAV*, hepatitis A virus; *HIV*, human immunodeficiency virus; *JEV*, Japanese encephalitis virus; *MERS*, Middle East respiratory syndrome; *RRV*, Ross River virus; *SARS*, severe acute respiratory syndrome; *WNV*, West Nile virus.

Management

Specific treatment may be commenced if available, depending on the likely diagnosis. This may have to be done without the benefit of laboratory confirmation. A low threshold for expert consultation is recommended to help guide investigations and management. Supportive treatment is very important and may include analgesia, fever-control measures and the maintenance of adequate hydration and electrolyte replacement.

Patients who are unwell or suspected to have a high-risk condition should be admitted to the hospital. Consideration can be given to discharging low-risk patients provided that adequate follow-up can be arranged, including the results of any outstanding tests. Public health notification of any suspected or proven notifiable diseases is essential.

Acknowledgement

The author wishes to thank Professor Bart Currie, Infectious Diseases Physician at Royal Darwin Hospital and the Menzies School of Health Research, for his helpful suggestions.

The author strongly recommends checking all drug doses and regimens carefully. The latest version of the Australian Therapeutic Guidelines (Antibiotic) or other appropriate local guidelines should be consulted.

It is the responsibility of the prescriber to check their patient's particular circumstances +/- check with their infectious disease specialist and/or local protocols.

SECTION 10

GENITOURINARY EMERGENCIES

Edited by *Biswadev Mitra*

10.1 Acute kidney injury

Nicholas Adams

ESSENTIALS

1 Acute kidney injury (AKI) is defined as a rapid reduction in the glomerular filtration rate marked by an acute increase in the serum creatinine (SCr) concentration.

2 The early stages of AKI are usually asymptomatic and the diagnosis is based on a decrease in urine output or an elevated SCr. It may take 24 hours or more for an initially normal SCr concentration definitely to increase and up to 48 hours to distinguish between early AKI and renal failure.

3 The basic processes causing AKI are renal hypoperfusion (prerenal causes); damage to glomeruli, tubules, interstitium or blood vessels (renal causes); or obstruction to urine flow (post-renal causes).

4 Prerenal factors are present in about 40% of persons with AKI. They include hypovolaemia, hypotension, oedematous states with a reduced 'effective' circulating volume, renal hypoperfusion and drugs.

5 Bedside correction of hypovolaemia should be based on the cardiovascular response to passive leg raise and the urine output response to intravenous fluid resuscitation.

6 Renal factors are present in about 50% of persons with AKI. Acute tubular necrosis (ATN) is the most common pathological process causing ARF and is classified as ischaemic ATN or ATN due to damage by toxins (e.g. myoglobin) or drugs. No therapeutic intervention has hastened the recovery of renal function in established ATN.

7 Obstruction is present in about 10% of persons with AKI. Hydronephrosis can occur in the absence of obstruction, and some persons with obstruction do not have a dilated urinary collecting system.

8 Urine output usually decreases in AKI and the patient may be oliguric (less than 400 mL/day) or anuric (less than 100 mL/day). Only a few conditions cause anuria: complete urinary tract obstruction, vascular lesions, severe ATN or rapidly progressive glomerulonephritis.

9 Intravenous mannitol and sodium bicarbonate to produce an alkaline diuresis as a means of preventing ATN in severe rhabdomyolysis has not been shown to be effective.

Introduction

The basic process in acute kidney injury (AKI) is a rapid (hours to days) reduction in the glomerular filtration rate (GFR) due to renal hypoperfusion; damage to glomeruli, tubules, interstitium or blood vessels; or obstruction to urine flow. The GFR is inversely related to the serum creatinine (SCr) concentration and the diagnosis of AKI is made when there is an acute increase in the SCr concentration with or without a decrease in the urine output. A simple definition of μAKI is an acute and sustained (lasting for 48 hours or more) increase in the SCr of 44 μmol/L if the baseline is less than 221 μmol/L or an increase in the SCr of more than 20% if the baseline is more than 221 μmol/L. A more comprehensive definition (the RIFLE system) is used to classify persons with acute impairment of renal function (Table 10.1.1).[1]

Aetiology and pathogenesis

The causes of AKI are grouped according to the source of renal injury: prerenal (hypoperfusion), renal (parenchymal) and post-renal (obstructive). More than one cause can be present simultaneously.

Pre-renal acute kidney injury

Prerenal AKI is initially an adaptive response to severe volume depletion and hypotension in structurally intact nephrons. Prerenal AKI that is prolonged or inadequately treated can be followed by parenchymal renal damage (acute tubular necrosis [ATN]). Prerenal AKI is a potentially reversible cause of acute renal failure (ARF).

Reductions in renal blood flow (RBF) and GFR occur in the setting of hypovolaemia, hypotension, oedematous states with a reduced 'effective' circulating volume (cardiac failure, hepatic cirrhosis, nephrotic syndrome) or impaired renal perfusion (renal artery stenosis, hepatorenal syndrome). Drugs that interfere with renal autoregulation (e.g. prostaglandin inhibitors, angiotensin-converting enzyme [ACE] inhibitors or angiotensin II receptor antagonists) can reduce glomerular perfusion.[2] The physiological responses to volume depletion and hypotension and the link to prerenal AKI are shown in Fig. 10.1.1.

Table 10.1.1 RIFLE classification of acute renal failure

Stage	*Serum creatinine (SCr) concentration*	*Urine output*
Risk	Increase of 1.5 times the baseline	<0.5 mL/kg/h for 6 h
Injury	Increase of 2.0 times the baseline	<0.5 mL/kg/h for 12 h
Failure	Increase of 3.0 times the baseline or SCr is 355 µmol/L or more when there has been an acute rise of greater than 44 µmol/L for 24 h or anuria for 12 h	<0.3 mL/kg/h
Loss	Persistent acute renal failure; complete loss of kidney function for longer than 4 weeks	
End-stage renal disease	End-stage renal disease for longer than 3 months	

Renal acute kidney injury

Ischaemic, cytotoxic or inflammatory processes may damage the renal parenchyma. The causes of the damage can be grouped according to the major structures that are damaged: vessels, glomeruli, renal tubules or renal interstitial tissue.

Vascular causes involving the larger vessels include acute thrombosis of the renal artery, embolism of the renal arteries, renal artery dissection and renal vein thrombosis. Microvascular causes include vasculitis, malignant hypertension and thrombotic microangiopathy (TMA).

The glomeruli are the site of injury in acute glomerulonephritis, which can cause proteinuria, haematuria, nephrotic syndrome or nephritic

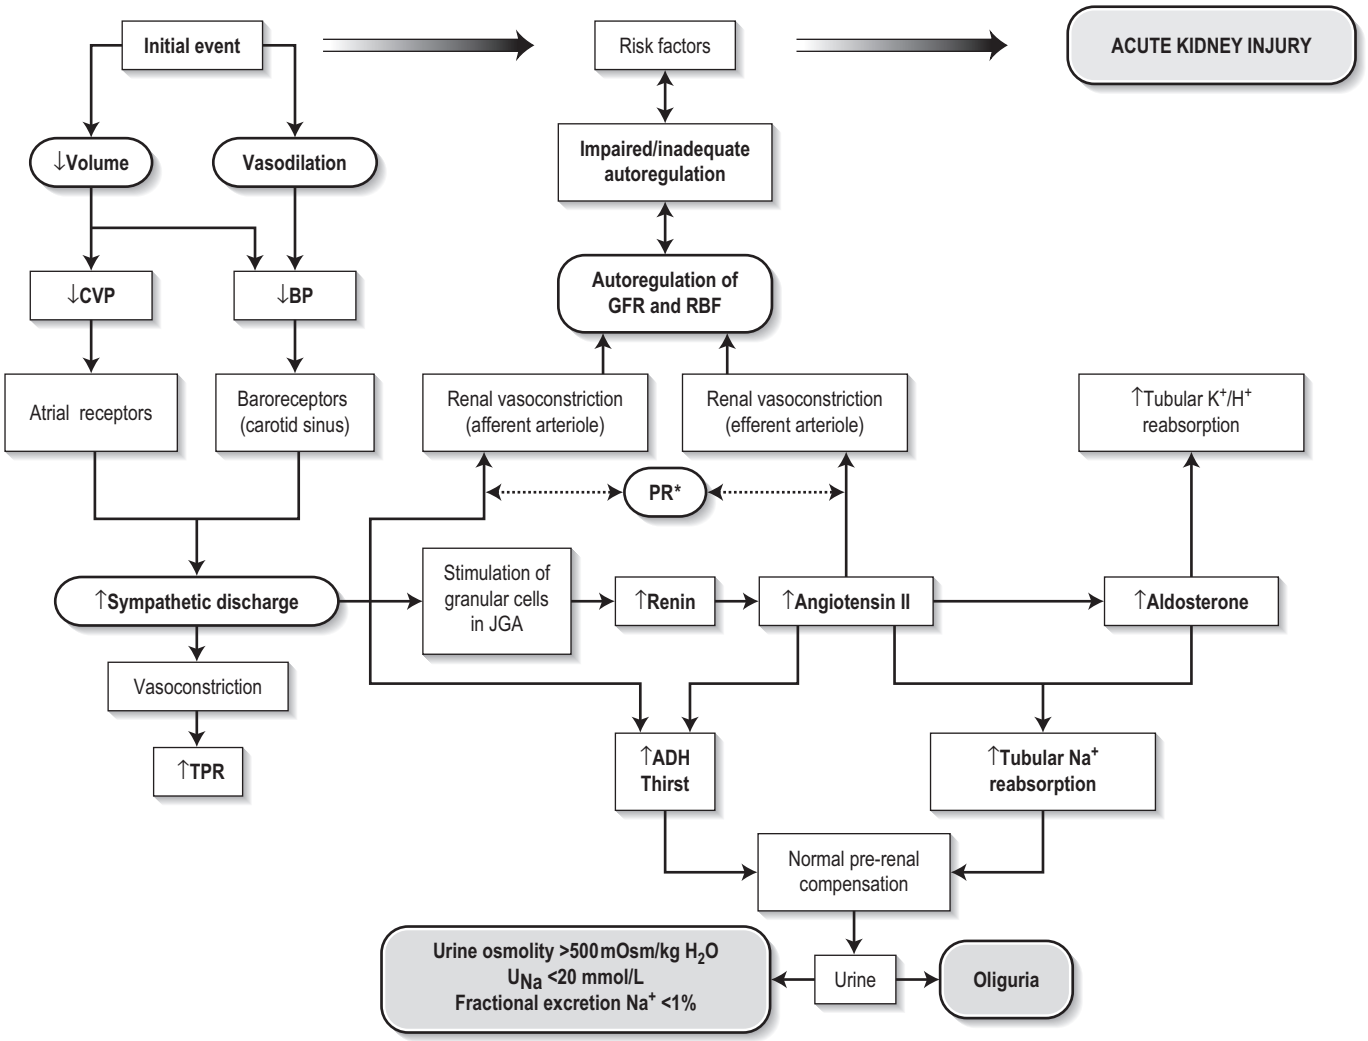

FIG. 10.1.1 Physiological response of the kidney to hypovolaemia or reduced perfusion. The normal response results in a reduced volume of concentrated urine. The presence of risk factors, impaired autoregulation or prolonged hypovolaemia can cause acute kidney injury. *ADH*, Antidiuretic hormone; *BP*, blood pressure; *CVP*, central venous pressure; *GFR*, glomerular filtration rate; *JGA*, juxtaglomerular apparatus; *PR**, renal prostaglandins; *RBF*, renal blood flow; *TPR*, total peripheral resistance.

syndrome. A number of different forms of glomerulonephritis have been described, generally diagnosed by the histological changes seen on renal biopsy. The distinction between these forms is not of direct concern for the emergency practitioner.

ATN is the most common pathological process causing AKI. Although the terminology suggests that the main cause is tubular damage, the actual pathophysiology is more complex: impaired autoregulation and marked intra-renal vasoconstriction (the main mechanism for the greatly reduced GFR), tubular damage (with cytoskeleton breakdown), increased tubuloglomerular feedback, endothelial cell injury, fibrin deposition in the microcirculation, release of cytokines, activation of inflammation and activation of the immune system.[3]

ATN is often classified as ischaemic ATN or cytotoxic ATN, but both processes may be present in some patients. Ischaemic ATN represents an advanced form of prerenal AKI, but the distinction between these two entities is based on histopathological changes and is of little use to the clinician. Important causes of cytotoxic ATN are listed in Box 10.1.1. Non-steroidal anti-inflammatory drugs (NSAIDs), ACE inhibitors and angiotensin receptor blockers (ARBs) often cause a gradual and asymptomatic decrease in the GFR, but they can also cause AKI. NSAIDs do not impair renal function in healthy persons, but can reduce the GFR in the elderly with atherosclerotic cardiovascular disease, in persons with chronic renal failure, when chronic prerenal hypoperfusion is present (e.g. cardiac failure, cirrhosis) or in persons using diuretics and calcium channel blockers.[4] AKI may occur after the administration of intravenous or intra-arterial radio-contrast agents. A number of risk factors have been identified for this, the most important being pre-existing renal impairment, hypovolaemia, a large contrast load and the use of hyperosmolar contrast agents.[5] Drugs that alter angiotensin levels (ACE inhibitors and ARBs) reduce renal perfusion by their antihypertensive effects or by impairing vasoconstriction of the efferent arteriole when renal perfusion is reduced by renal artery stenosis. The nephrotoxicity of haem pigments (myoglobin and haemoglobin) is enhanced by volume depletion, low urine flow rates and possibly low urine pH.

Abnormalities of renal interstitial structure and function represent only one feature of ATN; in acute tubule-interstitial nephritis (ATIN), however, they constitute the primary abnormality. The damage in ATIN is due to immunological mechanisms, the most important involving cell-mediated immunity. ATIN is usually due to an allergic reaction to a drug, commonly antibiotics (β-lactam antibiotics, sulphonamides, fluoroquinolones), NSAIDs, cyclooxygenase-2 inhibitors, proton pump inhibitors, diuretics, phenytoin, carbamazepine and allopurinol.

Box 10.1.1 Causes of toxic acute tubular necrosis

Exogenous agents
Radiocontrast
Non-steroidal anti-inflammatory drugs
Antibiotics: aminoglycosides, amphotericin B
Antiviral drugs: acyclovir, foscarnet
Immunosuppressive drugs: cyclosporin
Organic solvents: ethylene glycol
Poisons: snake venom, paraquat, paracetamol
Chemotherapeutic drugs: cisplatin
Herbal remedies
Heavy metals

Endogenous agents
Haem pigments: haemoglobin, myoglobin
Uric acid
Myeloma proteins

Post-renal acute kidney injury

Obstructive uropathy refers to the functional or structural processes in the urinary tract that impede the normal flow of urine; *obstructive nephropathy* is the renal damage caused by the obstruction. *Hydronephrosis* and *hydroureter* refer to dilatation of the renal urinary collecting system and the ureters, respectively. They may occur in the absence of obstruction and, conversely, may be absent in some patients with obstruction.

Casts or crystals within the renal tubular lumen can cause intrarenal obstruction. Extrarenal obstruction can develop in the urethra, bladder, ureter or pelvi-ureteric junction. Obstructive uropathy in adults is commonly caused by prostate disease or retroperitoneal neoplasm (cancer of the cervix, uterus, bladder, ovary or colon). Metastatic cancer, lymphomas or inflammatory processes in the retroperitoneum (appendicitis, diverticulitis, Crohn disease) or a neurogenic bladder can also cause obstructive uropathy. Bilateral renal stones are an uncommon cause of obstructive uropathy.

Obstructive nephropathy usually develops gradually and can cause chronic renal failure if the obstruction involves the urethra, bladder or both ureters. Unilateral ureteric obstruction will cause AKI only if it involves a single functioning kidney.

Epidemiology

Studies of the pathogenesis of community-acquired ARF have produced conflicting results. In one study, the major processes were identified as prerenal in 70% of cases, renal in 11% of cases and post-renal in 17% of cases.[6] There are geographical differences in the causes of ATN. In Africa, India, Asia and Latin America, ATN is usually caused by infections (e.g. diarrhoeal illnesses, malaria, leptospirosis), ingestion of plants or medicinal herbs, envenomation, intravascular haemolysis due to glucose-6-phosphate dehydrogenase deficiency or poisoning.

Prevention

Maintaining intravascular volume and renal perfusion

The rate and volume of intravenous fluid given to hypovolaemic persons depends on the nature of the intravascular depletion, the blood pressure and heart rate, the (estimated) volume of fluid lost, cardiac function and ongoing circulatory losses. The response to treatment is evaluated by simple bedside measurements (heart rate, blood pressure, urine output, cardiovascular response to passive leg raise).

Rhabdomyolysis

Most studies on the prevention of ATN after rhabdomyolysis have been in persons with crush injury after earthquakes, where the incidence of AKI is about 50%. In this situation, fluid resuscitation should, if possible, begin before the crush is relieved. These patients may require massive amounts of fluid because of fluid sequestration in the injured muscles. The goal of intravenous fluid treatment is to produce a urine output of 200 to 300 mL/h while myoglobinuria (discoloured urine) persists. There is no evidence to support this rate of fluid replacement in persons who have rhabdomyolysis and AKI without crush injury, although a urine output of 100 mL/h would be reasonable while the urine is discoloured. The intravenous administration of mannitol and sodium bicarbonate to produce an alkaline diuresis as a means of preventing ATN in severe rhabdomyolysis has not been shown to be effective.[7]

Radio-contrast nephropathy

Evidence associating radio-contrast agents with acute nephropathy remains controversial. Numerous studies have been published investigating reduction of the incidence of radio-contrast nephropathy. At present it is unclear whether any specific treatment, including intravascular volume expansion, is effective. Certainly N-acetyl cysteine administration before and after radio-contrast administration does not appear to be effective.[5]

Clinical features

The diagnosis of AKI should be considered when there is a decrease in urine output or an elevated SCr concentration. The clinical features depend on the pre-existing conditions that increase the risk of developing AKI, the initiating factor(s) and the effects of AKI (Fig. 10.1.2). The history should

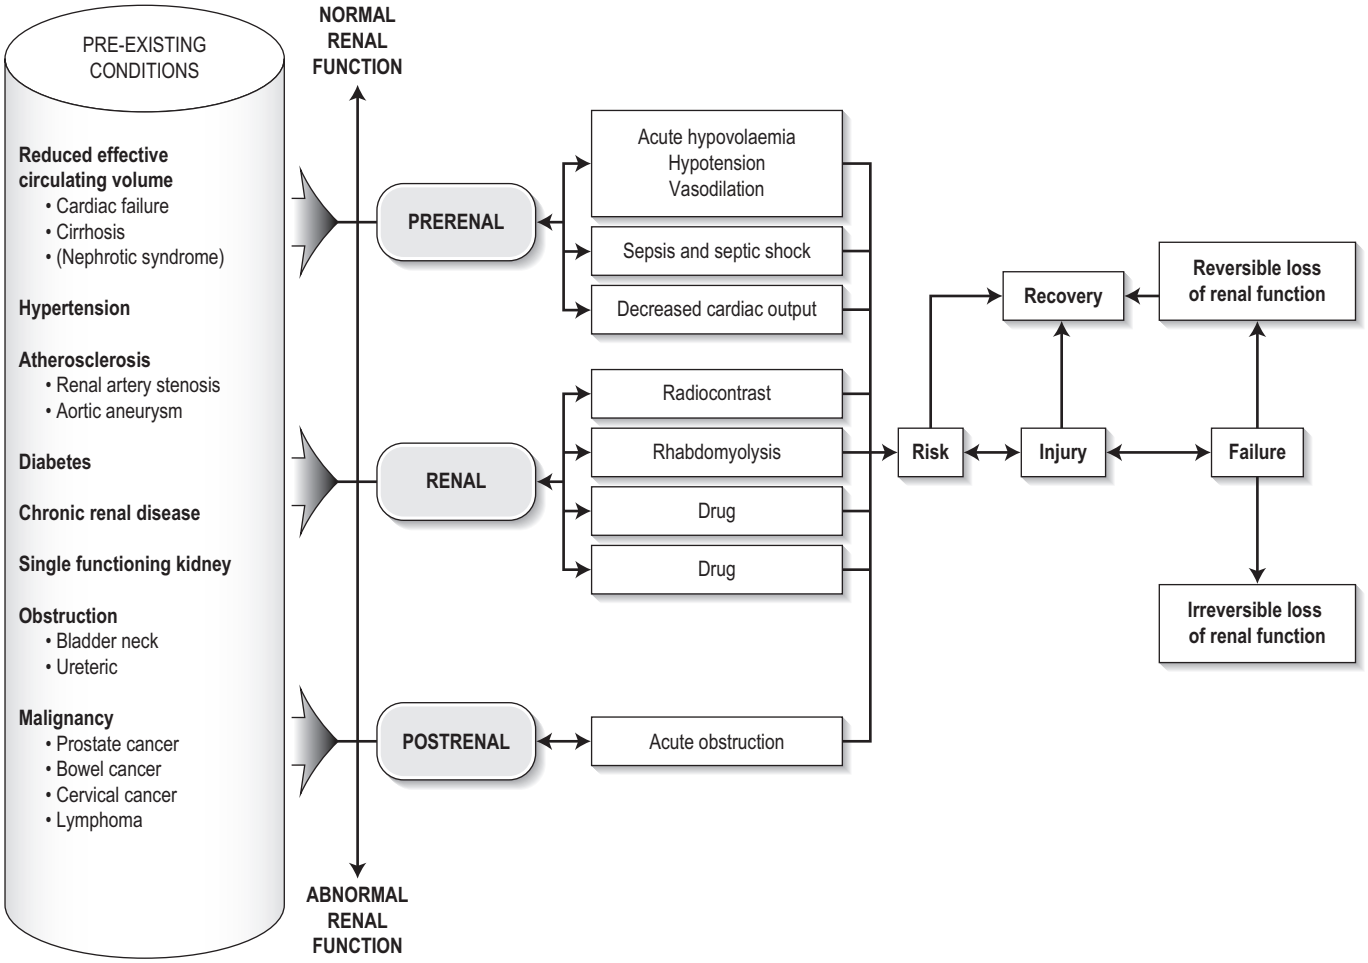

FIG. 10.1.2 The clinical presentation of acute kidney injury (AKI) depends on the presence of any pre-existing conditions, the precipitating event(s) that caused the AKI and the severity of the AKI.

Box 10.1.2 Evaluation of acute kidney injury

Assess the intravascular volume
Look for renovascular disease
Look for symptoms or signs of obstruction to urine flow
Systematic search for presence of infection or sepsis
Evaluate for pre-existing renal disease or chronic renal failure
Obtain a detailed history of medication or drug use
Consider the possibility of glomerulonephritis

include a detailed drug history, enquiry about recent invasive vascular or radiological procedures and any family history of renal disease. This is followed by clinical examination and evaluation of investigations. A number of key issues then need to be resolved (Box 10.1.2).

Evaluation of prerenal (intravascular volume) status

Imprecise terminology, such as 'dry' or 'dehydrated', should be avoided. 'Dehydration' refers to situations where more water than electrolyte(s) has been lost, shrinking body cells and increasing the serum sodium concentration and osmolality. In other words, 'dehydration' means water depletion. *Hypovolaemia* is a decrease in the intravascular volume due to loss of blood (haemorrhage, trauma) or loss of sodium and water (e.g. vomiting, diarrhoea, sequestration of fluid in the bowel, etc.).

The (bedside) assessment of the (extracellular) volume status determines the initial resuscitation strategy. This involves evaluation of heart rate and blood pressure, the state of the skin and mucous membranes and the jugular venous pulse. The examination also includes auscultation of the lungs (for pulmonary crackles), abdominal examination (for ascites or masses) and examination of the legs (for peripheral oedema).

The 'typical' features of intravascular volume depletion (tachycardia or hypotension or both in the supine position, or postural hypotension) are not as consistent or reliable as implied by many textbook descriptions. The presence of (supine) tachycardia has low sensitivity as a diagnostic feature of increasing hypovolaemia in healthy persons. An increase in the pulse rate of 30 beats/min or more between the supine and standing positions is a highly sensitive and specific sign of hypovolaemia after phlebotomy of large volumes (600 to 1100 mL) of blood, but the sensitivity is much less after phlebotomy of smaller volumes. The inability to stand long enough for vital signs to be measured because of severe dizziness is a sensitive and specific feature of acute large blood loss. A systolic blood pressure of 95 mm Hg or less in the supine position has high specificity but low sensitivity for hypovolaemia. Postural hypotension is present in 10% of normovolaemic people younger than 65 years and in up to 30% of normovolaemic people older than 65 years.[8]

The textbook descriptions of the signs of saline depletion in adults (dry mucous membranes, shrivelled tongue, sunken eyes, decreased skin turgor, weakness, confusion) are neither specific nor sensitive compared with laboratory tests for hypovolaemia. The presence of a dry axilla argues somewhat for the presence of saline depletion; the absence of tongue furrows and the presence of moist mucous membranes argue against the presence of saline depletion.

Evaluation of the renovascular state

Acute renal infarction is caused by dissection of the aorta or renal artery, embolism, renal artery thrombosis, renal vein thrombosis or renal artery aneurysm. Acute arterial occlusion is usually symptomatic, with the development of pain (loin, abdominal or back pain), haematuria, proteinuria, nausea and vomiting. Vascular occlusion of a single functioning kidney produces anuria.

Atheromatous disease of the renal arteries is common in persons older than 50 years with widespread atherosclerosis. Persons with stenosis or occlusion of one or both renal arteries can develop an elevation in SCr concentration after starting treatment with ACE or ARB drugs or they may develop acute on chronic renal failure.

Exclusion of thrombotic microangiopathy

TMA is a syndrome of microangiopathic haemolytic anaemia, thrombocytopaenia and varying degrees of organ injury caused by platelet thrombosis in the microcirculation. There are two clinically distinct entities: haemolytic uraemic syndrome (HUS) and thrombotic thrombocytopaenic purpura (TTP). HUS affects young children and causes AKI with absent or minimal neurological abnormalities. TTP occurs in adults and causes severe neurological involvement in most cases and variable degrees of renal damage. Both conditions are rare.

Pre-existing renal disease or chronic renal failure

It can be difficult to distinguish between chronic and acute renal impairment. The following features suggest the presence of chronic renal failure: documented renal impairment in the past, family history of renal disease, polyuria or nocturia, uraemic pigmentation, normochromic and normocytic anaemia or small kidneys on ultrasound or computed tomography (CT) scans. Renal size may be normal or increased in chronic renal failure associated with diabetes, polycystic kidney disease or amyloidosis.

Exclusion of urinary obstruction

The symptoms and signs of urinary tract obstruction depend on the site, the cause and the rapidity with which it develops. Pain is more common in acute obstruction and is felt in the lower back, flank or suprapubic region, depending on the level of the obstruction. Chronic obstruction is usually painless. Symptoms of prostatic obstruction include frequency, nocturia, hesitancy, post-void dribbling, poor urinary stream and incontinence. Bladder neck obstruction usually results in an enlarged (and palpable) bladder.

Recognition of rhabdomyolysis

Muscle necrosis releases intracellular contents into the circulation. This causes red-brown urine (which tests positive for haem in the absence of visible red cells on microscopy or tests positive for myoglobin with specific tests), pigmented granular casts in the urine, elevated serum creatine kinase (CK) levels that are five times or more above the upper limit of normal and clear serum (serum is reddish in haemolysis). The severity of the rhabdomyolysis ranges from asymptomatic elevations of muscle enzymes in the serum to AKI and life-threatening electrolyte imbalances.

Urine dipstick findings may be normal because myoglobin is renally cleared from the serum more rapidly than CK; thus myoglobinuria may be absent in patients with renal failure or those who present later in the illness. Muscle pain is absent in about 50% of cases and muscle swelling is an uncommon finding. Muscle weakness occurs in those with severe muscle damage. Fluid sequestration in muscles can cause hypovolaemia. Marked muscle swelling can cause a compartment syndrome.

Other blood test abnormalities include hyperkalaemia, AKI with rapid and marked elevation in SCr (e.g. 220 μmol/L per day), hypocalcaemia (which occurs early and is usually asymptomatic), hyperuricaemia, hyperphosphataemia, metabolic acidosis and disseminated intravascular coagulopathy.[7]

Acute kidney injury and acute renal failure

The early stages of AKI are usually asymptomatic and the diagnosis is based on an elevated SCr concentration. It may take 24 hours or more for an initially normal SCr concentration to show a definite increase and up to 48 hours after the event(s) that caused the AKI to distinguish between the early stages of AKI (risk and injury) and the development of renal failure.

The urine output usually decreases and the patient may be oliguric (urine output <400 mL/day) or anuric (urine output <100 mL/day). Persons with AKI and oliguria have more severe kidney impairment than those without oliguria. Only a few conditions cause complete anuria: total obstruction, vascular lesions, severe ATN or rapidly progressive glomerulonephritis. The clinical features caused by ARF are shown in Box 10.1.3.

Differential diagnosis

The diagnosis of AKI requires synthesis of data from the patient's history, physical examination, laboratory studies and urine output. The category of AKI (Risk, Injury or Failure) may be difficult to determine in the emergency department (ED) if the baseline SCr is unknown. The reversibility of the AKI may be inferred if there is a marked increase in urine output after correction of prerenal problems, but a reduction in SCr (due to an increase in GFR) may not be seen for 12 to 24 hours.

Box 10.1.3 Clinical features of acute renal failure

1. Anorexia, fatigue, confusion, drowsiness, nausea and vomiting, and pruritus
2. Signs of salt and water retention in the intravascular and interstitial spaces: elevated jugular venous pressure, peripheral oedema, pulmonary congestion, acute pulmonary oedema
3. Abnormal plasma electrolyte concentrations, particularly hyperkalaemia
4. Metabolic acidosis
5. Anaemia
6. Uraemic syndrome: ileus, asterixis, psychosis, myoclonus, seizures, pericardial disease (pericarditis, pericardial effusion, tamponade)

Criteria for diagnosis

Serum biochemistry

The following are measured: serum concentration of electrolytes (sodium, potassium, bicarbonate, chloride, calcium, phosphate), serum urea and SCr concentrations, random blood glucose, liver function tests, coagulation tests and CK concentration.

AKI causes acute elevations in the SCr concentration or serum urea concentrations or both. In prerenal AKI, the low urine flow rate favours urea reabsorption out of proportion to decreases in GFR, resulting in a disproportionate rise of serum urea concentration or blood urea nitrogen (BUN) concentration relative to the SCr concentration. However, serum urea concentrations depend on nitrogen balance, liver function and renal function. Severe liver disease and protein malnutrition reduce urea production, resulting in a low serum urea concentration. Increased dietary protein, gastrointestinal haemorrhage, catabolic states (e.g. infection, trauma) and some medications (corticosteroids) increase both urea production and serum urea concentration without any change in GFR.

The SCr concentration is the best available guide to the GFR. Acute reductions in GFR produce an increase in the SCr concentration. The changes in SCr concentration lag behind the change in GFR and can be affected by the dilutional effect of intravenous fluid. Correct interpretation of the SCr concentration extends beyond just knowing the normal values (Fig. 10.1.3). Creatinine is a metabolic product of creatine and phosphocreatine, which are found almost exclusively in skeletal muscle. The SCr concentration is affected by the muscle mass,

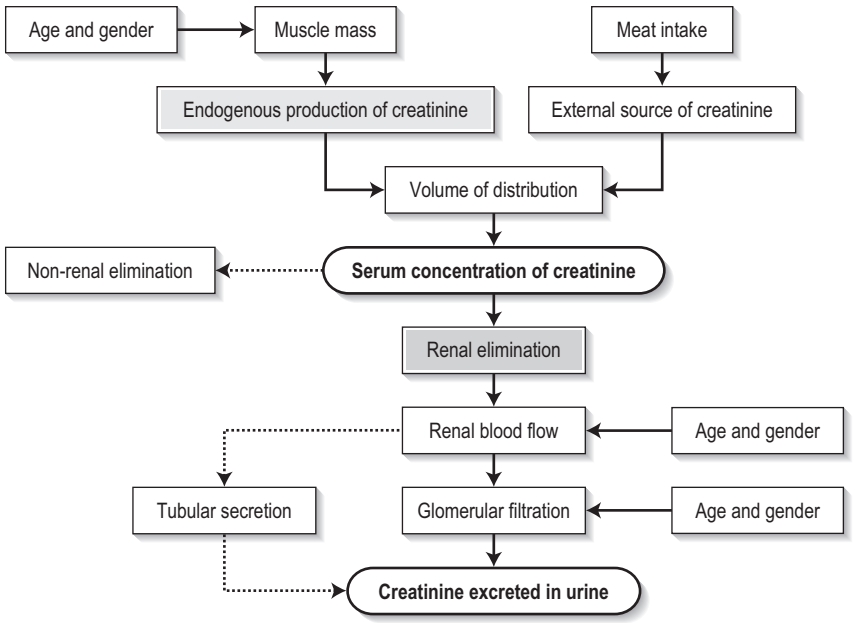

FIG. 10.1.3 Factors that determine the serum creatinine concentration.

$$CCr = \frac{(140 - age) \times weight}{0.814 \times SCr\ (\mu mol/L)} \quad \text{in males}$$

$$CCr = \frac{(140 - age) \times weight \times 0.85}{0.814 \times SCr\ (\mu mol/L)} \quad \text{in females}$$

Cockcroft–Gault formula

$$GFR\ (mL/min/1.73\ m^2) = 186 \times \left[\frac{SCr\ (\mu mol/L)}{88.4}\right]^{-1.154} \times age^{-0.203} \times \underset{\text{(if female)}}{0.742} \times \underset{\text{(if black)}}{1.210}$$

MDRD equation

FIG. 10.1.4 Formulae for calculating the creatinine clearance *(CCr)* or the glomerular filtration rate *(GFR)* from the serum creatinine concentration *(SCr)*. *MDRD*, Modified diet renal disease.

meat intake, GFR, tubular secretion (which can vary in the same individual and increases as the GFR decreases) and breakdown of creatinine in the bowel (which increases in chronic renal failure). The GFR decreases by 1% per year after 40 years of age, yet the SCr concentration remains unchanged because the decrease in muscle mass with age reduces the production of creatinine. The GFR (corrected for body surface area) is 10% greater in males than females, but men have a higher muscle mass per kilogram of body weight. The SCr concentration in men is thus greater than that in women.

The creatinine clearance (CCr) or GFR are estimated indirectly using formulae (Cockcroft-Gault formula or the modification of diet in renal disease [MDRD] study equation) based on the SCr concentration (Fig. 10.1.4).[9] These equations assume a steady-state SCr concentration and are inaccurate if the GFR is changing rapidly. They will also be less accurate in amputees, very small or very large persons or persons with muscle-wasting diseases.

Knowledge of a patient's baseline SCr concentration is important in assessing the severity and progression of AKI. Small changes when the baseline SCr concentration is low are more important than larger changes when the baseline SCr concentration is high. Major decreases in GFR can occur in the normal range of SCr concentration. If the previous SCr concentration is not known, the MDRD equation can estimate the expected (normal) SCr concentration (using a value for the GFR at the lower range of normal).

Hyperkalaemia is a common complication, with the serum K^+ usually rising by 0.5 mmol/L per day in ARF. The serum Ca^{2+} concentration may be normal or reduced in ARF. Both hypocalcaemia and hypercalcaemia may occur at different stages of ARF in rhabdomyolysis. Rhabdomyolysis is characterized by a very high blood CK concentration. Abnormal liver function tests invariably accompany the hepatorenal syndrome associated with hepatic cirrhosis.

Full blood examination

Anaemia develops rapidly in ARF, but its presence or the degree of anaemia does not reliably distinguish between acute and chronic renal failure. Leucocytosis is usually seen if sepsis is the cause of ARF. Eosinophilia is often present in acute interstitial nephritis, polyarteritis nodosa and atheroembolic disease. Anaemia

and rouleaux formation suggest a plasma cell dyscrasia. Disseminated intravascular coagulation can complicate ARF due to rhabdomyolysis. A microangiopathic blood film associated with ARF occurs in vasculitis or thrombotic thrombocytopenic purpura.

Serological tests

Tests for the detection of antinuclear antibody (ANA), antineutrophil cytoplasmic antibody (ANCA) or measurement of complement concentration are indicated in suspected cases of vasculitis or glomerulonephritis.

Urine tests

The results of urine analysis may be normal in AKI. A positive test for leucocytes, nitrates or both is found in urinary tract infections. A positive test for blood, protein or both suggests a renal inflammatory process. The presence of red cell casts on microscopy is diagnostic of glomerulonephritis.

Measurement of the concentration of electrolytes in the urine and calculation of their fractional excretion is of intellectual interest in understanding the pathophysiological responses of the nephron to different types of AKI. However, the calculations are cumbersome, the results inconsistent and the information obtained does not alter the patient's immediate treatment.

Imaging

A chest x-ray is taken to assess the heart size and the presence of cardiac failure, infection, malignancy or other abnormalities. Ultrasound can define renal size and demonstrate calyceal dilation and hydronephrosis, but the findings depend on the expertise of the operator. Obtaining adequate images is difficult in obese patients, in those with ascites or where there is a large quantity of gas within the bowel. Ultrasound also provides information about bladder size and can detect prostamegaly.

A normal ultrasound examination can occur in the very early stages of obstruction or if ureteric obstruction is due to retroperitoneal fibrosis or to infiltration by tumour. Hydronephrosis not due to obstruction occurs in pregnancy, vesicoureteric reflux or diabetes insipidus.

Doppler scans are useful for detecting the presence and nature of RBF in thromboembolism or renovascular disease; however, because RBF is reduced in prerenal or intrarenal AKI, test findings are of little use in the diagnosis of AKI. CT scans of the urinary tract evaluate renal size and renal position, renal masses, renal calculi, the collecting system and the bladder. Non-contrast CT is the examination of choice in persons with suspected renal calculi and can be used to assess the urinary tract in persons at risk of radiocontrast AKI. Injection of intravenous contrast is used for CT urography, CT angiography and CT venography, which may be necessary in some circumstances. Radionuclide can be used to assess RBF and tubular function.

Renal biopsy

A renal biopsy provides a tissue diagnosis of the intrarenal cause of AKI and is indicated if the findings will identify a treatable condition. A renal biopsy is also valuable when renal function does not recover after several weeks of ARF and a prognosis is required for long-term management.

Treatment

The basis of emergency management is recognizing that AKI is present, correcting reversible factors, providing haemodynamic support and treating life-threatening complications. This is followed by treatment (if available) of the specific cause of AKI and management of ARF by supportive measures and (if required) renal replacement treatment.

Correction of hypovolaemia

Hypovolaemia not only causes AKI but also worsens all forms of AKI. The clinical diagnosis of hypovolaemia can be difficult if the jugular venous pressure is not easily seen or if there is pre-existing cardiac failure. When there are definite signs of hypovolaemia, the patient is resuscitated with rapid infusion of crystalloid. If hypovolaemia is a possibility or if the person's urine output has decreased markedly, the patient should have 250 to 500 mL of crystalloid infused rapidly (fluid challenge) and the response (urine output, vital signs, jugular venous pressure) evaluated. An increase in urine output or in blood pressure following a fluid challenge suggests that hypovolaemia was present.

Invasive measurement of volume status using central venous and pulmonary artery catheters can increase mortality, lengthen hospital stay and increase the cost of care. There is no evidence to justify the routine use of these invasive measures in patients with AKI. The main indications for central venous cannulation in AKI in the ED are difficulties obtaining intravascular access in the limbs or the need to give drugs that can be given only into a large central vein (e.g. noradrenaline).

Haemodynamic support

AKI impairs the autoregulation of GFR and RBF throughout all ranges of mean arterial pressure. Renal perfusion in ATN is linearly dependent on mean arterial pressure even in the normal range of blood pressure. Episodes of mild or severe decrease in blood pressure lead to recurrent ischaemic injury. Inotrope/vasopressor drugs (noradrenaline or adrenaline) should be commenced if hypotension persists after the correction of hypovolaemia. Dopamine appears to have no clinical advantage compared with other agents and has, in fact, resulted in increased mortality in some studies.

Monitoring and maintaining urine output

Urinary Catheter

Accurate measurement of urine output requires insertion of a urinary catheter, but this is not needed in the less severe forms of AKI if there is frequent spontaneous voiding. A catheter is required initially in persons with oliguria or (apparent) anuria, shock or obstruction to bladder outflow.

Diuretics

Frusemide is used to produce a diuresis in the treatment of AKI due to hypercalcaemia and in the treatment of severe rhabdomyolysis. A trial of high-dose frusemide (80 to 120 mg intravenously) can be used in persons with AKI who have acute pulmonary oedema if dialysis is not readily available. Persons with less severe forms of AKI (e.g. risk or injury) who have a low urine output (<0.5 mL/kg per hour) that does not increase after correction of hypovolaemia are often given low doses of frusemide (e.g. 20 to 40 mg intravenously). A subsequent increase in urine output is not necessarily associated with a decrease in the SCr concentration. There is no evidence that the use of diuretics to convert the less severe forms of AKI from a (presumed) oliguric to a non-oliguric stage affects outcome.[10]

Electrolyte abnormalities

Potassium

The serum potassium concentration may be low, normal or high. AKI due to diarrhoea causes hypokalaemia and metabolic acidosis, whereas AKI due to vomiting or diuretics causes hypokalaemia with metabolic alkalosis. A serum potassium (K^+) below 3.0 mmol/L is treated with oral or intravenous potassium. Diabetic ketoacidosis (DKA) causes renal loss of K^+, depleting the body of potassium. Persons with AKI due to DKA who have a normal or low serum K^+ need intravenous potassium during treatment with intravenous fluids and insulin.

Hyperkalaemia is due to an imbalance between potassium intake and renal potassium excretion or follows redistribution of potassium from the intracellular to the extracellular space. Hyperkalaemia in AKI can be asymptomatic, produce electrocardiographic (ECG) changes or cause potentially fatal changes in cardiac rhythm.

The initial ECG changes in hyperkalaemia are shortening of the PR and QT intervals, followed by peaked T waves that are most prominent in leads II, III and V2 through V4 (Fig. 10.1.5). Marked ST-T segment elevation (pseudo-myocardial infarction pattern) may occur. Bradycardia with

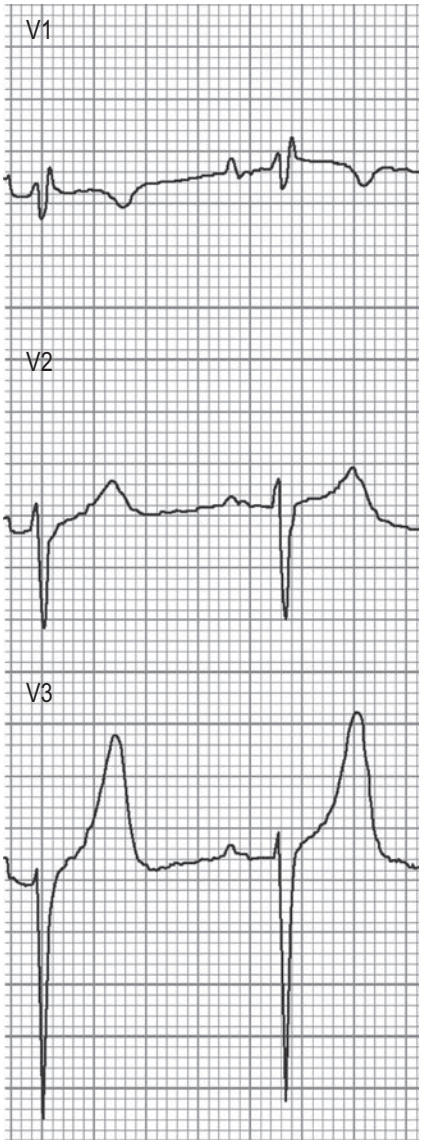

FIG. 10.1.5 The initial electrocardiographic changes in hyperkalaemia. The T waves in leads V3 to V5 are very tall and have a 'peaked' tip. The other findings (which may be unrelated to the hyperkalaemia) are the presence of a right bundle branch block pattern and a slightly prolonged PR interval.

sinoatrial (SA) block or atrioventricular block (including complete heart block) can develop and progress to periods of cardiac standstill or asystole. More commonly, the PR interval is prolonged and the QRS complex widened, with the QRS complex having a left- or right-bundle-branch-block configuration (Fig. 10.1.6). At high serum [K^+] (8 to 9 mmol/L), the SA node may stimulate the ventricles without ECG evidence of atrial activity (sinoventricular rhythm). When the serum [K^+] is 10 mmol/L or greater, SA conduction no longer occurs and junctional rhythms are seen. The width of the QRS complex continues to increase and, eventually, the QRS complexes

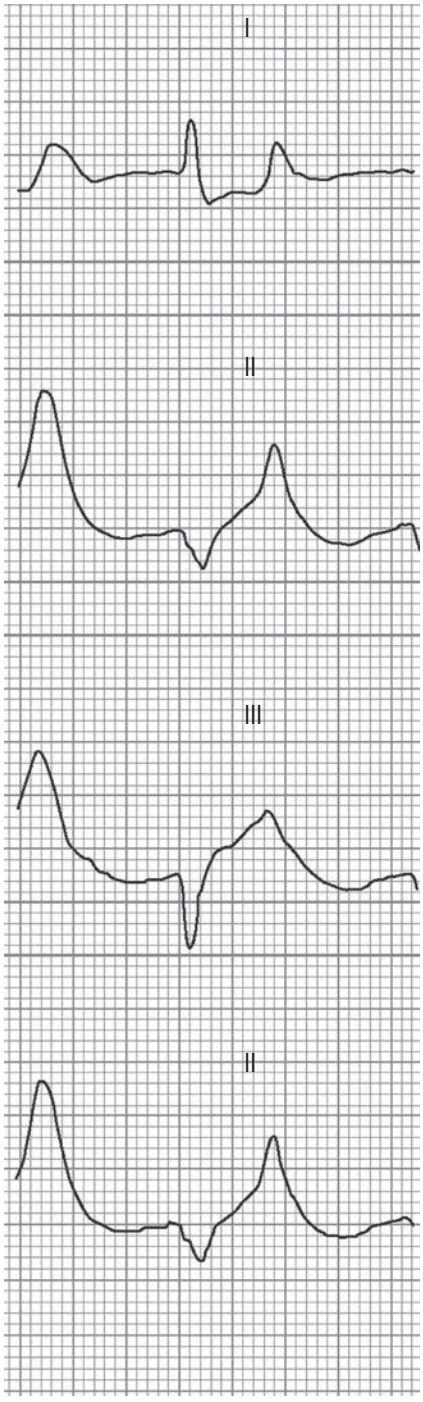

FIG. 10.1.6 Marked electrocardiographic changes in hyperkalaemia. The QRS complexes are widened and have a right bundle branch block type of configuration. Tall T waves are seen in the inferolateral leads. P waves are not visible and a junctional rhythm is present.

and T wave blend, producing a sine-wave ECG. At this stage ventricular fibrillation or asystole is imminent.[11]

The higher the serum [K^+] concentration, the more likely become ensuing ECG changes and life-threatening arrhythmias. However, nearly half of persons with a serum [K^+] greater than 6.8 mmol/L do not have ECG changes of hyperkalaemia. Physicians predict the presence of hyperkalaemia solely on the basis of ECG changes with a sensitivity of less than 50%.

Drugs, such as oral potassium tablets, ACE inhibitors and aldosterone antagonists, should be ceased in AKI. Hyperkalaemia is treated when the serum [K^+] is greater than 6.5 mmol/L (even if there are no ECG changes) or when there are ECG changes of hyperkalaemia. The emergency treatment of hyperkalaemia is covered in Chapter 12.2, Electrolyte disturbances.

Sodium

The sodium concentration in AKI may be normal, low (when water excess is present) or high (when water depletion is present). Patients with AKI and symptomatic hyponatraemia should be treated with haemofiltration or dialysis. Hypernatraemia is treated with a slow intravenous infusion of hypotonic saline or 5% dextrose.

Calcium, phosphate, uric acid and magnesium

The serum calcium concentration is normal or slightly reduced in the Risk and Injury stages of AKI and is moderately reduced in later stages. Hypocalcaemia does not require therapy unless tetany is present. Hyperphosphataemia is present in nearly all persons with ARF but does not require treatment in the ED.

Hyperuricaemia is common in AKI but also occurs in chronic renal failure and in persons without AKI. Episodes of acute gout are very uncommon in AKI and the hyperuricaemia does not need treatment. Hypermagnesaemia is common in AKI but is usually asymptomatic. Severe symptomatic hypermagnesaemia can occur if magnesium is administered to persons with AKI.

Acid-base abnormalities

Increased loss of bicarbonate-rich intestinal secretions (due to diarrhoea or an ileal conduit) can cause AKI with a normal anion-gap metabolic acidosis. AKI accompanied by acid loss from the stomach (vomiting or nasogastric suction) or caused by diuretics can result in a hypochloraemic metabolic alkalosis. Persons at the Risk and Injury stages of AKI often have a decrease in the serum bicarbonate concentration. More severe AKI causes a mild to moderate metabolic acidosis with an increased anion gap. This acidosis does not usually require specific treatment. Severe acidosis occurs in rhabdomyolysis and in lactic acidosis. The presence of a very severe metabolic acidosis in AKI is an indication for dialysis.

Fluid overload

The management of AKI in patients with peripheral oedema or pulmonary congestion

due to cardiac failure is challenging. The clinical diagnosis of hypovolaemia in these patients is difficult and rapid intravenous administration of large volumes of fluid can worsen the pulmonary congestion or heart failure. Hypovolaemia is treated (or excluded) in these cases by assessing the response to small-volume (200 mL) fluid challenges.

Patients with acute pulmonary oedema may have a raised SCr, which can be due to chronic renal failure, AKI or acute-on-chronic renal failure. These patients usually improve following treatment with vasodilators, continuous positive airway pressure (CPAP) ventilation and loop diuretics (frusemide 40 to 80 mg intravenously). Patients with AKI and acute pulmonary oedema who do not respond to these measures need haemofiltration or haemodialysis.

Hypertension

Persons with AKI may have an elevated blood pressure that predated the renal injury, or AKI itself may cause hypertension. A markedly elevated blood pressure reading (>180/120 mm Hg) in a person with AKI can be treated with glyceryl trinitrate applied as a skin patch (at a dose of 25 to 50 mg), sublingual nifedipine (5 to 10 mg) or oral hydralazine (20 mg). Intravenous drugs (glyceryl trinitrate or hydralazine) are used if AKI is associated with a hypertensive emergency, such as acute pulmonary oedema, hypertensive retinopathy or hypertensive encephalopathy.

Specific causes of acute kidney injury

Obstruction

Obstruction is relieved by decompression or diversion of the urinary tract. The site of the obstruction determines the technique used: placement of a Foley catheter or insertion of a suprapubic catheter, ureteral catheters (stents) or nephrostomy tubes. Relief of obstruction is often followed by a post-obstructive diuresis. Fluid replacement after relief of obstruction is based on frequent measurements of urine volume and urinary electrolytes.

Other causes

Specific treatments include immunosuppressive agents (for glomerulonephritis or vasculitis), plasma exchange (for TMA), systemic anticoagulation or revascularization (for renovascular disease).

Management of acute tubular necrosis

Reduction of damage/accelerating recovery

Despite much experimental laboratory work and numerous clinical trials, no therapeutic intervention has hastened the recovery of renal function in established ATN. Therapeutic trials of dopamine, atrial natriuretic peptide and various growth factors have been ineffective. The use of high-dose loop diuretics to convert oliguric ATN to non-oliguric ATN was based on the observation that patients with non-oliguric ATN had a lower mortality and better renal recovery rates than those with oliguric ATN. The use of high-dose loop diuretics does not affect the duration of ATN, the need for dialysis or the outcome.

Supportive treatment

This includes monitoring fluid input and fluid output, measuring serum electrolyte values frequently, preventing sepsis by reducing the number of intravenous lines and removing urinary catheters if possible, culturing periodically and using antibiotics when clinically indicated. The fluid intake is restricted to insensible water loss (about 500 mL/day in the absence of fever) plus all measured fluid losses (urine output, gastrointestinal losses, chest tube drainage). Nephrotoxic agents should be avoided and the dosage of renally excreted drugs reduced. The increase in SCr lags behind the decrease in GFR; therefore drug doses should be calculated based on a GFR of less than 10 mL/min per 1.73 m^2 rather than on the SCr value.

Renal replacement treatment

Renal replacement treatment (RRT) is required in most patients with oliguric ARF and one-third of patients with nonoliguric ARF. The indications for RRT are summarized in Box 10.1.4.

Box 10.1.4 Indications for renal replacement treatment in acute kidney injury

- Oliguria (urine output <200 mL/12 h) or anuria (urine output 0–50 mL/12 h)
- Serum urea concentration >35 mmol/L
- Serum creatinine concentration >400 μmol/L
- Serum potassium concentration >6.5 mmol/L or rapidly rising
- Serum sodium concentration <100 mmol/L or >160 mmol/L
- Pulmonary oedema not responding to diuretics
- Severe (uncompensated) metabolic acidosis with pH <7.1
- Uraemic syndrome (asterixis, psychosis, myoclonus, seizures, pericarditis); overdose with a dialyzable toxin

Presence of two or more indications in a patient means that renal replacement will be needed.

Prognosis

The prognosis of ARF is largely dependent on the underlying cause and the presence of co-morbidities. Mortality varies from about 40% in those with no co-morbidity to more than 80% in those who have three or more failed organ systems.

10.2 The acute scrotum

Gino Toncich

ESSENTIALS

1 Torsion is the most time-critical diagnosis in acute scrotal pain.

2 Early surgery is mandatory if the diagnosis is strongly suspected. No investigation should delay surgery.

3 Colour Doppler ultrasound is helpful and is best used when testicular ischaemia must be excluded in an inflammatory mass or in an older patient.

4 Torsion of an appendage can be diagnosed clinically by finding a small blue lump in the scrotal sac (with normal scrotum and non-tender testes) and can be managed non-operatively.

5 Epididymo-orchitis is rare in adolescence and torsion should be suspected. Colour Doppler ultrasound may be used to exclude torsion if suspicion remains.

6 Masses found on ultrasound should be followed up, as traumatic injury can bring attention to an undiscovered tumour.

7 Ultrasound is unreliable in diagnosing testicular rupture.

8 Early surgery in scrotal trauma allows diagnosis and treatment of rupture as well as early evacuation of other haematomas with shorter inpatient stays and less pain.

TORSION OF THE SPERMATIC CORD (TESTICLE)

Torsion is a twisting not of the testicle but of the spermatic cord, which then interferes with the vascularity of the testicle, ultimately leading to infarction.

Aetiology

The normal postero-lateral testicular anchoring to the scrotal sac is missing due to an enlarged tunica vaginalis, which surrounds the whole of the testes and epididymis. The testis floats freely like a clapper inside a bell. Contraction of the cremaster causes the testes to be rotated, thereby twisting the cord.[1]

Pathology

The twisting of the cord causes obstruction of the lymphatic and venous outflows, leading to venous engorgement; eventually it occludes the arterial inflow. Damage depends on the degree of torsion. Less than one turn (360 degrees) may partially occlude flow, whereas two or more turns (720 degrees) may occlude arterial flow completely, with necrosis occurring in less than 2 hours.[1,2]

Classical clinical presentation

- There is a sudden onset of severe scrotal or abdominal pain. Between one-third and one-half of patients have had previous episodes of acute scrotal pain.[3]
- Patient presents with pallor and vomiting.
- The testis is tender and riding high in the scrotum.
- There is loss of the cremasteric reflex; also scrotal oedema, testicular swelling tenderness and retraction.
- There are no irritative voiding symptoms.
- Systemic signs such as fever are usually absent.
- Urinalysis is normal.

Van Glabeke studied over 500 children who had mandatory exploration and found that these clinical signs had false-negative rates of 10% to 40% and false-positive rates of 30% to 70%.[4]

Intermittent torsion of the testis

This is a syndrome of recurrent acute scrotal pain, usually lasting less than 2 hours, which resolves spontaneously.[5] Some of these cases show evidence of torsion on later exploration.

Differential diagnosis of acute testicular pain

The differential diagnoses to consider in acute testicular pain are listed in Box 10.2.1.

Traps in the clinical diagnosis

There are many potential pitfalls in the clinical diagnosis of the acute scrotum[4]:

- Age: The abnormality is present for life, so the torsion could potentially occur at any age. In those under 18 years of age, an acutely painful scrotum should always be considered to be torsion.[3] It is most common in adolescence,[6] with less than 4% of torsions in men over age 30. The increase in sexually transmitted diseases among teenagers may confuse the diagnosis. There is an old surgical aphorism that says, 'When do you diagnose epididymo-orchitis in a teenager? Answer: After you have fixed the torsion'.
- Pain: In 25% of cases pain is *not* sudden in onset, nor is it necessarily severe. However, some patients with epididymo-orchitis (EDO) do have severe pain.[1,3]
- Localization: Some patients may have no scrotal pain but may have all their pain referred to the lower abdomen or inguinal area. The scrotum must always be examined in males with lower abdominal pain.
- Abnormal position of testis: this is seen only if rotation of 360 degrees or greater occurs.[3]
- Previous repair: Torsion can occur in a testis that has previously been fixed, especially if absorbable sutures have been used.[5]
- Dysuria: Irritative voiding symptoms rarely occur with torsion and suggests infection.[3]
- Fever: Temperatures above 102°F have been noted in up to 15% of torsion patients.[1]
- Clinical findings remain misleading and none can reliably exclude the diagnosis of torsion.[7]

Idiopathic scrotal oedema

Investigations

Surgical exploration of the scrotum

This is the investigation of choice where the diagnosis of torsion is likely; it also maximizes the chance of saving the testis. Delaying the diagnosis is 'castration by neglect'.[3,7] Surgical exploration requires only a skin incision and has no major complications.[4,7]

Low rates of torsion diagnosed at operation have led to interest in other tests to predict torsion preoperatively.

Colour Doppler imaging of the testis

This is useful in diagnosing torsion and also in elucidating other scrotal pathology. Comparison of blood flow to the asymptomatic side is crucial. If there is reduced flow to one side, then some degree of torsion must be suspected. If the testis has untwisted, hyperaemic flow may be noted. The false-negative rate of colour Doppler imaging (CDI) for torsion can be as high as 40%[4] and is affected by the following:

- Lack of sensitivity in low-flow states
- False flow in early torsion, where hyperaemia and venous engorgement can be seen
- Incomplete torsion or detorted testes
- Inexperience of the operator or inappropriate settings of the ultrasound
- Failure to compare low flow to the normal side[2]

Role of investigations in suspected testicular torsion

No investigation should delay surgical referral.[1,3] When there is a high clinical suspicion of torsion, the only investigation is surgical exploration of the scrotum. CDI may be organized on advisement from the surgeon.

If torsion is unlikely clinically but must be excluded, CDI can be used provided that it is available on an urgent basis.[1,3,7]

Treatment

Manual untwisting

This manoeuvre is not universally recommended and should be done only as a temporizing measure or when surgical exploration cannot be performed. The spermatic cord is infiltrated with local anaesthetic and the testis is untwisted. Untwisting is done by turning the left testis anticlockwise (outward) and the right testis clockwise, like opening the pages of a book.[8]

Surgery

An obviously infarcted testis is removed at the initial surgery. A viable testis is sutured into place on the scrotal wall. It is vital that the normal side also be explored and fixed to the scrotal wall, as the abnormality is bilateral in most cases. Retorsion following orchidopexy has occurred when absorbable sutures were used.[1,3–6] Testicular fasciotomy has been done to increase the salvage rate.[4]

Prognosis

Viability depends on the number of twists and the time taken to untwist the testis. There is 100% salvage if the testis is untwisted in less than 4 hours, but this falls to 50% within 24 hours. There have been rare case reports of salvage after 30 hours.

Long-term follow-up of salvaged testes shows that 75% have a reduction in volume. Abnormalities are also seen in sperm volume, motility and morphology. These abnormalities are not seen in patients who have had an infarcted testis removed at the initial operation. This suggests some anti-spermatogenesis effect caused by the damaged testicle.[1,3,5]

Torsion of a testicular appendage

These are embryological remnants found as small (<5 mm) pedunculated structures that may twist on their pedicles. If the appendage can be isolated in the scrotum, a small blue lump may be isolated: 'the blue dot sign'. These do not require surgery and can be treated with analgesia. Late presentations may include scrotal or testicular swelling, in which case they should be treated as torsion until proved otherwise.[1]

Acute epididymo-orchitis

Introduction

This is a clinical syndrome resulting from pain and swelling of the epididymis (and testis) of less than 6 weeks' duration. Chronic epididymitis is a long-standing condition of epididymal or testicular pain, usually without swelling.[2]

Aetiology

A variety of organisms may be responsible for EDO (Box 10.2.2).

The most likely cause depends on the patient's demographic group. For heterosexual males under 35 years of age, the agent is usually gonococcus or chlamydia. These organisms are also responsible for infection in homosexual males under 35 years (where anal sex is practised), but coliforms and even *Haemophilus* can cause infection.

In males older than 35 years, EDO is usually due to obstructive urological disease, so coliforms predominate. EDO may also be part of a systemic disease, for example, mumps.

EDO is usually thought to be an ascending infection from the urethra or prostate, but it can also be part of a generalized systemic disease. The infection spreads from epididymis to testicle, and eventually may become one large inflammatory mass. Isolated orchitis is rare and usually due to viral causes, which are spread via the bloodstream.[9–12]

Box 10.2.2 Causative agents in epididymo-orchitis

Bacterial: *Neisseria gonorrhoeae, Escherichia coli, Pseudomonas aeruginosa*, coliforms, *Klebsiella, Mycobacterium tuberculosis, Chlamydia trachomatis*
Viral: mumps
Drugs: amiodarone epididymitis
Fungal: cryptococcal
Parasitic: filariasis (usually chronic).

Clinical presentation

The exact features depend on the underlying cause and whether both the epididymis and the testicle are involved. Often the epidymis is painful and tender but, in older men, the whole testicle swells to the size of an Emu egg.

The pain may come on suddenly or slowly. The scrotal swelling and tenderness is relieved by elevating the testis. The spermatic cord is usually tender and swollen. Associated symptoms of urethritis suggest a sexually transmitted infection (STI), whereas bladder symptoms (abdominal pain tenderness) suggest a urinary tract infection (UTI).

In younger males (under 35 years) a history of sexually transmitted disease may be elicited. It is important to take a sexual history and also ask about anal intercourse.

In the older patient there may history of instrumentation, intercurrent UTI or prostatism. Pyuria is common.

Investigations

Urethral swabs

Urethral discharge may not be seen if the patient has just voided, so a urethral swab and smear should be examined for white blood cells (WBCs). If there are more than five WBC per high-powered field, then urethritis is likely. The presence of intracellular diplococci confirms the diagnosis of gonorrhoea; their absence suggests chlamydia.[9]

Urine testing

A standard mid-stream urine (MSU) to look for the presence of WBC or gram negative organisms should be sent for older patients or those with urinary symptoms and abdominal pain as well as EDO.

For those with urethritis or suspected STI, the Australian STI management guidelines

recommend sending a first-pass urine to the lab for nucleic acid amplification tests (NAATs) looking for chlamydia and gonorrhea.[10]

Differential diagnosis

In the acute non-traumatic setting, the most important differential diagnosis is torsion of the testicle.[9] Where a large mass is in the scrotum, incarcerated hernias must be considered. Swollen or indurated red scrotal skin in the high-risk patient may indicate Fournier gangrene.

If the clinical features and MSU do not differentiate, then ultrasound may help to exclude other causes of an acute scrotum.

Treatment

Symptomatic treatment consists of bed rest, analgesia and scrotal supports.

If the cause is secondary to a sexually transmitted disease, appropriate antibiotics should be chosen after urethral swabs have been taken—for instance, a single dose of ceftriaxone (250 mg stat) for gonorrhoea and a 14-day course of doxycycline (100 mg) or roxithromycin (300 mg) for chlamydia.[10,12] The patient's sexual partners should also be investigated and treated. Tests for syphilis, HIV and even hepatitis should be performed.

If the infection is secondary to a UTI, an appropriate antibiotic, such as amoxicillin/clavulanic acid 500/125 bd or trimethoprim 300 mg qd for 14 days, should be used.[12] Antibiotic choice can be adjusted according to the urine culture results. Investigation for underlying urinary tract obstruction should be undertaken according to clinical features.

Complications

These include abscess formation, testicular infarction, chronic pain and infertility.

Necrotizing fasciitis of the scrotum

Fournier gangrene is a necrotizing fasciitis (mixed aerobic/anaerobic infection) of the perineum that often involves the scrotum.[13,14]

Risk factors for development are as follows:

- Impaired immunity (e.g. from diabetes or steroid use)
- Trauma to the genitalia
- Spreading of ano-rectal infections

Clinical features

- Prodromal symptoms of fever and lethargy for 2 to 7 days
- Intense genital pain, out of all proportion to the clinical findings
- Tenderness associated with oedema of the overlying skin; pruritus may also be present
- Progressive erythema of the overlying skin
- Dusky appearance of the overlying skin; subcutaneous crepitation
- Obvious gangrene of a portion of the genitalia; purulent drainage from wounds

Computed tomography (CT) a may show air along the fascial planes or deeper tissue involvement. Imaging studies should not delay surgical debridement when there is clinical evidence of progressive soft tissue infection.

Treatment of necrotizing fasciitis consists of early aggressive surgical debridement of necrotic tissue, broad-spectrum antibiotic therapy, and hemodynamic support as needed.[13,14]

Traumatic Injury to the Testicle

Blunt trauma

The mobility of the testicle, cremaster muscle contraction and the tough capsule usually protect the testicle from injury. However, a direct blow that drives the testicle against the symphysis pubis may result in contusion or rupture. Typical mechanisms are a direct kick to the groin or handlebar and straddle injuries.[15]

The types of injury include the following:

- Scrotal-wall haematomas
- Tunica vaginalis haematoma (haematocoele)
- Intratesticular (subcapsular) haematoma
- Testicular dislocation

The most serious is testicular rupture, where the tunica is split, allowing blood and seminiferous tubules to extrude into the tunica vaginalis. This occurs in up to 50% of blunt trauma. Complete disruption of the testis may occur.

Ultrasound examination is not 100% sensitive in detecting testicular rupture. Conservative management with analgesia, antibiotics and scrotal support may be considered.[16]

Indications for exploratory surgery include the following:

- Uncertainty in diagnosis after appropriate clinical and radiographic evaluations
- Clinical findings consistent with testicular injury
- Disruption of the tunica albuginea on ultrasound
- Absence of blood flow on scrotal ultrasound images with Doppler studies
- Expanding or large haematocoeles (e.g. 5 cm or larger), which should be explored
- Smaller haematocoeles, which are often explored because it has been shown that such practice allows for more optimal pain control and shorter hospital stays

It should be noted that 10% to 15% of testicular tumours present after an episode of trauma; therefore any abnormalities on ultrasound examination should be followed to resolution if surgery is not performed.

Early surgical exploration with evacuation of blood clots in the tunica vaginalis and repair of testicular rupture results in a shortened hospital stay and a faster return to normal activity. Conservative management is complicated by secondary infection of the haematocoele, frank acute necrosis of the testis and delayed atrophy due to pressure effects of haematoma. The orchidectomy rate for early exploration is only 9%, compared with 45% for those managed non-operatively.

Penetrating

- This is due to gunshot wounds, stab wounds, self-mutilation and animal bites. Extensive degloving injuries involve accidents with heavy machinery.
- Up to 75% of injuries are associated with additional injury, so a careful exam should be made of the perineum, rectum and urethra.
- Early surgical referral, wound toilet and antibiotics will be the mainstays of treatment.

CONTROVERSIES AND FUTURE DIRECTIONS

- Should all patients with suspected torsion go straight to surgical exploration, and is there is any role for investigations in older or low-probability patients?
- Should all patients with scrotal and testicular injury have routine surgical exploration regardless of ultrasound findings?
- Should attempts at testicular salvage be abandoned in favour of orchidectomy of the affected side following trauma in order to preserve spermatogenesis of the other side?

10.3 Renal colic

Sean Arendse

ESSENTIALS

1. **The lifetime risk of developing kidney stones is 1 in 10 for men and 1 in 35 for women.**
2. **Approximately 75% of all stones are calcium based.**
3. **Management usually comprises adequate analgesia and hydration.**
4. **Computed tomography or intravenous pyelography establishes the diagnosis and evaluates the possibility of obstruction.**
5. **Most stones (90%) are passed spontaneously within 1 month.**
6. **Obstruction, infection and intractable pain necessitate admission to hospital.**
7. **Urology follow-up is essential to minimize further episodes.**

Introduction

The risk of kidney stones is about 1 in 10 for men and 1 in 35 for women. Between 4% and 8% of the Australian population suffer from kidney stones at any given time. The rate is about four to five times higher in 'stone belt' areas.[1] It occurs most frequently between the ages of 20 and 50 years, with a male:female ratio of approximately 3:1. About 50% of patients experience only a single episode, but the remaining 50% have recurrent episodes within 5 years.

Most calculi are believed to originate in the collecting system (renal calyces and pelvis) before passing into the ureter. Supersaturation with stone-forming substances (calcium, phosphate, oxalate, cystine or urate), combined with a decrease in urine volume and lack of chemicals that inhibit stone formation (such as magnesium, citrate and pyrophosphate) result in the production of a calculus. In addition to this, infection with urea-splitting organisms that produce an alkaline urinary pH frequently contribute to the growth of 'struvites' or triple phosphate (calcium, magnesium and ammonium phosphate) stones.

Less commonly, mixed stones occur via nucleation with sodium hydrogen, urate, uric acid and hydroxyapatite crystals, providing a core to which calcium and oxalate ions adhere (heterogeneous nucleation).

Approximately 75% of all stones are calcium based, consisting of calcium oxalate, calcium phosphate or a mixture of the two. Ten percent are uric acid based, 1% are cystine based and the remainder are primarily struvite.

Predisposing factors for stone formation include dehydration and low fluid intake, hypertension, prolonged immobilization, strong family history of nephrolithiasis, hyperparathyroidism, peptic ulcer disease (hyperexcretion of calcium), small bowel disease such as Crohn disease or ulcerative colitis (hyperoxaluria) and gout (hyperuricaemia). Myeloproliferative disorders, malignancy, glycogen storage disorders, renal tubular acidosis and the use of certain medications (calcium supplements, acetazolamide, vitamins C and D and antacids) may also be conducive to nephrolithiasis.

Persistent obstruction of the ureter leads to hydronephrosis of the urinary tract and may precipitate renal failure. Common sites of obstruction are the ureteropelvic junction, pelvic brim and vesicoureteric junction.

Pathophysiology of pain

The mechanisms implicated in the production of the pain associated with renal colic are an increase in renal pelvic pressure, ureteric spasm, local inflammatory effects at the level of the calculus and increased peristalsis and pressure proximal to the calculus.

Acute obstruction of the upper urinary tract from a calculus results in increased pressure in the renal pelvis, which, in turn, induces the synthesis and secretion of renal prostaglandins, in particular PGE2, which promotes a diuresis by causing dilatation of the afferent arteriole, thus further elevating renal pelvic pressure. Acute obstruction and renal capsular tension are believed to be the cause of the constant ache in the costovertebral angle.

In experiments utilizing isolated ureteric smooth muscle, prostaglandins have also been shown to increase phasic and tonic contractile activity, resulting in ureteric spasm and severe, colicky pain.

Presentation

The pain of renal colic has been described as the worst pain a person can endure. The classic textbook description is of severe intermittent flank pain of abrupt onset originating from the area of the costovertebral angle and radiating anteriorly to the lower abdominal and inguinal regions. Testicular or labial pain may be present and may suggest the location of the stone as in a low ureteric position. Urinary frequency or urgency often develops as the stone nears the bladder. Nausea and vomiting frequently accompany the pain and about one-third of patients complain of gross haematuria.

Examination

Examination usually reveals an agitated, pacing patient unable to find a comfortable position. Pulse rate and blood pressure may be elevated secondary to the pain. Fever is unusual and suggests infection. The abdominal examination may reveal only signs of an early ileus with hypoactive bowel sounds and a distended abdomen, but it should not be omitted as it is extremely useful in excluding other intra-abdominal or retroperitoneal causes of the pain (such as pancreatitis, cholecystitis, appendicitis or leaking or rupture of the abdominal aorta).

Investigations

Urinalysis usually shows red blood cells, although the absence of red cells in the urine in the setting of colicky flank loin-to-groin pain does not rule out nephrolithiasis, and between 10% and 30% of patients with documented nephrolithiasis do not have haematuria.[2] Nitrites, leucocytes or micro-organisms in the urine suggest either the complication of an infection or a diagnosis of acute pyelonephritis. Urine culture is thus indicated. Electrolyte studies may demonstrate obstruction or suggest an underlying metabolic abnormality, such as hypercalcaemia, hyperuricaemia or hypokalaemia. A slightly elevated white blood cell count may occur with renal colic, but a count greater than 15,000/mm^3 suggests active infection, as does a fever. Renal tract obstruction with concomitant infection is a urological

Box 10.3.1 Differential diagnosis of renal colic

- Renal carcinoma producing blood clots that temporarily occlude the ureter
- Ectopic pregnancy
- Ovarian torsion
- Abdominal aortic aneurysm
- Acute intestinal obstruction
- Pyelonephritis
- Appendicitis
- Diverticulitis
- Narcotic seekers and Munchausen syndrome

emergency and must be treated immediately and aggressively.

A pregnancy test should be performed in all women of childbearing age, as a positive result needs further investigation to exclude ectopic pregnancy.

Many conditions may have a similar presentation to renal colic; examination and investigations should be directed towards confirming the diagnosis of nephrolithiasis and excluding the other conditions in the differential diagnosis (Box 10.3.1).

Radiological examination

A variety of imaging modalities are used to evaluate renal colic. Their pros and cons are listed in Table 10.3.1.

Most stones (90%) are radiopaque and theoretically should be visible on plain x-ray; if seen, they are irregularly shaped densities on abdominal radiography. However, a plain x-ray alone is not usually sufficient to make the diagnosis of nephrolithiasis, as its sensitivity, of only around 60%, is poor. Phlebitis in the pelvic veins and calcified mesenteric lymph nodes may add confusion, and many small stones may be obscured by the bony density of the sacrum.

Computed tomography (CT) with or without contrast is the first-line test in most centres and has become the adopted gold standard, with high sensitivity (97%) and specificity (96%) for uretero-lithiasis.[3] Nearly all stones are opaque on CT; thus the size of the stone and its position can be accurately measured. Other positive findings include perinephric stranding, dilatation of the kidney (hydronephrosis) or ureter and low density of the kidney, suggesting oedema. Low-dose protocols have allowed a drastic reduction in the effective dose, thus limiting the biological risk due to ionizing radiation. Other strategies to contain the radiation exposure include the dual-split bolus dual-energy CT and the adaptive statistical image reconstruction.

The intravenous pyelogram (IVP) was the standard investigative tool for the evaluation of renal colic until the widespread adoption of CT. It establishes the diagnosis of calculus disease in 96% of cases and determines the severity of obstruction. Classic findings of acute obstruction include a delay in the appearance of one kidney, a dilated ureter and a dilated renal pelvis. The use of IVP has declined more recently, likely due to worse quality than non-contrast CT, lack of bowel preparation, being potentially nephrotoxic from contrast agents, serious allergic and anaphylactic reactions and radiation exposure. There is currently a worldwide shift away from IVP toward using non-contrast CT to evaluate ureteric colic.[4]

Ultrasonography is a useful, safe and a non-invasive alternative when renal function is impaired, risk from radiation is high (e.g. pregnancy) or contrast media are contraindicated. It can identify the stone and its location and demonstrate proximal obstruction—such as hydroureter or a dilated pelvis—as well as the size and configuration of each kidney. Unfortunately, however, it cannot indicate the size of the stone. Ultrasound has significantly lower sensitivity than intravenous urography (IVU) and misses more than 30% of stones. However, point-of-care ultrasound in the hands of appropriately trained emergency physicians in cases of moderate to high pre-test probability of ureteric calculi (as calculated by tools such as the STONE score) can be diagnostic of stone disease.[5]

Magnetic resonance imaging (MRI) can easily depict a dilated ureter and demonstrate the level of obstruction without using ionizing radiation or contrast, but the accuracy of MRI for stones may be lower than that of IVU, as its spatial resolution is often not high enough to detect small stones. When used in combination with ultrasound, it may have a role in the evaluation of loin pain, especially in the pregnant patient; however, it is expensive, time-consuming and usually not readily available to most emergency departments.

Table 10.3.1 Pros and cons of imaging modalities in renal colic

	Pros	*Cons*
Computed tomography (CT)	High sensitivity (97%) High specificity (96%) Nearly all stones are opaque Can accurately measure stone size Can detect obstruction Can diagnose other causes of flank pain Can avoid the use of contrast	Exposes patient to radiation, high cost
Abdominal radiography (KUB)	Readily available, fast	Low sensitivity, exposes patient to radiation
Intravenous urography	Provides information regarding size and location of stone and measurement of renal function	Potential for contrast reaction Exposes patient to radiation More time-consuming than CT Cannot exclude alternative diagnoses
Magnetic resonance imaging	Useful in pregnant patients Does not use ionizing radiation Does not use contrast	Not readily available Time-consuming Accuracy may be less than that of intravenous urography (IVU)
Ultrasound	Non-invasive No exposure to ionizing radiation Modality of choice in pregnant patients	Lower sensitivity than IVU Size of stone cannot be accurately measured May not be readily available, requires a skilled operator

KUB, Kidney, ureter, bladder.

Management

As 90% of stones are passed spontaneously, the most urgent therapeutic step is relief of pain along with the provision of adequate hydration and anti-emetics. Intramuscular non-steroidal anti-inflammatory drugs (NSAIDs) offer the most effective sustained analgesia for renal colic in the emergency department and seem to have fewer side effects than other forms of analgesia.[6]

At 30 minutes, NSAIDs are equivalent to opioids or paracetamol in the relief of acute renal colic pain. There has been less vomiting and fewer requirements for rescue analgesia with NSAIDs compared with opioids. Patients treated with NSAIDs as compared with paracetamol required less rescue analgesia.[7] Common available alternative options include NSAIDs delivered orally or per rectum. Opiates can be used for breakthrough pain.

Buscopan, an antimuscarinic agent used to treat smooth muscle spasm, has been shown to decrease ureteric activity to some degree in 80% of the subjects studied. However, one study comparing it with an NSAID found that buscopan was less effective and associated with significant side effects, including dry mouth, photophobia, urgency, urinary retention and constipation, thus significantly limiting its use in renal colic.[8]

Box 10.3.2 Indications for hospital admission in renal colic

Presence of infection
Deteriorating renal function
Persistent pain requiring parenteral narcotics
Stone greater than 5 mm in diameter
Extravasation of dye (uncommon)

The role of alpha agonists in renal colic continues to be hotly debated. Although there is some evidence that they may reduce time to stone expulsion, particularly in the case of distal ureteric calculi, there is little evidence for their use in the emergency department setting.[9,10]

Intravenous crystalloid should be administered to ensure a urine volume of 100 to 200 mL/h in those unable to tolerate oral fluids.

The size, shape and site of the stone at initial presentation are factors that determine whether a stone will pass spontaneously or require removal. Stones less than 5 mm in diameter in patients without associated infection or anatomic abnormality pass within 1 month in 90% of cases, stones 4 to 6 mm in diameter pass 50% of the time, but only 5% of stones larger than 7 mm pass; hence these usually require elective surgical removal. The overall passage rate for ureteral stones is as follows:

- Proximal ureteral stones, 25%
- Mid-ureteral stones, 45%
- distal ureteral stones, 70%.

Disposition

Most patients with renal colic can be discharged with oral analgesia (paracetamol and NSAIDs), hydration and a referral for outpatient urology.

Indications for admission to hospital are listed in Box 10.3.2.

Further intervention is required if obstruction with hydro-nephrosis is present, the stone is a large stag horn calculus or the patient continues to have pain and no stone is passed within 2 to 3 days. A percutaneous nephrostomy allows drainage of an obstructed kidney until the blockage can be removed, either by ureteroscopic procedures for low stones or by open surgery for large or infected stones. Extracorporeal shockwave lithotripsy is preferred for single or small (<2 cm) stones that are otherwise uncomplicated, as it has minimal complications and morbidity.

Urology follow-up is essential for all patients, for elective removal of stones when complications have not ensued and for the prevention of recurrence. Indications for stone removal include stone diameter greater than 7 mm, stone obstruction associated with infection, single kidneys with obstruction and bilateral obstruction.

Precautions

Renal colic, having minimal findings on examination, is a common presentation offered by those seeking narcotics or with Munchausen syndrome; treating physicians should be aware of this. However, it is essential to give analgesia to patients suffering from renal colic, and it is preferable to give patients analgesia unnecessarily rather than cause unnecessary suffering. Features suggesting narcotic seeking are discussed in Chapter 21.5.

Conclusion

Renal colic is an acutely distressing medical condition that requires a careful evaluation of symptoms and signs to ensure timely analgesia, recognition of other causes of acute abdominal pain and avoidance of inappropriate narcotic usage.

CONTROVERSIES AND FUTURE DIRECTIONS

- Controversies in the management of renal colic relate largely to analgesia. Traditionally it has been taught that parenteral narcotics provide fast and effective pain relief; however, with the advent of injectable NSAIDs, some argue that these should be the first line of care.

SECTION 11

ENDOCRINE EMERGENCIES

Edited by *Mark Little*

11.1 Diabetes mellitus and hypoglycaemia: an overview

Anthony F.T. Brown

ESSENTIALS

1 **Type I diabetes is characterized by pancreatic beta cell destruction with an absolute insulin deficiency, usually but not exclusively associated with autoimmune damage.**

2 **Type II diabetes results from a progressive insulin secretory deficiency on the background of insulin resistance.**

3 **Diabetic ketoacidosis (DKA) and hyperosmolar hyperglycaemic state (HHS) are both life-threatening acute complications of diabetes mellitus.**

4 **The aim of excellent long-term blood sugar control is an HbA1c (glycated haemoglobin) level of less than 7.5% without frequent disabling hypoglycaemia for the prevention of microvascular disease, and 6.5% in those at increased risk of arterial disease.**

5 **Oral antidiabetic drug groups include the sulphonylureas, biguanide metformin, alpha-glucosidase inhibitor acarbose, the thiazolidinediones pioglitazone and rosiglitazone, and dipeptidyl peptidase 4 (DDP-4) inhibitors, such as sitagliptin.**

6 **Optimal blood sugar control aids in reducing the incidence of multisystem diabetic complications.**

7 **Hypoglycaemic coma requires immediate treatment with intravenous glucose. Intramuscular glucagon 0.5 to 2.0 mg may be used if liver glycogen stores are adequate, and can be given pre-hospital.**

DIABETES MELLITUS

Classification system and diagnostic criteria

The diagnosis and management guidelines for diabetes were revised in 2016 by the American Diabetes Association.[1] The classification of type I and type II diabetes mellitus was retained, with the recommended criteria for the diagnosis of diabetes as a fasting plasma glucose of 7 mmol/L or greater (fasting is defined as no calorie intake for ≥8 hours), a random plasma glucose of over 11 mmol/L associated with polyuria, polydipsia and weight loss, or an HbA_{1C} (glycated haemoglobin) level of ≥6.5%. The oral glucose tolerance test is no longer routinely recommended.

Aetiology

The exact aetiology of diabetes is unclear. Type I diabetes is characterized by pancreatic beta cell destruction with an absolute insulin deficiency usually, but not exclusively, associated with autoimmune damage from a range of antibodies including islet cells (ICA), glutamic acid decarboxylase, insulin, tyrosine phosphatases and zinc transporter (ZnT8). Genetic and environmental factors are implicated, such as some human leucocyte antigen (HLA) types (most Caucasian patients are HLA-DR3 or DR4 or both), and abnormal immune responses, such as following viral infection. Certain genes are also implicated as co-contributors, particularly sites on chromosomes 6, 7, 11, 12, 14 and 18.

Type II diabetes is far more common, and results from a progressive insulin secretory deficiency on the background of insulin resistance.[1] Genetic factors are implicated by strong familial aggregation of cases, and environmental factors in the context of genetic susceptibility, including obesity and diet. Populations with an increasing predisposition to type II diabetes encompass East Asians including China and the Western Pacific.

Although type I diabetes occurs most frequently among Caucasians throughout the world, diabetes in Australia is three times more common in the Aboriginal community. Other groups with a high prevalence include Pacific Islanders and Native Americans.

Diabetes secondary to other conditions

Diabetes mellitus may be secondary to conditions that damage the exocrine pancreas

Table 11.1.1 Pharmacokinetic characteristics of currently available human insulins

Insulin	*Onset of action*	*Peak of action*	*Duration of action*
Lispro	5–15 min	1–2 h	4–5 h
Regular	30–60 min	2–4 h	6–8 h
NPH	1–2 h	5–7 h	13–18 h
Glargine	1–3 h	4–8 h	13–20 h
Detemir	2–4 h	8–10 h	18–30 h

including chronic pancreatitis, carcinoma of the pancreas and pancreatectomy, haemochromatosis, cystic fibrosis, pregnancy (gestational) and endocrinopathies, such as Cushing syndrome, acromegaly, phaeochromocytoma and glucagonoma.[2]

Drug-induced diabetic state

Certain drugs can impair glucose tolerance or cause overt diabetes mellitus. These include glucocorticoids, the oral contraceptive pill, thiazide diuretics at higher doses, clozapine, tacrolimus, sirolimus and ciclosporin, pentamadine (which may also cause severe hypoglycaemia) and HIV protease inhibitors.

Emergency presentations of a high blood sugar

Diabetic ketoacidosis (DKA) and hyperosmolar hyperglycaemic state (HHS) are both life-threatening acute complications of diabetes mellitus. Although important differences do exist, the pathophysiology and treatment are similar. DKA is usually seen in type I diabetes and HHS in patients with type II, but both complications can occur in type I and type II diabetes. See Chapter 11.2 for the diagnosis and management of DKA and HHS.

General management of diabetes mellitus

Aims of long-term blood sugar control

The aim of optimal long-term blood sugar control is an HbA1c (glycated haemoglobin) level of less than 7.5% without frequent disabling hypoglycaemia for the prevention of microvascular disease, and 6.5% in those at increased risk of arterial disease.[3] This should be represented by a pre-prandial blood glucose level of 4.0 to 7.0 mmol/L and a post-prandial blood glucose level of less than 9.0 mmol/L.

Insulins

Insulin was first administered to humans in 1922. Animal insulins (bovine, porcine) have been used for many years but, in the 1980s, human insulins became commercially available. Today, with the widespread availability of human insulins, animal insulins are of historical interest only.

Types of insulins

Table 11.1.1 lists the different types of insulins and the important parameters of each type. Mixtures of short- and intermediate-acting insulins are also available: Humulin 30/70 (30% regular/70% NPH) and Humalog Mix50 (50% lispro protamine/50% insulin lispro).

Antidiabetic drugs

Two major groups of oral hypoglycaemic agents used in the management of type II diabetes are the sulphonylureas and the biguanides. The sulphonylurea group of drugs acts by stimulating the pancreatic secretion of insulin, and the biguanide metformin acts by suppressing hepatic glucose production and enhancing the peripheral use of glucose. It is the first-choice medication, particularly in the overweight patient.

Other oral agents now available for the treatment of diabetes include the alpha-glucosidase inhibitor acarbose, which acts on the gastrointestinal tract to interfere with carbohydrate digestion, but flatulence and diarrhoea may be troublesome. The thiazolidinediones, such as pioglitazone and rosiglitazone, act primarily by reducing insulin resistance, thereby enhancing the effect of circulating insulin. Rosiglitazone increases the risk of myocardial infarction and cardiovascular deaths, and thus should be avoided in ischaemic heart disease.[4] All thiazolidinediones must be avoided in people with moderate or severe heart failure. Finally, the dipeptidyl peptidase 4 (DDP-4) inhibitors, such as sitagliptin, inhibit DDP-4 to prolong the action of the incretin hormones.

Other non-diabetic drugs

Angiotensin-converting enzyme inhibitors delay the onset of diabetic nephropathy even in normotensive patients with diabetes. Statins are important in the strict treatment of dyslipidaemia in diabetic patients.

Box 11.1.1 Causes of hypoglycaemia

Diabetic patients

- Medication change or error, particularly with insulin or oral hypoglycaemic sulphonylurea (very rarely metformin)
- Inadequate dietary intake
- Excessive calorie use, such as exercise

Any patient

- Insulin, sulphonylurea, salicylates, β-blockers, quinine, chloroquine, valproic acid, pentamidine (note ingestion of any these may be accidental, deliberate or malicious)
- Ethanol
- Liver disease
- Sepsis, other critical illness
- Malnourishment, including anorexia nervosa
- Post-gastrointestinal surgery 'dumping syndrome'
- Adrenal insufficiency
- Hypopituitarism
- Islet cell tumour/extrapancreatic tumour
- Tumour-related, such as mesenchymal, epithelial or endothelial tumours
- Artefact 'Munchausen syndrome'

DIABETIC HYPOGLYCAEMIA

Hypoglycaemia is more common in type I diabetes. The critical plasma level at which hypoglycaemia manifests varies between different individuals, but symptoms are likely below a plasma glucose of 3.5 mmol/L. Precipitants include exercise, a late meal, inadequate carbohydrate intake, errors of insulin dosage and ethanol ingestion.

Hypoglycaemia may also occur in the non-diabetic patient, precipitated by a variety of conditions (Box 11.1.1).[5]

Clinical features

Hypoglycaemia produces neurological and mental dysfunction from tremor, sweating and anxiety to cognitive impairment, seizures and coma. Less commonly, it can present with hypothermia, behavioural changes and transient neurological deficits. In some instances, hypoglycaemia is relatively asymptomatic.

Management of hypoglycaemic coma

- The ABC approach is important in the patient with coma.
- Give 50 mL of 50% glucose intravenously initially after taking a blood sugar level.

Further glucose administration is often necessary, such as an infusion of 10% dextrose.
- Alternatively give 0.5 to 2 mg of glucagon intramuscularly when venous access has not been established or has failed. Glucagon is unhelpful in the patient with liver disease and depleted glycogen reserves.

CONTROVERSIES

- Non-parenteral insulin delivery, such as nasal, oral or intra-pulmonary.
- The combination use and risk–benefit profile of newer antidiabetic drugs, such as the thiazolidinediones and DDP-4 inhibitors.

11.2 Diabetic ketoacidosis and hyperosmolar, hyperglycaemic state

Anthony F.T. Brown

ESSENTIALS

1 Diabetic ketoacidosis (DKA) consists of the triad of ketonaemia, hyperglycaemia and acidaemia—a high anion-gap metabolic acidosis.

2 DKA is caused by insulin omission or error, intercurrent illness (including infection) or is a presenting feature of new diabetes.

3 Key management components of DKA include:

- fluids (0.9% normal saline) to replace deficits of sodium of 7 to 10 mmol/kg and water 100 mL/kg
- soluble insulin infusion at 0.1 unit/kg/h to a maximum of 6 units/h to suppress ketogenesis, reduce blood sugar and help correct the electrolyte abnormalities
- potassium replacement, providing the serum (potassium) is less than 5.5 mmol/L and there is urine output (note anuria is rare in DKA)
- education—all patients on insulin need to know the 'sick day rules', plus be familiar with regular home testing for capillary blood sugar.

4 Meticulous monitoring and documentation of treatment in DKA are essential.

5 Hyperosmolar hyperglycaemic state (HHS) is characterized by hypovolaemia, marked hyperglycaemia (>30 mmol/L) without ketonaemia or acidosis, and a raised osmolality usually >320 mOsmol/kg.

6 Mortality and morbidity of HHS are greater than with DKA, usually related to the older age of patients, co-morbidities and complications, such as stroke.

7 Treatment of HHS is similar to DKA except:

- lower dose insulin infusion rate is used at 0.05 unit/kg/h
- this infusion rate is titrated against the serum osmolarity rather than ketoacids
- 0.9% normal saline is used and *only* changed to half normal (0.45%) saline if the osmolality *and* glucose are not declining
- low-molecular-weight heparin (LMWH) thromboprophylaxis is indicated.

Introduction

Diabetic ketoacidosis (DKA) is an acute, potentially life-threatening complication in an insulin-dependent diabetic and in some type II diabetics. It consists of the triad of ketonaemia, hyperglycaemia and acidaemia—a high anion-gap metabolic acidosis. Although DKA is preventable, its prevalence and suboptimal management may highlight shortfalls in the quality of care for patients with diabetes. The mortality rate in developed countries has dropped to <1%.

Hyperosmolar hyperglycaemic state (HHS) is characterized by hypovolaemia, marked hyperglycaemia (>30 mmol/L) *without* ketonaemia or acidosis, and a raised osmolality usually >320 mOsmol/kg. It comes on more insidiously and has a worse prognosis with an increased mortality of around 15% to 20% and greater morbidity, in part related to underlying chronic medical disorders, and often occurring in an older population.

Epidemiology and aetiology

An annual incidence of DKA of approximately 1:170 patients with type I diabetes is reported, or 2 episodes per 100 patient years of diabetes, for a prevalence of 4.6 to 8 episodes per 1000 patients with diabetes.[1,2] The mortality rate in developed countries is under 1% most commonly due to cerebral oedema particularly in children/young adults, severe hypokalaemia, adult respiratory distress syndrome (ARDS) and co-morbid conditions such as sepsis or acute myocardial infarction (MI).

DKA may be the presenting feature of new diabetes mellitus (3% to 25% DKA), but it more

usually follows intercurrent illness in a patient with known autoimmune type I diabetes (35% DKA); when there has been an insulin error with poor compliance or inadequate insulin (30% DKA); and/or for instance an insulin infusion pump blockage. A variant of type II diabetes is also 'ketosis-prone (type II) diabetes', usually in the obese with a strong family history. This was originally described in Africans and African Americans, but is now noted worldwide.

Pathogenesis

DKA arises from an absolute or relative lack of insulin accompanied by an increase in counter-regulatory hormones, such as glucagon, cortisol and growth hormone.[1,3] Insulin absence leads to increased hepatic gluconeogenesis and glycogenolysis, with an incomplete lack of insulin related to greater hyperosmolarity (in HHS). Lack of insulin and excess counter-regulatory hormones increase lipolysis and free fatty acid production as an alternate energy source. This leads to subsequent ketone body formation produced from acetyl coenzyme A, mainly in hepatic mitochondria, including acetone, beta-hydroxybutyrate and acetoacetate, and a reduced ability to prevent ketonaemia.

HHS is the other end of the hyperglycaemia spectrum from DKA, occurring with a relative rather than an absolute deficiency of insulin leading to a greater level of hyperglycaemia, therefore higher hyperosmolarity than is seen in DKA. The degree of dehydration is greater (typically 10% to 15% body weight), but significant ketosis does not occur. HHS is more insidious in onset than DKA and patients with HHS are typically older with pre-existing type II diabetes. However, HHS is seen in young adults and even teenagers.

Clinical features

Malaise and fatigue on a background of polyuria, polydipsia, weakness and fatigability are common, but gastrointestinal symptoms, such as nausea, vomiting and abdominal pain, may predominate.[3] Lack of a history of diabetes does not rule out the diagnosis of DKA, as it may be a first presentation, often presaged by recent, unexplained rapid weight loss.

Laboured, sighing respirations with an increased rate and depth, known as Kussmaul breathing, are characteristic of DKA in association with dehydration causing decreased tissue turgor, a dry mouth and sweet foetor of pear drops (ketotic), which is not always noticed. The conscious level may be reduced, but coma is rare.

Look carefully for signs of an underlying precipitating cause. This can include chest, urine or skin infection, such as boils, as well as meningitis or an acute abdomen, although non-surgical upper abdominal pain is common in DKA. A silent MI is another potential cause. In those with HHS, look out for the complications of acute MI, stroke or arterial thrombosis.[4,5]

The urine output should be measured regularly, which does not always require urinary catheterization. Likewise, invasive haemodynamic monitoring should not be instituted as a 'routine' for patients with DKA or HHS. It should be reserved for severe cases and those who fail to respond, or in the elderly who are at risk of fluid overload. In addition, venous blood gases are sufficient to monitor progress in DKA, rather than repeated arterial sampling.

Diagnostic criteria

Diabetic ketoacidosis

- Metabolic acidosis with pH <7.3 or serum bicarbonate <15 mmol/L.
- Ketonaemia >3.0 mmol/L, or marked ketonuria >2+on dipstick (note urinalysis may miss 3-beta hydroxybutyrate early).
- Hyperglycaemia with blood glucose >11 mmol/L.

Hyperosmolar hyperglycaemic state

Note that there is no precise definition of HHS, but it is characterized by[5]:

- Hyperglycaemia. Serum glucose >30 mmol/L.
- Hyperosmolality. Serum osmolality >320 mOsmol/kg. (If unable to measure regularly, use an approximation of the osmolarity = [2 × Na + glucose + urea].)
- Significant dehydration with hypovolaemia.
- Minimal ketonaemia (<3.0 mmol/L) with no more than 1 + ketonuria on urinalysis.
- pH >7.30, bicarbonate >15 mmol/L.

Typical deficits per body weight

Diabetic ketoacidosis

- Water 100 mL/kg
- Sodium 7 to 10 mmol/kg
- Potassium 3 to 5 mmol/kg.

Hyperosmolar hyperglycaemic state

- Water 100 to 220 mL/kg
- Sodium 5 to 13 mmol/kg
- Potassium 4 to 6 mmol/kg.

Investigations

Blood testing

Measure both glucose and ketones in capillary blood hourly until they are near to the normal range. Or measure serum urea and electrolytes (U&Es), glucose and pH initially hourly, then 2-hourly once the serum glucose and capillary glucose are in agreement. Venous blood sampling is acceptable rather than repeated arterial punctures, but an intra-arterial line may be sited for repeat blood sampling (although it is not essential).

Send blood cultures if there is evidence of an underlying septic process, but remember that a mild leucocytosis is common in DKA, and should not be interpreted as signifying infection.

Urinalysis

DKA is highly likely in the presence of glycosuria and ketonuria in an unwell patient. Send the urine for microscopy and culture to rule out a urinary tract infection. Check a beta-HCG.

Electrocardiograph

Perform an early electrocardiograph to look for T-wave changes as a first indicator of hyperkalaemia (tall and peaked) or hypokalaemia (flat or inverted), or a clinically silent MI as a precipitant of HHS or DKA.

Point-of-care testing

Point-of-care testing for blood glucose and ketones, such as beta-hydroxybutyrate, is helpful at triage and to monitor the response to treatment.

Differential diagnosis of diabetic ketoacidosis

Other causes of high anion-gap (>16) metabolic acidosis include:

- alcoholic or fasting ketoacidosis
- lactic acidosis (multiple causes)
- uraemia
- methanol, ethylene glycol (note ethanol predominantly leads to a lactic acidosis)
- salicylate, iron, isoniazid ingestion.

Other causes of hyperglycaemia include:

- HHS
- drugs, such as corticosteroids, octreotide, thiazide diuretics, ritonavir, diazoxide and atypical antipsychotics (clozapine, olanzapine, risperidone, quetiapine – these may actually precipitate DKA soon after commencement, even in the absence of weight gain)[6]
- critical illness
- endocrine, such as Cushing syndrome, acromegaly, phaeochromocytoma, glucagonoma, VIPoma.

Management

Diabetic ketoacidosis

The treatment of DKA is rigorous and requires careful monitoring of the patient, both clinically and biochemically. Ideally, all observations and results are entered onto a purpose-designed record sheet, such as an integrated care pathway that includes data recording and guidance.[7]

Table 11.2.1 Replacement normal saline fluid regimen in a well 70 kg patient[a] with diabetic ketoacidosis, who is not haemodynamically compromised/in shock

Litre	*Time (hours from starting treatment)*
First at 1000 mL/h	0–1
Second at 500 mL/h+K	1–3
Third at 500 mL/h+K	3–5
Fourth at 250 mL/h+K	5–9
Fifth at 250 mL/h+K	9–13
Reassess cardiovascular status after 12 h and adjust rate accordingly	
Sixth at 166 mL/h+K	13–19

[a]In a small (<70 kg), young adult (18 to 25 years) adopt a slower rate initially, with total volume replacement over 24 to 48 hours to reduce the risk of cerebral oedema.
K, Potassium.

Severe diabetic ketoacidosis

Severe DKA necessitating intensive management includes a venous or arterial pH <7.1, ketonaemia >6 mmol/L, bicarbonate <5 mmol/L, hypokalaemia on admission (<3.5 mmol/L), Glasgow coma scale (GCS) <12, systolic blood pressure (BP) <90 mmHg and SaO_2 <92% on room air.

Fluid regimen

Intravenous fluids should be started within 30 min of the patient's arrival in the emergency department (ED). A shocked patient should receive a fluid bolus on arrival to restore perfusion, although care is needed in patients with co-morbidities, such as the elderly with heart or renal impairment, to avoid fluid overload.

Fluid rate

Give patients who are not shocked 1 L 0.9% normal saline over 1 hour, then at a rate of 500 mL/h for 4 hours with added potassium, then 250 mL/h for the next 8 hours, again with added potassium.[1] A suggested fluid regimen is shown in Table 11.2.1 that delivers 5 L of IV fluid over the first 13 hours of treatment.

Most intravenous fluid regimens recommend replacing the total volume deficit (often 10% of body weight) by 24 hours. However, in a patient with significant co-morbidities, it is prudent (although unproven) to aim to correct half the fluid deficit in the first 24 hours and the remainder in the next 24 hours. Likewise, adopt a slower rate initially in a child/young adult aged 18 to 25 years with the total volume replaced over 24 to 48 hours to reduce the risk of cerebral oedema (see Table 11.2.1).[1]

Cerebral oedema

The incidence of cerebral oedema is greatest in children under 12 years, and becomes rare over the age of 20 years. It may relate to a lower $pH/PaCO_2$ and a higher potassium and urea at presentation, and smaller increases in serum sodium. The aetiology remains unclear and may also relate to cerebral hypoperfusion followed by reperfusion, with an increased risk associated with early (in first hour) insulin administration (odds ratio [OR] 12.7) and large volumes of fluid in the first 4 hours (OR 6.55).[8] Headache is the earliest feature, followed by lethargy and a decreased conscious level.

Choice of fluid

There are no data from randomized controlled trials to support the choice of one crystalloid over another in the treatment of DKA. The risk of hyperchloraemic acidosis from the use of large volumes of normal saline with renal vasoconstriction and slowing of resolution of acidosis is not clinically significant. In addition, colloids are a less physiological replacement for electrolyte losses and are not recommended.

Addition of 10% dextrose

If serum (glucose) falls to <15 mmol/L, add 10% dextrose at 125 mL/h alongside the 0.9% saline infusion, with continuance of the insulin infusion until the electrolyte and volume losses have been replaced and the ketoacidosis/ketonaemia has been cleared.

Insulin

An intravenous insulin infusion should be started within 60 minutes of the patient's arrival in the ED.

Insulin infusion regimen

A standard regimen is an infusion of soluble insulin, made up by adding 50 units of soluble insulin to a total of 50 mL in 0.9% saline to produce a solution containing 1 unit/mL. Do *not* start this insulin infusion until the serum (potassium; K) has been checked to make sure it is not below the lower limit of the reference range; that is, it should be greater than 3.4 mmol/L. If it is below this, begin the IV fluids with potassium first, prior to commencing the insulin infusion.

Run the infusion at an initial rate of 0.1 units/kg/h (to a maximum of 6 units/h). Adjust the rate to reduce the serum (glucose) by around 3 mmol/L/h, with a rise in the serum (bicarbonate) of at least 3 mmol/L/h, and or a fall in (ketones) of at least 0.5 mmol/L/h.

When the serum (glucose) is less than 15 mmol/L, halve the insulin infusion rate and then adjust it to maintain the serum (glucose) between 9 and 14 mmol/L[7], as well as adding 10% dextrose at 125 mL/h to the normal saline IV until the ketonaemia is cleared (discussed earlier).

Remember when prescribing insulin always to write 'units' in full rather than as 'u', as the latter is too easily confused with a 0 (zero) and a 10-fold dose increase can be given in error.

Initial hypokalaemia

Severe hypokalaemia is associated with arrhythmias and sudden death in DKA. Replace the potassium prior to commencing any insulin if below 3.4 mmol/L (discussed earlier).

Switching to intermittent insulin

Switching from an insulin infusion to intermittent insulin is unlikely to occur until the patient is on the medical ward. If ED staff do supervise cessation of an insulin infusion, ensure the first subcutaneous insulin dose is given at least 1 h *before* the infusion is stopped in association with a meal, providing *all* the following criteria have been met before ceasing the insulin infusion:

- serum (glucose) <11 mmol/L
- pH >7.30
- serum ketones <0.6 mmol/L
- serum bicarbonate >15 mmol/L
- patient is eating and drinking normally, with a normal conscious level.

Potassium replacement

Initial hyperkalaemia followed by hypokalaemia are the most common life-threatening electrolyte problems seen in DKA. Therefore the serum (K) must be monitored closely and treatment planned to treat either condition rapidly, particularly the risk of hypokalaemia. A typical total body deficit of potassium in DKA is 3 to 5 mmol/kg.[1,2]

Hyperkalaemia from intracellular shift from the acidosis and lack of insulin seen in the early phase of DKA may cause life-threatening dysrhythmias. This hyperkalaemia rapidly resolves soon after fluid and insulin commencement.

Conversely, add potassium to intravenous fluids once the serum (K) is below 5.5 mmol/L and the patient is passing urine. However, do not add potassium to the first fluid bolus infused rapidly for volume resuscitation.

Infusion rate

Replacing potassium at 10 to 20 mmol/h is usually sufficient, with the rate adjusted to the serum (K) measurement, with the aim of maintaining serum (K) in the range 4 to 5 mmol/L. Use premixed intravenous potassium in fluid bags with an intravenous fluid infuser to avoid dosing or infusion rate errors.

Education and prevention

Arguably, every episode of DKA represents a failure of patient education, except for those patients in whom DKA is the first presentation of diabetes mellitus. All patients treated with insulin must understand 'sick day rules' to increase their normal insulin dose by 4 units or more when they have an intercurrent illness, even if they are not eating, as their insulin requirements will rise. Stopping insulin because a person is 'not eating properly' is all too common and an entirely avoidable precipitant of DKA.

Hyperosmolar, hyperglycaemic state

The management of HHS is similar to that of DKA, although patients are older, the water deficit is considerably greater, the sodium and potassium deficits greater and the overall mortality and morbidity higher. Focal or global neurological changes may occur, including an altered conscious level, coma, seizures and stroke (cause or effect).

Give 0.9% normal saline for initial volume resuscitation, with insulin by intravenous infusion and potassium supplementation to maintain serum (K) between 4 and 5 mmol/L, similar to DKA. In addition, the fall in serum osmolality is monitored as a marker of response to treatment.

Severe hyperosmolar hyperglycaemic state

Severe HHS necessitating intensive management includes an osmolality >350 mOsmol/kg, sodium >160 mmol/L, creatinine >200 µmol/L or urine output <0.5 mL/kg/h, hypokalaemia on admission (<3.5 mmol/L), GCS <12, systolic BP <90 mm Hg, SaO_2 <92% on room air and a venous or arterial pH <7.1. (Look for other causes, such as a concomitant lactic acidosis.)

Management differences in hyperosmolar hyperglycaemic state (to diabetic ketoacidosis)

Insulin infusion

Start fluid replacement first, *before* commencing an insulin infusion at 0.05 units/kg/h to a maximum of 3 units, as a patient with HHS may be more sensitive to insulin, plus the replacement of fluid alone will lead to a fall in serum glucose. Aim for a rate of decline in serum osmolarity of less than 3 mOsmol/kg/h and in blood glucose of not more than 5 mmol/L/h.

Reduce the insulin infusion rate when the serum (glucose) drops to 15 to 18 mmol/L, to maintain serum (glucose) in the range 10 to 15 mmol/L until the serum osmolarity is less than 315 mOsmol/kg. Complete normalization of osmolarity and electrolytes may take up to 72 hours.

Fluid choice

Use 0.9% normal saline as the principal fluid to restore circulation volume.[5] An initial rise in serum sodium may occur due to a shift of water intracellularly from a lowering of the blood glucose, which is not an indication to use a more hypotonic solution (normal saline is already relatively hypotonic compared to serum in HHS).

Only change to 0.45% half-normal saline if the serum osmolality *and* blood sugar are not reducing. Avoid a rapid fall in serum sodium, which should not exceed 10 mmol/L/24 h.[5]

Other considerations

- Shock may be partly cardiogenic rather than due to volume depletion. Thus invasive monitoring, central venous access and the use of vasoactive drugs rather than fluid alone will be required in this circumstance.
- Give LMWH for thromboprophylaxis as there is a higher risk of developing venous thromboembolism including during the 3 months post-hospital discharge.[9]

Miscellaneous issues

There are no data to support the use of phosphate or magnesium in the treatment of DKA or HHS, despite there often being hypophosphataemia and hypomagnesaemia.

Heparin thromboprophylaxis is not used routinely in DKA, nor are antibiotics in the absence of a focus of infection or sepsis, even though it is common for the white cell count to be mildly elevated.

Sodium bicarbonate should never be used in DKA if the pH is greater than 7.0 and even below that level its value is unproven. Significant disadvantages of giving IV bicarbonate are a rapid fall in serum (K), worsened intracellular acidosis, reduced tissue oxygen delivery, a delay in clearing ketones and a possible association with cerebral oedema.

CONTROVERSIES

- Choice and rate of intravenous fluid replacement and its impact on the unexpected but devastating development of cerebral oedema (usually seen in children).
- Titrating insulin use against β-hydroxybutyrate rather than serum glucose.
- Point-of-care measurement of beta-hydroxybutyrate is becoming more widespread, although its precise role in the care of patients with DKA is yet to be determined (discussed earlier).
- Use of ultrafast-acting insulin analogues subcutaneously in the treatment of DKA in children.

11.3 Thyroid and adrenal emergencies

Andrew Maclean

ESSENTIALS

1 **The thyroid and adrenal emergencies that pose an acute threat to life are thyroid storm, myxoedema coma and acute adrenal insufficiency. Diagnosis of these conditions requires a high index of suspicion and treatment frequently must be initiated on clinical rather than laboratory diagnosis.**

2 **Common features of thyroid storm are fever, alteration in mental state, cardiovascular complications, such as tachyarrhythmias and cardiac failure, and signs of hyperthyroidism. Treatment is with β-blockers, drugs that block thyroid hormone synthesis and release, and corticosteroids.**

3 **Common clinical signs of myxoedema coma are an alteration in conscious state, hypothermia and features of hypothyroidism. Treatment is with intravenous tri-iodothyronine and corticosteroids.**

4 **The most important clinical feature of acute adrenal insufficiency is hypotension unresponsive to fluid therapy. Although hyponatraemia and hyperkalaemia are usual in acute adrenal insufficiency, serum electrolytes may be normal. Treatment is with intravenous corticosteroid replacement on suspicion of the diagnosis.**

5 **General supportive measures and treatment of the precipitating event must parallel the specific treatment regimen in all of these conditions.**

Introduction

Four conditions are covered in this chapter: thyrotoxicosis, hypothyroidism, hypoadrenal states and hyper adrenal states. Patients with the first three present relatively infrequently to emergency departments (EDs), but all four conditions are potentially fatal if they go unrecognized and untreated. The most common cause of Cushing syndrome is exogenous steroid administration. An inability to produce endogenous steroids in times of physiological stress and therefore the potential for adrenal insufficiency occurring with insufficient replacement therapy must be considered in such patients.

THYROTOXICOSIS

Aetiology, genetics, pathogenesis and pathology

Normal secretion of thyroid hormone relies on an intact feedback loop involving the hypothalamus, pituitary gland and thyroid gland. Thyrotropin-releasing hormone (TRH) released from the hypothalamus stimulates thyroid-stimulating hormone (TSH) production in the anterior pituitary, which stimulates thyroid hormone release from thyroid follicular cells. Thyroid hormones suppress TRH and TSH production, and act at a cellular level, binding with nuclear receptors to enable gene expression and protein synthesis. Thyroid hormone may also have an effect on modulating cellular metabolism.

There are a number of pathological causes of thyrotoxicosis (Table 11.3.1). Graves disease is an autoimmune condition related to a combination of genetic and environmental factors, including iodine intake, stress and smoking. The thyrotoxicosis of Graves disease is caused by autoantibodies, which stimulate the thyroid resulting in excess thyroid hormone production.

Thyroiditis may be acute (rare), subacute or chronic. Inflammation of the thyroid is associated with damage to follicles with the release of thyroid hormone. Subacute thyroiditis (de Quervain syndrome, also known as subacute granulomatous) may follow a viral infection and is typically painful, with localized tenderness and neck pain, sometimes with odynophagia.

Multinodular goitre occurs in areas of both iodine deficiency and sufficiency, indicating that a multiplicity of genetic and environmental factors is at play. Fibrosis, hypercellularity and colloid cysts are the main pathological findings.

Epidemiology

Graves disease accounts for at least 80% of cases of thyrotoxicosis.[1] The prevalence increases in areas with high iodine intake. Graves disease has a strong female predominance, affecting up to 2% of all women.[1] Thyrotoxicosis due to Graves disease usually occurs in the second to fourth decades of life, whereas the prevalence of a toxic nodular goitre increases with age.

Clinical features

The signs and symptoms of hyperthyroidism are secondary to the effects of excess thyroid hormone in the circulation. The severity of the signs and symptoms is related to the duration of the illness, the magnitude of the hormone excess and the age of the patient. These symptoms and signs are summarized in Box 11.3.1, which illustrates the wide spectrum of possible clinical features.

A comprehensive history and physical examination should be performed, with particular attention to weight, blood pressure, pulse rate

Table 11.3.1 Causes of thyrotoxicosis

Primary hyperthyroidism	Graves disease Toxic multinodular goitre Toxic adenoma
Thyroiditis	de Quervain syndrome (subacute) Postpartum Radiation
Central hyperthyroidism	Pituitary adenoma Ectopic thyroid tissue Metastatic thyroid tissue
Drug-induced	Lithium Iodine (including radiographic contrast) Amiodarone Excess thyroid hormone ingestion ('factitious thyrotoxicosis')

Box 11.3.1 Clinical features of thyrotoxicosis

Nervousness, irritability
Heat intolerance and increased sweating
Tremor
Weight loss and alteration in appetite
Palpitations and tachycardia, particularly atrial fibrillation
Widened pulse pressure
Exertional intolerance and dyspnoea
Frequent bowel movements
Fatigue and muscle weakness
Thyroid enlargement (depending on cause)
Pretibial myxoedema (with Graves disease)
Menstrual disturbance and impaired fertility
Mental changes
Sleep disturbances
Changes in vision, photophobia, eye irritation, diplopia, lid lag or exophthalmos
Dependent lower extremity oedema
Sudden paralysis, with or without hypokalaemia

and rhythm, looking specifically for cardiac failure, palpation and auscultation of the thyroid to determine thyroid size, nodularity and vascularity, neuromuscular examination and an eye examination for evidence of exophthalmos or ophthalmoplegia.

Clinical investigations and criteria for diagnosis[1–3]

The TSH level is the single best screening test for hyperthyroidism. Hyperthyroidism of any cause (except excess TSH production from the anterior pituitary) results in a lower than normal TSH. The reference range is 0.4 to 5.0 mIU/L depending on the method.

Other laboratory and isotope tests may include:

- Free thyroxine (T_4) or free tri-iodothyronine (T_3) assay, when there is strong clinical suspicion of hyperthyroidism but the TSH is high or high normal.
- Thyroid autoantibodies, including TSH receptor antibody. These are not routine but may be helpful in selected cases.
- Radioactive iodine uptake and/or thyroid scan. These tests are helpful in establishing the cause of the hyperthyroidism, but are not part of the ED assessment.

Treatment

Mild hyperthyroidism does not require any treatment in the ED and the patient may simply be referred to an appropriate outpatient clinic. Any features of thyroid storm (discussed later) mandate admission, as does any significant intercurrent illness. Atrial arrhythmias should be controlled by the use of β-blockers, aiming to achieve a rate of less than 100 beats/min.

Ensure that all bloods have been collected first if thyroid-blocking drugs are to be commenced in the ED. High doses of thyroid-blocking drugs are often required to gain an initial response, after which the dose can be tapered.

Commence carbimazole 10 to 45 mg daily or propylthiouracil 200 to 600 mg daily in two or three divided doses initially, using the larger doses for more severe cases.[3] Ideally, discuss the initiation of these agents with the physician who will continue managing the patient after his or her discharge from the ED.

Thyroid storm

Aetiology

Thyroid storm occurs in about 1% of patients with hyperthyroidism. It usually occurs as an acute deterioration in a patient with poorly controlled or undiagnosed hyperthyroidism, precipitated by factors such as surgery, trauma, infection, radioiodine treatment, use of iodinated contrast, exogenous thyroxine ingestion or any other significant stressor.

The diagnosis is entirely clinical, as there is no test to differentiate a thyroid storm from thyrotoxicosis. The mortality rate, if untreated or if the diagnosis is missed, is over 90%. Death is usually due to cardiovascular collapse.

Clinical features of a thyroid storm

The symptoms and signs of thyrotoxicosis are present and significantly exaggerated, with the abrupt onset of a combination of the following:

- fever >37.6°C up to 41°C
- cardiovascular complications:
  - tachycardia with pulse rates up to 200 to 300/min, including rapid atrial fibrillation
  - wide pulse pressure
  - high output cardiac failure
- alteration in mental state, varying from agitation and restlessness to delirium, coma and seizures
- abdominal pain with vomiting and diarrhoea.

Differential diagnosis

The following differential diagnoses of a thyroid storm need to be considered:

- sepsis
- heat stroke
- malignant hyperthermia
- neuroleptic syndrome
- sympathomimetic ingestion
- drug withdrawal (including alcohol)
- phaeochromocytoma crisis.

Treatment

The treatment of thyroid storm is directed to blocking thyroid hormone synthesis and release, the peripheral effects of the thyroid hormones, and corticosteroids.

β-Blockers

β-Blockade is the most important factor in decreasing morbidity and mortality. Many of the peripheral manifestations of hyperthyroidism, in particular the cardiovascular effects, are reduced by the use of propranolol. Propranolol also inhibits the peripheral conversion of T_4 to T_3 as well as antagonizing the effects of thyroid hormones and the hypersensitivity to catecholamines.

Give intravenous increments of 0.5 mg initially up to 10 mg total with continuous cardiovascular monitoring. Subsequent doses of 40 to 120 mg 6-hourly orally can be given.

β-Blockers should treat the cardiac failure secondary to the tachyarrhythmia or high cardiac output, but may cause complications in patients with pre-existing heart disease or asthma.

In this situation, use the short-acting β-blocker esmolol, as any adverse effects will be of brief duration. Give a 250 to 500 μg/kg bolus followed by an infusion starting at 50 to 100 μg/kg/min titrated to effect. Another option is to use the combination of a β-blocker and digoxin.

Thyroid-blocking drugs

Give propylthiouracil 900 to 1200 mg loading dose orally or via a nasogastric tube if necessary. This is followed by 200 to 300 mg 4- to 6-hourly. Propylthiouracil acts by preventing hormone synthesis by blocking the iodination of tyrosine and also inhibits the peripheral conversion of T_4 to T_3.

Iodine in large doses inhibits the synthesis and release of thyroid hormones and may be given either orally as Lugol's iodine, 30 to 60 drops daily in divided doses, or intravenously as sodium iodide 1 g 12-hourly. Iodine should not be given until at least 1 hour after anti-thyroid medication has been commenced as otherwise it will provide substrate for the production of more thyroid hormone. Lithium carbonate may be used in patients allergic to iodine or be added when there is difficulty with control.[3]

Cholestyramine also can be considered, which acts by binding with thyroxine after biliary excretion and hence increases elimination.

Corticosteroids

Corticosteroids are given to inhibit the peripheral conversion of T_4 to T_3 and as a relative deficiency may also be present. Hydrocortisone 100 mg IV 6-hourly or dexamethasone 4 mg IV 12-hourly are used.

General supportive measures

Dehydration and electrolyte disturbances need correction. Aggressive treatment of hyperthermia with cooling measures and paracetamol are necessary, but induction of shivering should be avoided. Salicylates are contraindicated as they displace T_4 from binding proteins. In addition, it

is essential to look for and treat any precipitating cause, which will improve the prognosis.

Prognosis

Mortality rates are high, at 10% to 30%, despite treatment.

Apathetic hyperthyroidism

Patients with this condition are generally older, although it has been recorded in all age groups. The clinical picture is of a depressed mental state with cardiac complications, in particular cardiac failure. Weight loss is usually not significant and eye signs are rare. Most of the usual hyperkinetic manifestations of hyperthyroidism are absent. Treatment is as for standard hyperthyroidism.

HYPOTHYROIDISM

Aetiology, genetics, pathogenesis and pathology

Hypothyroidism results from the undersecretion of thyroid hormone from the thyroid gland. Causes of primary hypothyroidism include iodine deficiency, chronic autoimmune thyroiditis (Hashimoto thyroiditis), congenital, surgical removal of the thyroid gland, post-radioactive iodine, thyroid gland ablation and external irradiation. A significant number of cases are idiopathic. Secondary causes of hypothyroidism include pituitary and hypothalamic disease.

Epidemiology

Iodine deficiency is the most common cause worldwide, whereas in areas of iodine sufficiency, autoimmune disease and hypothyroidism secondary to treatment of hyperthyroid disease are more common. The prevalence of hyperthyroidism in adults is around 2% in women and 0.2% in men.[1] Congenital hypothyroidism is rare, occurring in about 1:4000 births.

Clinical features

The symptoms of hypothyroidism are related to the duration and severity of hypothyroidism, the rapidity with which hypothyroidism occurs and the psychological characteristics of the patient. These are summarized in Box 11.3.2.

A complete evaluation, including a comprehensive history, physical examination and appropriate laboratory evaluation should be performed in every patient with a goitre. Patients with chronic thyroiditis have a higher incidence of other associated autoimmune disorders, such as vitiligo, rheumatoid arthritis, Addison disease, diabetes mellitus and pernicious anaemia.

Box 11.3.2 Clinical features of hypothyroidism

- Dry skin and cold intolerance
- Coarse facial features
- Enlarged tongue
- Coarse brittle hair or loss of hair, loss of outer third of eyebrows
- Periorbital oedema
- Fatigue
- Constipation
- Weight gain/obesity
- Memory and mental impairment, decreased concentration
- Depression, personality changes
- Yellow skin (carotenaemia)
- Swelling of ankles
- Irregular or heavy menses and infertility
- Hoarseness
- Myalgias
- Goitre
- Hyperlipidaemia
- Delayed relaxation phase of tendon reflexes, ataxia
- Sinus bradycardia (atrioventricular block, rare)
- Cardiac failure, pericardial effusion (rare)
- Hypothermia (uncommon)

Clinical investigations and criteria for diagnosis

Laboratory evaluation

Perform a TSH assay as the primary test to establish the diagnosis of hypothyroidism if raised. The reference range is 0.4 to 5.0 mIU/L depending on the method. Additional tests may include free thyroxine assay and thyroid autoantibodies. A combination of an elevated TSH and low free thyroxine is diagnostic.[3–5] A patient may be hypothyroid with a TSH greater than twice the reference interval, but with a free thyroxine within the normal range. Subnormal thyroxine with a normal TSH can occur in secondary hypothyroidism.

Thyroid autoantibodies are positive in 95% of patients with autoimmune thyroiditis (Hashimoto thyroiditis). The high titres are of value in making this specific diagnosis.

Other investigations

A thyroid scan and/or an ultrasound are useful if structural thyroid abnormalities are suspected.

Thyroid nodules are not uncommon with chronic thyroiditis and carry a small risk of thyroid cancer.

Treatment

Start thyroxine at 50 to 100 µg orally daily in adults under 60 years of age without evidence of ischaemic heart disease. Too rapid commencement of full thyroid hormone replacement may cause myocardial ischaemia from increased myocardial oxygen consumption without a corresponding increase in cardiac output. The initial daily replacement dose is therefore 25 µg thyroxine in the elderly and where there is suspicion of heart disease. This dose should remain unchanged for 3 to 4 weeks to allow a steady state to be reached. It is appropriate to start this in the ED, when a firm diagnosis has been made and appropriate follow-up arranged.

The dose of thyroxine is then increased in 25 to 50 µg increments at not less than 4-weekly intervals, until the optimum dose is reached as determined by clinical response and TSH level. Consider admission for any patient with coexistent unstable angina to monitor cardiac function. Any features of myxoedema coma (discussed later) also mandate admission.

Myxoedema coma

The clinical syndrome of altered mental state, features of hypothyroidism and hypothermia is referred to as myxoedema coma, or sometimes as myxoedema crisis. There is usually a precipitating event, such as infection, stroke, trauma, myocardial infarction or administration of drugs, particularly phenothiazines, phenytoin, amiodarone, propranolol or lithium, that initiates this terminal decompensation phase of hypothyroidism.

The mortality for myxoedema coma remains up to 50% despite aggressive treatment.

Clinical features

- Altered mental state, usually coma due to cerebral oedema, hypoxia and hypercarbia.
- Seizures may precede coma in 25% of patients.
- Hypothermia with temperature usually less than 32.2°C. Notably, patients do not shiver.
- Hypoventilation resulting in hypoxia and hypercarbia.
- Cardiovascular complications, including hypotension and bradycardia, with heart rate inappropriate for the hypotension. Pericardial effusion, rarely with cardiac tamponade.
- Hypoglycaemia (common).
- Hyponatraemia.
- Paralytic ileus, megacolon, and urinary retention.
- Usual clinical features of hypothyroidism (see Box 11.3.2).

Treatment

Treatment should commence on clinical suspicion.

Administration of thyroid hormones

Tri-iodothyronine Intravenous T3 may give a faster clinical response in myxoedema coma, as

it is the active form of the hormone, although there is no consensus as to whether T3 or T4 replacement is preferable.[4] Give T3 as an initial IV bolus of 25 to 50 µg followed by 10 to 20 µg 8-hourly to a maximum of 60 µg/day. Alternatively, commence an infusion with a lower total dose of 20 µg/day, as large initial doses appear unnecessary for recovery and may, in fact, be harmful. Oral or nasogastric replacement of T3 is not recommended in the initial phase of management because of unreliable gastrointestinal absorption.

Thyroxine The use of T4 is supported as the gradual delivery of T3 through the peripheral conversion of T4 is better tolerated and as the onset of action is more predictable. Give a 400 to 500 µg IV bolus (300 µg/m²), followed by 50 µg IV daily until oral therapy is tolerated. Combined approaches are now also described.

Corticosteroids

Corticosteroids are given as there is impaired response to stress and the potential for coexistent adrenal insufficiency. Give hydrocortisone 100 mg IV 6-hourly. If an adrenocorticotrophic hormone (ACTH) stimulation test is being considered, give dexamethasone 4 mg until results are known.

General supportive measures

Requires correction of ventilatory, circulatory, temperature and metabolic abnormalities, and includes the use of warm humidified oxygen. Look for and treat any precipitating cause. Finally, avoid sedative drugs and watch out for water overload.

HYPOADRENAL STATES

Aetiology, genetics, pathogenesis and pathology

Glucocorticoids act to produce multiple effects on metabolism, including gluconeogenesis, mobilization of fatty acids and amino acids, inhibiting the effects of insulin and ketogenesis. Glucocorticoids have anti-inflammatory effects related to the inhibition of production and the reduction of the effects of cytokines and the reduction of cell-mediated immunity. They also maintain the normal response of the vascular system to vasoconstrictors. In addition, glucocorticoids affect the regulation of body water by increasing free water excretion. This occurs by an increase in the glomerular filtration rate as well as inhibition of migration of water into cells. Aldosterone acts primarily to cause the reabsorption of sodium and the excretion of potassium and hydrogen ions.

Table 11.3.2 Causes of adrenal insufficiency

Primary (Addison disease)	Autoimmune surgical removal
	Infection (tuberculosis, viral, fungal)
	Haemorrhage, including Waterhouse–Friedrichsen syndrome
	Congenital
Secondary	Exogenous steroid suppression (single most common cause of adrenal insufficiency)
	Endogenous steroid (from tumour)
	Pituitary failure (hypopituitarism)

The adrenals normally respond within minutes by elevating corticosteroid levels in response to any physiological or pathological stress. When glucocorticoid insufficiency is present such stressors may result in hypotension, shock and ultimately death if left untreated.

Primary adrenal insufficiency (Addison disease)

Primary adrenal insufficiency (Addison disease) is due to the inability of the adrenal cortex to produce adequate levels of adrenal hormones. Hyponatraemia, hyperkalaemia, acidosis and elevated serum creatinine occur mainly due to aldosterone deficiency, whereas hypoglycaemia is related to cortisol deficiency. Hypercalcaemia occurs as a result of reduction in the glomerular filtration rate as well as increased proximal tubular reabsorption of calcium. Also, there may be some increased mobilization of calcium from bone in patients with adrenal insufficiency.

Secondary adrenal insufficiency

Secondary adrenal insufficiency is due to failure of adequate ACTH from the pituitary gland (Table 11.3.2). Hyponatraemia still occurs in secondary adrenal insufficiency, but is due to cortisol deficiency.[6,7]

The majority of presentations of acute adrenal insufficiency occur as an exacerbation of a chronic disease process where there is a malfunctioning adrenal system. Acute precipitating factors include sepsis, major trauma, surgery and a myocardial infarct.

Causes of primary or secondary adrenal insufficiency

The cause of 80% of primary adrenal insufficiency is autoimmune. Other causes of acute adrenal gland insufficiency include primary or secondary malignancy, infection (e.g. tuberculosis), adrenal infarction or haemorrhage (Waterhouse–Friedrichsen syndrome) seen in meningococcaemia or severe sepsis, and drugs. Primary adrenal insufficiency also occurs in up to 20% of patients with AIDS. Up to 60% of patients with sepsis have a low baseline cortisol level, although fewer meet criteria for insufficiency on suppression testing.[5,8]

The most common cause of secondary adrenal insufficiency is suppression of the adrenopituitary axis by long-term corticosteroid therapy, although other causes include pituitary failure, such as panhypopituitarism or isolated ACTH production failure.

Clinical features

Suspect adrenocortical failure in any hypotensive patient when no apparent cause is found, particularly anyone who is unresponsive to fluid therapy. Orthostatic postural hypotension is almost always present. Other common features include abdominal pain, which may be severe, with vomiting.

Less obvious findings are weakness, anorexia, diarrhoea, postural syncope, mucocutaneous pigmentation/vitiligo (only with primary adrenal disease) and a dulled mental state.

Hypercalcaemia and/or hyperkalaemia can be the first sign of adrenal insufficiency in the critically ill patient. The other features of adrenal insufficiency may be masked by coexisting illness, but the possibility of adrenal insufficiency should always be considered.

Differential diagnosis

The diagnosis of adrenal insufficiency in the early stages is difficult as weakness, lethargy and gastrointestinal symptoms are common and nonspecific. Consider adrenal insufficiency in any patient presenting with these symptoms when more common causes have been excluded.

Clinical investigations

Laboratory findings

The classical laboratory findings are hyponatraemia (due to sodium depletion and the intracellular movement of sodium), hypochloraemia and

hyperkalaemia (due to acidosis and aldosterone deficiency). Mild hypercalcaemia (in 10% to 20% of cases) and a non-anion-gap metabolic acidosis may be seen. Hypoglycaemia, if present, is usually mild. However, all basic laboratory investigations can be within normal limits, even in the presence of an addisonian crisis.

Anti-adrenal antibodies are positive in 70% of patients with autoimmune adrenalitis.

Criteria for diagnosis

Baseline cortisol and ACTH levels should be taken prior to treatment. The normal reference range for cortisol is 200 to 650 nmol/L. An ACTH level should be <50 ng/L, although interpretation needs to take into account the time of day when the sample is taken. ACTH should be high in primary adrenal disease and low in pituitary disease.

The Synacthen stimulation test is the definitive investigation and may be required if the initial test results are not diagnostic. It is usually performed during a hospital stay, when Synacthen 250 µg is administered intramuscularly and cortisol levels are taken at baseline, 30 and 60 minutes. A baseline or post-Synacthen cortisol level of >550 nmol/L is considered normal.

Treatment

Corticosteroid replacement

Do not delay treatment awaiting confirmatory results if acute adrenal insufficiency is suspected.

Give immediate corticosteroid replacement with either intravenous hydrocortisone or dexamethasone. Dexamethasone is recommended when the diagnosis has not been confirmed by laboratory investigations, as it does not interfere with the cortisol assay. Give 10 mg dexamethasone IV stat followed by 4 mg IV 8-hourly. Alternatively, give hydrocortisone at a dose of 250 mg stat followed by 100 mg IV 6-hourly.

Fluid replacement therapy

Give normal saline 1 L stat, then titrated to response, although the total volume deficit is rarely greater than 10% body weight. Intravenous dextrose should be given at the same time, either separately or as 5% dextrose in normal saline to avoid hypoglycaemia.

General supportive measures

These include treatment of hypoglycaemia and other electrolyte replacement abnormalities, although most will be corrected with saline rehydration alone. Mineralocorticoid replacement is usually not necessary in the acute crisis, if salt and water replacement are adequate.

Once the crisis has been successfully treated, it is important to investigate and manage the cause, and to develop a maintenance regimen.

Prognosis

The patient with acute adrenal insufficiency may die if the diagnosis is not made promptly. When the diagnosis is suspected and treatment is early, the outcome is favourable depending on the nature of any precipitating illness.

Response to severe illness

The normal response to severe illness should see cortisol levels rising to at least 500 nmol/L. States of 'relative adrenal insufficiency' are described where glucocorticoid administration diminishes or even eliminates the requirements for vasopressor agents, even though measured cortisol levels are normal or close to normal.[5] There is no consensus on what constitutes 'normal' cortisol levels in severe illness.

Up to 60% of patients with severe sepsis may have some degree of adrenal insufficiency depending upon the threshold cortisol level used.[8] Moreover, it appears that it is the delta cortisol rather than the basal cortisol level that is associated with clinical outcome.[9] Repeat adrenal function testing is indicated in patients with severe illness who remain unstable or who fail to improve with aggressive supportive therapy.

The use of hydrocortisone has been recommended in septic shock after an abnormal 250 µg Synacthen stimulation test.[6] This should continue for a week if adrenal insufficiency is confirmed.

HYPERADRENAL STATES

Aetiology, pathogenesis and epidemiology

Cushing disease usually refers to hyperadrenalism due to a pituitary adenoma. Cushing syndrome occurs as a result of hyperadrenalism from exposure to excess glucocorticoids over a prolonged period. Endogenous causes of Cushing syndrome are related to primary adrenal disorders, such as adrenal adenoma, carcinoma or hyperplasia, or are secondary to ACTH or corticotropin-releasing hormone stimulation and ectopic ACTH production from bronchogenic carcinoma or carcinoid tumours in particular. However, by far the most common cause of Cushing syndrome is from the exogenous (iatrogenic) administration of steroids.

The incidence of Cushing syndrome ranges from 0.7 to 2.4 per million population per year, but the reported prevalence in obese patients with type II diabetes may be between 2% and 5%.[7]

Clinical features

The classical clinical features of Cushing syndrome are increased body weight with central obesity, rounded face, hypertension, fatigue, weakness and proximal myopathy, hirsutism, striae, bruising, decreased libido, amenorrhoea, depression and/or personality changes, osteopaenia or fracture. Proximal weakness or myopathy is useful to differentiate simple obesity (strong limbs) from possible Cushing syndrome (relative weakness for the patient's size).

Clinical investigations and criteria for diagnosis

Laboratory tests

Full blood examination may reveal polycythaemia, neutrophilia and eosinophilia. Electrolytes may show hyperglycaemia, hypokalaemia and metabolic alkalosis.

24-h urinary cortisol level

A measured 24-hour urinary cortisol level with a value more than four times the upper normal range is rare except in Cushing syndrome (normal range 100 to 300 nmol/24 hour).

Overnight dexamethasone suppression test

This is an outpatient screening test for Cushing syndrome[2]:

- Day 1, 09:00 hours: 5 mL blood taken for baseline cortisol
- Day 1, 23:00 hours: 1 mg dexamethasone taken orally
- Day 2, 5 mL blood for cortisol.

The baseline reference range for cortisol is 200 to 650 nmol/L. The day 2 cortisol level should drop to lower than 50% of the baseline level, indicating normal suppression and excluding Cushing syndrome.

Long dexamethasone suppression test

The long dexamethasone suppression test is performed as an inpatient, using increasing doses of dexamethasone to determine at what level suppression occurs, with testing of both cortisol and ACTH levels. Cushing syndrome only suppresses at high doses.

Other tests

A chest x-ray is important if bronchogenic carcinoma of the lung is suspected. Magnetic resonance imaging of the adrenals and/or head is used for the identification of tumours.

Treatment

Treatment will depend on the cause. When a pituitary or adrenal adenoma is identified,

optimal treatment is removal of the tumour.[3,7] Glucocorticoid replacement is then required for up to 2 years following surgery to allow full recovery of the normal pituitary–adrenal axis.

Pharmacological blockade of adrenal corticosteroid production may be required in some circumstances. Ketoconazole, amino-glutethimide, Metapirone and mitotane may be used for this purpose.

CONTROVERSIES

- What constitutes 'normal' cortisol levels in severe illness.
- Whether T3 or T4 replacement therapy is preferable in myxoedema coma.
- Differentiating simple obesity with hypertension from Cushing syndrome.

SECTION 12

METABOLIC EMERGENCIES

Edited by *Mark Little*

12.1 Acid–base disorders

Alan Gault

ESSENTIALS

1 **Acid–base homeostasis is one of the most tightly regulated systems within the body. It is maintained by buffering, respiratory and renal mechanisms.**

2 **Most acid–base disturbances are complex and require a systematic approach to determine underlying processes.**

3 **High-anion-gap metabolic acidosis and respiratory acidosis are both common in emergency medicine and should direct the clinician to determine and treat the aetiology.**

4 **Administration of $NaHCO_3$ is not routine; however, it is indicated in severe hyperkalaemia, sodium channel blockade and other selected poisonings.**

5 **Lactate levels greater than 4 mmol/L are associated with raised mortality and should highlight the need for resuscitation and immediate assessment of precipitating pathology.**

Introduction

Acid–base disorders are commonly encountered in the emergency department (ED) and their recognition is important for the diagnosis, assessment of severity and monitoring of many disease processes. Although these disorders are usually classified according to the major metabolic abnormality present (acidosis or alkalosis) and its origin (metabolic or respiratory), it is important to realize that acid–base disorders of a mixed type commonly occur, and that the recognition and assessment of these are more complex.

Carbon dioxide (CO_2) produces acid when in solution and altering $PaCO_2$ through changes in ventilation can produce or remove acid from the body. The terms respiratory acidosis/alkalosis refer to the pH shifts resulting from alterations in $PaCO_2$ from changes in ventilation. Bicarbonate (HCO_3^-) acts as a base in solution with bicarbonate accumulation resulting in a more alkaline state and its wasting or consumption indicating a more acidic state. The terms metabolic acidosis/alkalosis refer to pH shifts characterized by alterations in bicarbonate levels. By convention, the overall pH abnormality as defined by the blood gas assessment is termed alkalaemia (for pH >7.44) or acidaemia (pH <7.34).

Acid–base homeostasis

Acid–base status is one of the most tightly regulated systems in the body. The term compensation is used to describe the processes by which shifts in plasma pH are attenuated. These mechanisms include buffering, respiratory manipulation of CO_2 and renal handling of bicarbonate. Buffering with plasma proteins, haemoglobin and the carbonic-acid–bicarbonate systems provide the most immediate mechanism. This is followed by respiratory compensation, which occurs within minutes and is achieved by alterations in alveolar ventilation. Renal compensation usually takes hours to days to take effect.

Acidaemia

Systemic acidaemia is defined as the presence of an increased concentration of hydrogen ions ($[H^+]$) in the blood. An acidaemia can result from respiratory acidosis, metabolic acidosis or both in combination. The physiological effects of acidaemia are a decrease in the affinity of haemoglobin for oxygen and an increase in serum K^+ of approximately 0.4 to 0.6 mmol/L for each decrease in pH of 0.1.[1] Although the presence of acidaemia is often associated with a poor prognosis, the presence of acidaemia per se usually has few clinically significant effects. It is the nature and severity of the underlying illness that principally determines the outcome.

Metabolic acidosis

Metabolic acidosis is defined as an increase in the $[H^+]$ of the blood as a result of increased acid production or bicarbonate wasting from the gastrointestinal (GI) or renal tract. The cause is often multifactorial and can be further classified into 'anion-gap' and 'non-anion-gap' (or hyperchloraemic) metabolic acidosis.

Table 12.1.1 Causes of high-anion-gap metabolic acidosis

Acid	*Cause*
Lactic acid	Numerous causes—see Box 12.1.1
Ketoacids	Diabetic ketoacidosis Alcoholic ketoacidosis Starvation ketoacidosis
Phosphate and sulphate	Renal failure Uraemia
Other	Ethylene glycol—oxalic, glycolic, glyoxylic acid Methanol—formic acid Salicylate—salicylic, salicyruic, gentisic acid Toluene—benzoic, hippuric acid Paraldehyde—acetic acid Ethanol—acetic, lactic acid Uraemia

High-anion-gap metabolic acidosis (Table 12.1.1)

As electro-neutrality must exist in all solutions, the anion gap represents the concentration of anions that are not commonly measured. The most commonly used formula for the calculation of the anion gap is:

$$AG = [Na^+] - ([Cl^-] + [HCO_3^-])$$

The normal value for the anion gap depends on the type of biochemical analyser used and, while the upper limit of normal has been commonly quoted as 14, the mean range with some modern analysers is only 5 to 12.[2] In the normal resting state, the serum ionic proteins account for most of the anion gap, with a lesser contribution from other 'unmeasured' anions, such as phosphate (PO_4^-) and sulphate (SO_4^-). In pathological conditions where there is an increase in the concentration of unmeasured anions, high-anion-gap metabolic acidosis (HAGMA) results. The anions responsible for the increase in the anion gap depends on the cause of the acidosis. Lactic acid is the predominant anion in hypoxia and shock, PO_4^- and SO_4^- in renal failure, keto-acids in diabetic, alcoholic and starvation keto-acidosis, glycolic, glyoxylic and oxalic acid in ethylene glycol poisoning and formic acid in methanol poisoning.

Of the causes of a HAGMA, lactic acidosis is the most commonly encountered in the ED and is defined as a serum lactate of >2.5 mmol/L (Box 12.1.1). The presence of lactic acidosis is determined by the balance between lactate production and metabolism. In the seriously ill patient, it is common for increased production and decreased metabolism to be present simultaneously.

It is important to realize that in many conditions, a variety of factors may produce the acidosis and that multiple anions may be involved in the production of anion-gap acidosis. In a patient with HAGMA, non-anion-gap metabolic acidosis may also co-exist.

Box 12.1.1 Causes of hyperlactataemia

Type A: imbalance between oxygen demand and supply	**Type B: metabolic derangements**
Carbon monoxide poisoning	$Beta_2$-agonists
Cyanide poisoning	Cancer
Iron poisoning	Ethanol
Isoniazid poisoning	Hepatic failure
Excessive oxygen demand	Inborn errors of metabolism
• Seizure	Ketoacidosis
• Hyperpyrexia	Metformin/Phenformin
• Shivering	Sepsis
• Exercise	Vitamin deficiency (thiamine, biotin)
Shock	Paracetamol poisoning
Severe anaemia	Salicylate poisoning
Hypoxia	

Box 12.1.2 Causes of non-anion-gap metabolic acidosis

GIT Bicarbonate Loss	**Renal bicarbonate loss**
Diarrhoea	Uretoenterostomy
Small bowel fistula	Renal tubular acidosis
Pancreatic fistula	Adrenal insufficiency
Drugs	**Excess chloride administration**
Carbonic anhydrase inhibitors	
• Acetazolamide	
• Topiramate	
Acidifying agents	
• Ammonium chloride	
Cholestyramine	

GIT, Gastrointestinal tract.

Non-anion-gap metabolic acidosis (Box 12.1.2)

Non-anion-gap metabolic acidosis results from the loss of HCO_3^- from the body, rather than from increased acid production. To maintain electro-neutrality, chloride is usually retained by the renal tubules when HCO_3^- is lost and the hallmark of non-anion-gap acidosis is an elevation of the serum chloride. The causes of non-anion-gap metabolic acidosis are further classified according to the site of HCO_3^- loss. GI losses can occur with lower GI tract (GIT) fluid losses that are rich in HCO_3^- or with cholestyramine ingestion due to binding of HCO_3^- in the gut. Renal losses can occur with renal tubular acidosis (RTA), carbonic anhydrase inhibitor therapy or adrenocortical insufficiency. Occasionally, direct chloride excess drives the renal bicarbonate loss (again due to electro-neutrality)—which can be observed with large volumes of chloride-rich crystalloid administration (chiefly normal saline).

Renal tubular acidosis (Table 12.1.2) RTA is a group of conditions where there is an inability to acidify the urine. It occurs either from impaired secretion of H^+ in the distal convoluted tubule or failure to reabsorb HCO_3^- in the proximal convoluted tubule. This may result in a chronic metabolic acidosis, with hypokalaemia, nephrocalcinosis, rickets or osteomalacia. There are three subtypes of RTA and many different causes. In the ED it is most commonly due to the abuse of ibuprofen.

Low-anion-gap metabolic acidosis (Box 12.1.3) This is uncommon in the ED. It can occur in disease states that result in an increase in unmeasured cations or falsely measured high chlorine concentrations.

Treatment of metabolic acidosis

The treatment of acidosis should usually be directed primarily towards the correction of the underlying cause. Intravenous HCO_3^- is of use in the presence of severe acidosis and hyperkalaemia, sodium channel blockade (e.g. tricyclic antidepressant), salicylate and methanol poisoning. The use of HCO_3^- in patients with diabetic ketoacidosis and lactic acidosis associated with sepsis or severe cardiorespiratory disease does not appear to improve outcome.[3–5] The potential hazards of HCO_3^- therapy include fluid overload, hypernatremia, hypokalaemia, alkalemia, decreased ionized serum calcium, tissue injury from extravasation and worsening of intracellular acidosis.

Respiratory acidosis (Box 12.1.4)

Respiratory acidosis may be acute or chronic and is defined as an elevation of the arterial partial pressure of carbon dioxide (PCO_2). It is due to alveolar hypoventilation. This can result from central depression in respiratory drive, neuromuscular weakness, mechanical factors, lung parenchymal disorders and ventilation/perfusion mismatch. With significant elevations in CO_2, sweating, tachycardia, confusion and mydriasis occur. When the PCO_2 is greater than 80 mm Hg, the level of consciousness is usually depressed, known as CO_2 narcosis.

Treatment

The treatment of respiratory acidosis is directed towards reversal of the causative factors while supporting and promoting ventilation. Indications for and methods of therapy are clinically determined.

Alkalaemia

Alkalaemia is defined as a decrease in $[H^+]$ in the blood. Extreme alkalaemia may cause altered mental status, tetany and seizures. These are

Table 12.1.2 Types and causes of renal tubular acidosis

Type	*Anatomical location*	*Pathophysiology*	*Causes*
Type 1	Distal—collecting tubules	Failure to secrete H^+	Hereditary Autoimmune • Sjogren syndrome • Systemic Lupus Erythematosus (SLE) • Rheumatoid arthritis Nephrocalcinosis Sickle cell anaemia Toxins • Lithium • Toluene • Amphotericin B • Ifosfamide Liver cirrhosis
Type 2	Proximal tubules	Failure to reabsorb HCO_3^-	Hereditary Amyloidosis Multiple myeloma Paroxysmal nocturnal haemoglobinuria Toxins • HAART • Ifosfamide • Lead • Cadmium
Type 3	Combined type 1 + 2		
Type 4	Adrenal gland	Hypoaldosteronism	Aldosterone deficiency • Primary hypoaldosteronism • Hyporeninaemic hypoaldosteronism Aldosterone resistance • NSAIDs • ACE inhibitors • Spironolactone • Trimethoprim • Pseudohypoaldosteronism

ACE, Angiotensin-converting enzyme; *HAART*, highly active antiretroviral therapy; *NSAIDs*, non-steroidal anti-inflammatory drugs.

Box 12.1.3 Causes of low-anion-gap metabolic acidosis

Increased unmeasured cations
Hypercalcaemia
Hypermagnesaemia
Lithium
Multiple myeloma and other gammopathies
Dilution

Artefactual
Bromism
Iodism
Hypoalbuminaemia
Hypertriglyceridaemia

Box 12.1.4 Causes of respiratory acidosis

Acute respiratory acidosis
Airway obstruction
Aspiration

Bronchospasm

Drug-induced CNS depression
Hypoventilation of Central Nervous System (CNS) origin
• e.g. Cerebral tumour
Hypoventilation of Peripheral Nervous System (PNS) origin
• e.g. Guillain-Barré Syndrome (GBS) or Organophosphate (OP) poisoning
Pulmonary disease

Chronic respiratory acidosis
Pulmonary disease
• e.g. emphysema, pulmonary fibrosis
Neuromuscular disorders
• e.g. muscular dystrophy

Obesity
Severe kyphoscoliosis

predominantly related to a reduction in the concentration of ionized calcium, which is more commonly present in respiratory alkalosis due to anxiety, than from other causes. Like acidaemia, there are metabolic and respiratory processes by which it occurs.

Metabolic alkalosis (Box 12.1.5)

Metabolic alkalosis most commonly results from loss of acid from the GIT; however, renal acid losses or the accumulation of bicarbonate from exogenous sources can also contribute.

Box 12.1.5 Causes of metabolic alkalosis

Chloride responsive (Urinary chloride <10 mmol/L)
Gastrointestinal losses
• Vomiting
• Nasogastric suctioning
• Bulimia nervosa
• Pyloric stenosis
• Tetrahydrocannabinol (THC)-induced cyclical vomiting
Diuretics
Chloride losing enteropathy
Chloride losing nephropathy

Chloride unresponsive (Urinary chloride >20 mmol/L
Bartter syndrome
Liddle syndrome
Gitelman syndrome

Liquorice excess (glycyrrhizic acid)
Conn syndrome (primary hyperaldosteronism)
Excess bicarbonate administration
• Antacids
• Dialysis
• Milk-alkali syndrome

Diagnostically and therapeutically, metabolic alkalosis can be divided into two distinct aetiological groups—chloride-responsive and chloride-unresponsive metabolic alkalosis.

Chloride-responsive metabolic alkalosis arises from conditions that result in both chloride and volume loss. Reduction in extracellular volume leads to increased mineralocorticoid activity causing the reabsorption of sodium and the excretion of hydrogen with bicarbonate retention. The urine is usually alkaline with higher concentrations of bicarbonate; thus minimal chloride is excreted to maintain electro-neutrality. Hence a urinary chloride <10 mmol/L is a common finding in these conditions. The commonest causes seen in the ED are as a result of severe and prolonged vomiting and diuretic use.

Chloride-unresponsive metabolic alkalosis is typically due to disease states that either result in mineralocorticoid excess in the absence of hypovolaemia and chloride wasting, or congenital disorders with defects in the various ionic transport channels within the kidney. As extracellular volume is either normal or increased, urinary chloride is typically >20 mmol/L. These conditions are seen in the ED infrequently.

Treatment should be directed primarily towards correction of the underlying cause.

Respiratory alkalosis (Box 12.1.6)

Respiratory alkalosis can also be acute or chronic, of which the acute form is most commonly encountered in the ED.

Respiratory alkalosis may physiologically occur in the general population secondary to exercise, altitude-related hypoxia and stimulation of the medullary respiratory centre by progesterones during pregnancy. Disease states that

Box 12.1.6 Causes of respiratory alkalosis

Central nervous system-mediated hyperventilation	**Pulmonary-mediated hyperventilation**
Psychogenic	Congestive cardiac failure
Raised intracranial pressure	Mechanical hyperventilation
Cerebrovascular accidents	Pulmonary emboli
	Pneumonia
Hypoxia-mediated hyperventilation	**Toxin-induced hyperventilation**
Altitude	Salicylates
Anaemia	Nicotine
V/Q mismatch	Xanthines
Sepsis	Caffeine
	Sympathomimetics

give rise to respiratory alkalosis are more likely to be seen in the ED. Treatment is again directed towards correcting the underlying cause.

Systematic acid–base interpretation

A systematic stepwise approach to acid–base interpretation is beneficial in the evaluation of disturbances as they are often multiple. What follows is an example of a conventional methodology as outlined by Whittier and Rutecki[6]:

Step 1: what is the pH (primary acid–base disturbance)?

- Acidaemia exists if pH <7.40
- Alkalaemia exists if pH >7.44.

Step 2: determine whether the primary process is respiratory, metabolic or both

- Respiratory acidosis exists if $PaCO_2$ >44 mm Hg
- Respiratory alkalosis exists if $PaCO_2$ <40 mm Hg
- Metabolic acidosis exists if HCO_3^- <25 mEq/L
- Metabolic alkalosis exists if HCO_3^- >25 mEq/L

Step 3: calculate the anion gap

$$AG = [Na^+] - ([Cl^-] + [HCO_3^-])$$

Step 4: check for the degree of compensation

- Metabolic acidosis: For every 1 mEq/L decrease in HCO_3^-, $PaCO_2$ should decrease by 1.3 mm Hg.
  - Expected $CO_2 = 1.5 \times [HCO_3^-] + 8 \ (+/\times -2)$
- Metabolic alkalosis: For every 1 mEq/L increase in HCO_3^-, $PaCO_2$ should increase by 0.6 mm Hg
  - Expected $CO_2 = 0.7 \times [HCO_3^-] + 20 \ (+/-5)$
- Respiratory acidosis: For every 10 mm Hg increase in $PaCO_2$, HCO_3^- should increase by 1 mEq/L (acute) or 4 mEq/L (chronic)
- Respiratory alkalosis: For every 10 mm Hg decrease in $PaCO_2$, HCO_3^- should decrease by 2 mEq/L (acute) or 5 mEq/L (chronic).

Step 5: determine if there is a 1:1 relationship between the anions in the blood (presence of a delta gap)

In HAGMA, this step determines whether there is a concurrent non-anion-gap metabolic acidosis or metabolic alkalosis. There should be a 1:1 relationship between the rise in the anion gap over normal and the decrease in the bicarbonate. If the bicarbonate is higher than predicted, then a metabolic alkalosis is also present. If the bicarbonate is lower than predicted, then a non-anion-gap acidosis is also present.

Lactate gap

Lactate gap is the difference in lactate concentrations measured by laboratory analysis and point-of-care analysis. Some point-of-care analysers are unable to distinguish between lactate and glycolate—the major metabolite in ethylene glycol poisoning—and give a falsely elevated lactate result. The presence of a lactate gap helps refine the risk assessment in the setting of a suspected ethylene glycol intoxication.

CONTROVERSIES

- Whether the Stewart approach is advantageous in teaching and characterizing acid–base abnormalities compared to traditional approaches.

12.2 Electrolyte disturbances

John Pasco

ESSENTIALS

1 Sodium disorders are relatively common in hospitalized patients and elderly people.

2 The brain is most at risk from acute hyponatraemia because the osmotically expanded intracellular volume may induce increased intracranial pressure (hyponatraemic encephalopathy).

3 Treatment of hyponatraemia needs to be carefully individualized because of the risk of osmotic myelinolysis.

4 Hypernatraemia has a high in-hospital mortality rate, which often reflects severe associated medical conditions.

5 Although usually benign, hypokalaemia may cause cardiac arrhythmias and rhabdomyolysis. Oral replacement is usually sufficient, except where there is severe myopathy or cardiac arrhythmias.

6 Electrocardiogram changes in the presence of hyperkalaemia require urgent potassium-lowering measures and myocardial protection with calcium.

7 Management of severe hypercalcaemia includes enhancement of renal excretion of calcium, inhibition of osteoclast activity and treatment of the underlying condition.

8 Acute symptomatic hypocalcaemia should be treated with intravenous calcium.

9 Hypomagnesaemia is difficult to diagnose because its symptoms are non-specific and the serum level often does not reflect the true magnesium status of the patient. It usually exists as a 'deficiency triad' with hypokalaemia and hypocalcaemia.

10 Hypermagnesaemia is often iatrogenic, particularly in elderly patients or patients with renal impairment and/or chronic bowel conditions receiving magnesium therapy.

HYPONATRAEMIA

Introduction

Hyponatraemia, defined as serum sodium concentration of less than 130 mmol/L, is a common condition. The prevalence is estimated at 2.5% in hospitalized patients, two-thirds of whom develop the condition while in hospital.

Pathophysiology

Hyponatraemia is almost always associated with extracellular hypotonicity, with an excess of total body water relative to sodium (hypotonic hyponatraemia). The exceptions are:

- Normotonic hyponatraemia (pseudohyponatraemia): an artefactually low, and rarely seen, sodium measurement seen in hyperlipidaemia and hyperproteinaemia.
- Hypertonic hyponatraemia: a dilutional lowering of the measured serum sodium concentration in the presence of osmotically active substances, such as glucose, mannitol, glycerol and sorbitol. In the presence of hyperglycaemia, the true serum sodium can be estimated by adjusting the measured serum sodium upwards by 1 mmol/L for each 3 mmol/L rise in glucose above normal.

Hyponatraemia causes cellular swelling as water moves down an osmotic gradient into the intracellular fluid. Most of the symptomatology of hyponatraemia is produced in the central nervous system (CNS) by the swelling of brain cells within the rigid calvarium, causing raised intracranial pressure (hyponatraemic encephalopathy). As intracranial pressure rises, adaptive responses come into play, returning brain volume towards normal and restoring cellular function.

For this reason, chronic hyponatraemia is generally better tolerated than acute hyponatraemia. Patients can become encephalopathic when hyponatraemia develops rapidly and the adaptive responses have not had time to develop or fail.

Hyponatraemic encephalopathy carries a high mortality (50%) if left untreated.

Aetiology and classification

Hypotonic hyponatraemia may be classified according to the volume status of the patient (hypovolaemic, euvolaemic or hypervolaemic).

Hypovolaemic hyponatraemia

These patients have deficits in both total body sodium and total body water, but the sodium deficit exceeds the water deficit. Causes are listed in Box 12.2.1. Determination of the urinary sodium concentration can differentiate renal or extra renal losses. Extrarenal losses are usually associated with low urinary sodium concentrations (<20 mmol/L) and hyperosmolar urine. The exception is with severe vomiting and metabolic alkalosis, where bicarbonaturia obligates renal sodium loss and urinary sodium is high (>20 mmol/L), despite volume depletion. However, urinary chloride, a better indicator of extracellular fluid (ECF) volume, is low.

Euvolaemic hyponatraemia

Total body water is increased with only minimal change in total body sodium. Volume expansion is mild and usually not clinically detectable. Causes are listed in Box 12.2.2.

Box 12.2.1 Causes of hypovolaemic hyponatraemia

Renal losses (urinary [Na] >20 mmol/L)
Diuretics
Mineralocorticoid deficiency—Addison disease
Salt-losing nephropathy
Ketonuria
Osmotic diuresis—glucose, mannitol, urea
Bicarbonaturia with metabolic alkalosis

Extrarenal losses (urinary [Na] <20 mmol/L)
Vomiting—self-induced, gastroenteritis, pyloric obstruction
Diarrhoea
Excessive sweating
Blood loss
Third-space fluid loss—burns, pancreatitis, trauma

Box 12.2.2 Causes of euvolaemic hyponatraemia

- Psychogenic polydipsia
- Iatrogenic water intoxication
  - Absorption of hypotonic irrigation fluids during TURP
  - Inappropriate intravenous fluid administration
- Postoperative hyponatraemia (elevated ADH levels)
- Non-osmotic ADH secretion
  - Glucocorticoid deficiency
  - Severe hypothyroidism
  - Thiazide diuretics
- Drugs (ADH analogues, potentiation of ADH release, unknown mechanisms)
  - Psychoactive agents: phenothiazines, SSRIs, TCAs, MAOIs, 'ecstasy'
  - Oxytocin
  - Anticancer agents: cyclophosphamide, vincristine, vinblastine
  - NSAIDs
  - Carbamazepine
  - Chlorpropamide
- SIADH

Hypervolaemic hyponatraemia

Total body water is increased in excess of total body sodium. Causes include congestive cardiac failure, hepatic cirrhosis with ascites, nephrotic syndrome and chronic renal failure.

Clinical features

In addition to the features of the underlying medical condition and alteration in extracellular volume, clinical manifestations of hyponatraemia per se usually develop when serum sodium is less than 130 mmol/L. The severity of symptoms depends partly on the absolute serum sodium concentration and partly on its rate of fall. At sodium concentrations from 125 to 130 mmol/L, the symptoms are principally gastrointestinal, whereas at concentrations below 125 mmol/L, the symptoms are predominantly neuropsychiatric. The principal signs and symptoms of hyponatraemia are listed in Box 12.2.3.

Population groups particularly prone to acute hyponatraemic encephalopathy have been identified (Box 12.2.4).

Premenopausal women appear at risk because oestrogen and progesterone are thought to inhibit the brain Na-K-ATPase and increase circulating levels of antidiuretic hormone (ADH).

Psychogenic polydipsia occurs primarily in patients with schizophrenia or bipolar disorder. These patients develop hyponatraemia with a far lower fluid intake than is usually necessary (over 20 L of water/day in a 60 kg man, in the absence of elevated levels of ADH) and it may arise through a combination of factors: antipsychotics, increased thirst perception, enhanced renal response to ADH and a mild defect in osmoregulation.

Exercise-associated hyponatraemia occurs in endurance athletes and mainly relates to the consumption of excessive fluid.

Hyponatraemia in AIDS is common and associated with a high mortality. It may be secondary to syndrome of inappropriate ADH (SIADH), adrenal insufficiency or volume deficiency with hypotonic fluid replacement.

'Ecstasy' (MDMA) been associated with acute hyponatraemia due to a combination of increased secretion of ADH and drinking large quantities of water in an attempt to prevent dehydration.

Box 12.2.3 Clinical manifestations of hyponatraemia

- Anorexia
- Nausea

- Menstruating females
- Elderly women on thiazide diuretics
- Prepubescent children
- Psychiatric polydipsic patients
- Hypoxaemic patients
- AIDS patients
- Patients taking 'Ecstasy' (MDMA)
- Endurance athletes

Syndrome of inappropriate antidiuretic hormone secretion

This is a diagnosis of exclusion and is characterized by inappropriately concentrated urine in the setting of hypotonicity. It accounts for approximately 50% of all cases of hyponatraemia. These patients have elevated serum ADH levels without an obvious volume or osmotic stimulus. The diagnostic criteria for SIADH secretion are shown in Box 12.2.5 and conditions associated with the syndrome are listed in Box 12.2.6.

Box 12.2.5 Diagnostic criteria for syndrome of inappropriate antidiuretic hormone

- Hypotonic hyponatraemia
- Urine osmolality >100 mmol/kg (i.e. inappropriately concentrated)
- Urine sodium >20 mmol/mL while on a normal salt and water intake
- Absence of extracellular volume depletion
- Normal thyroid and adrenal function
- Normal cardiac, hepatic and renal function
- No diuretic use

Box 12.2.6 Conditions associated with syndrome of inappropriate antidiuretic hormone

- Neoplasms (ectopic ADH production)
  - Bronchogenic carcinoma
  - Pancreatic carcinoma
  - Lymphoma
  - Mesothelioma
  - Thymoma
  - Carcinoma of the bladder

  - Hydrocephalus
  - Brain tumour
  - Delirium tremens
  - Guillain–Barré syndrome
  - Stroke
  - Subdural or subarachnoid bleed
- HIV infection
  - *Pneumocystis carinii* pneumonia

ADH, Antidiuretic hormone; *CNS*, central nervous system.

Clinical investigations

Measurement of serum and urine sodium concentrations and osmolalities, in addition to clinical assessment of volume status, are essential for the assessment of hyponatraemia (Fig. 12.2.1).

Treatment

There is ongoing controversy over the treatment of hyponatraemia because of the risk of osmotic demyelination, which is discussed below.

Treatment of the underlying cause is obviously essential; it should be carefully individualized and depends on the presence of symptoms, the

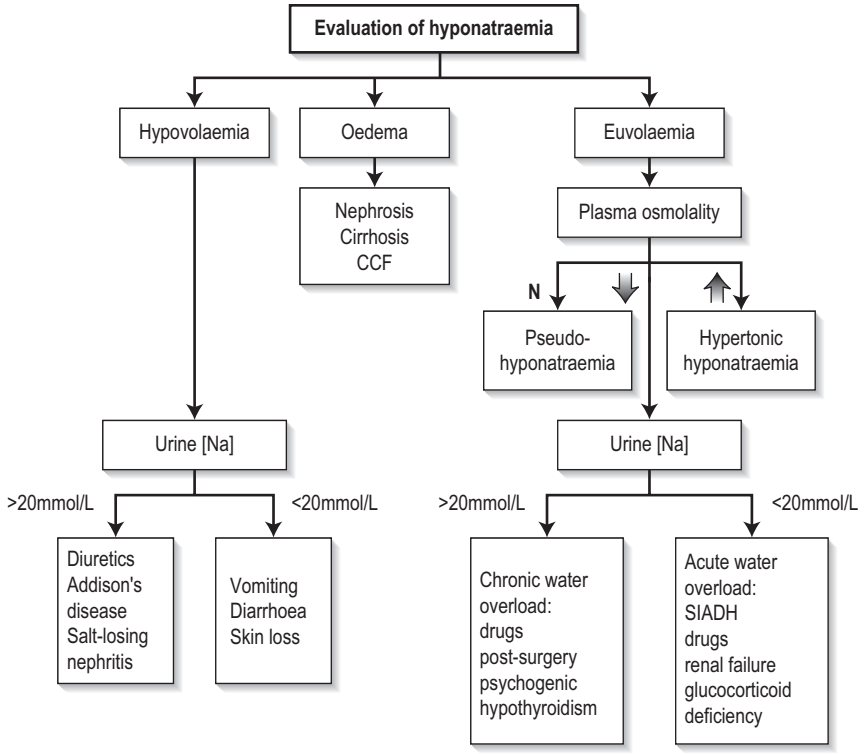

FIG. 12.2.1 Assessment of hyponatraemia. *CCF,* Congestive cardiac failure; *SIADH*, syndrome of inappropriate antidiuretic hormone. (Modified with permission from Walmsley R, Cuerin M. *Disorders of Fluid and Electrolyte Balance*. Bristol: John Wright & Sons; 1984.)

duration of the hyponatraemia and the absolute value of sodium. Ideally, correction of the serum sodium should be of a sufficient pace and magnitude to reverse the manifestations of hypotonicity but not be so rapid and large as to pose a risk of the development of osmotic demyelination.

Acute (<48 hours onset) symptomatic hyponatraemia (hyponatraemic encephalopathy)

Acute symptomatic hyponatraemia is a medical emergency requiring prompt and aggressive treatment, aiming to achieve a serum sodium level of at least 125 mEq/L. An immediate increase in serum sodium concentration by 8 mEq/L over 4 to 6 hours is recommended. This can be achieved by infusing hypertonic saline (3% NaCl) at a rate of 1 to 2 mL/kg/h, which should raise the serum sodium by 1 to 2 mmol/L/h. Where neurological symptoms are severe, hypertonic saline can be infused at 4 to 6 mL/kg/h. Serum sodium concentrations should be monitored closely. Other measures to reduce intracranial pressure, such as intubation and intermittent positive pressure ventilation, may also be required.

Chronic (>48 hours onset or unknown) symptomatic hyponatraemia

Chronic hyponatraemia presents the greatest dilemma. Care must be taken with correction of sodium as these patients are at the greatest risk of developing osmotic demyelination, yet the presence of encephalopathy mandates urgent treatment. In these patients, hypertonic saline can be infused so that a correction rate of no more than 1 to 1.5 mmol/L/h is maintained. Therapy with hypertonic saline should be discontinued when (1) the patient becomes asymptomatic, (2) the serum sodium has risen by 20 mmol/L, or (3) the serum sodium reaches 120 to 125 mmol/L. Thereafter, slower correction with water restriction should follow. The serum sodium should never be acutely elevated to hypernatraemic or normonatraemic levels and should not be elevated by more than 25 mmol/L during the first 48 hours of therapy.

Chronic (>48 hours onset or unknown) asymptomatic hyponatraemia

In this situation, saline infusion is usually not required and patients can be managed by treating the underlying disorder, discontinuing diuretic therapy or restricting fluids. Fluid restriction is inexpensive and effective but is often limited by patient non-compliance. Other treatment options include pharmacological inhibition of ADH with demeclocycline, which is limited by its neuro- and nephrotoxic side effects, or increasing solute with the use of furosemide or urea.

Osmotic myelinolysis

This is an iatrogenic disorder which develops progressively over 3 to 5 days following the correction of hyponatraemia. It classically produces symmetrical lesions centred on the midline of the pons and was originally described as 'central pontine myelinolysis'. However, about 10% of cases involve extrapontine lesions. It is reported as occurring in 25% of severely hyponatraemic patients following correction of serum sodium. Clinically, the disorder is initially manifested by dysarthria, mutism, lethargy and affective changes, which may be mistaken for psychiatric illness. Classically, pseudobulbar palsy and spastic quadriparesis are observed. Recovery is usually gradual and incomplete, although both fatalities and complete recovery are reported. Demyelination in the central pons and extrapontine sites can be demonstrated on magnetic resonance imaging (MRI) scan or at autopsy.

It appears that the risk of developing osmotic myelinolysis is associated with severity and chronicity of hyponatraemia. It rarely occurs if the serum sodium is >120 mmol/L or where hyponatraemia has been present for <48 hours. Alcoholics, malnourished patients, hypokalaemic patients, burn victims and elderly patients on thiazides seem to be most at risk of developing osmotic demyelination

Both the rate and the magnitude of sodium correction appear important in the development of osmotic myelinolysis. To date, although there is no agreed rate of correction regarded as completely safe, most authorities suggest that the serum sodium concentration should not rise by more than 10 to 14 mmol/L during any 24-hour period.

HYPERNATRAEMIA

Introduction

Hypernatraemia (Na >150 mEq/L) is much less common than hyponatraemia.

It is important to recognize hypernatraemia because it is usually associated with severe underlying medical illness. It is a condition of hospitalized patients, the elderly and dependent people. The incidence of hypernatraemia in hospitalized patients ranges from 0.3% to 1%, with from 60% to 80% of these developing hypernatraemia after admission. In-hospital mortality is high (40% to 55%).

Pathophysiology

Hypernatraemia is a relative deficiency of total body water compared to total body sodium, thus rendering the body fluids hypertonic. The normal compensatory response

Box 12.2.7 Causes of hypernatraemia

Altered perception of thirst
Osmoreceptor damage/destruction
- Exogenous: trauma
- Endogenous: vasculitis, carcinoma, granuloma

Idiopathic: psychogenic, head injury

Exogenous increase in salt intake

GIT, Gastrointestinal tract.

includes stimulated thirst—the most important response—and renal water conservation through ADH secretion. In the absence of ADH, water intake can match urinary losses because of increased thirst, but where the thirst mechanism is absent or defective, patients become hypernatraemic even in the presence of maximal ADH stimulation. Therefore hypernatraemia is usually seen where water intake is inadequate, that is, in patients too young, too old or too sick to drink, with no access to water or with a defective thirst mechanism.

Extracellular hypertonicity causes a shift of water from the intracellular space until there is osmotic equilibrium. The resultant cellular contraction may explain some of the clinical features of hypernatraemia. The brain is especially at risk from shrinkage because of its vascular attachments to the calvarium. Haemorrhage may occur if these vascular attachments tear.

As with hyponatraemia, the rate and magnitude of the rise in sodium determine the severity of the symptoms, which is a reflection of the brain's capacity to adapt to the deranged osmotic conditions.

Aetiology and classification

The clinical causes of hypernatraemia are listed in Box 12.2.7. Population groups at particular risk of developing hypernatraemia are listed in Box 12.2.8.

Hypernatraemia is classified into three categories based on extracellular volume status:

Box 12.2.8 Groups at particular risk for hypernatraemia

Elderly or disabled, unable to obtain oral fluids independently
Infants
Inpatients receiving: hypertonic infusions tube feedings osmotic diuretics lactulose mechanical ventilation
Altered mental status
Uncontrolled diabetes mellitus
Underlying polyuric disorders

Hypovolaemic hypernatraemia

This occurs where there is loss of both total body water and sodium, but with a greater loss of water. Renal causes include osmotic diuresis and diuretic excess. Urinary sodium is usually >20 mmol/L. Extrarenal losses include profuse diarrhoea, sweating, burns and fistulae. Urinary sodium is usually <20 mmol/L.

Euvolaemic hypernatraemia

This is the most common form of hypernatraemia. Patients have pure water losses, with intracellular dehydration as water shifts according to the osmotic gradient. Hypernatraemia in these patients occurs only when there is no accompanying water intake, that is, restricted access to water or a defect in thirst sensation.

Extrarenal losses are usually seen in skin losses in burns patients and via the respiratory system in respiratory infections and at high altitude. Renal water loss is usually due to diabetes insipidus—a failure of ADH production or secretion (central diabetes insipidus) or a failure of the collecting duct of the kidney to respond to ADH (nephrogenic diabetes insipidus).

Hypervolaemic hypernatraemia

This is not very common. These patients are typically extracellular volume expanded but intracellular volume depleted. It is seen following resuscitation with sodium bicarbonate, with the use of hypertonic saline solutions, with excess salt intake, in primary hyperaldosteronism and in Cushing syndrome.

Clinical features

In addition to the features of the underlying medical condition and alteration in extracellular volume, the clinical features of hypernatraemia per se are primarily CNS. Early symptoms are anorexia, nausea and vomiting; lethargy, hyperreflexia, confusion, seizures and coma occur later.

Treatment

The speed at which hypernatraemia is corrected should take into account the rate of development and severity of symptoms. Too rapid correction, especially in chronic hypernatraemia, can cause cerebral oedema or isotonic water intoxication. The rate of correction of chronic hypernatraemia should not exceed 0.5 to 0.7 mmol/L/h.

Treatment is based on clinical assessment of the patient's volume status.

Hypovolaemic hypernatraemia

These patients require restoration of the volume deficit with isotonic saline, colloid or blood in the first instance, to prevent peripheral vascular collapse and treatment of the underlying cause. Following this, the water deficit is corrected with 0.45% saline, 5% dextrose or oral water.

The water deficit is calculated as follows:

$$\text{Water deficit} = \text{total body water} \times (1 - Na2/Na1)$$

where Na2 = desired sodium, Na1 = actual sodium and total body water is usually 60% of the body weight. The calculated normal daily maintenance fluids should be added to the above volumes.

Euvolaemic hypernatraemia

Calculate the water deficit as above and replace the deficit and ongoing losses with 5% dextrose, 0.45% saline or oral water. To avoid cerebral oedema, particularly in chronic hypernatraemia, 50% of the water deficit should be replaced over the first 6 to 12 hours and the rest given slowly over 1 to 2 days. Serum sodium estimations should be repeated at regular intervals.

Hypervolaemic hypernatraemia

Removal of sodium is required with the use of diuretics, such as furosemide, and discontinuation of causative agents. Furosemide causes excretion of more water than sodium, so a hypotonic fluid, such as 5% dextrose, may need to be infused. In severe cases or in renal failure, dialysis may be required.

HYPOKALAEMIA

Introduction

Hypokalaemia may be defined as a serum potassium concentration of less than 3.5 mmol/L. It is usually considered to be severe when this is less than 2.4 mmol/L.

Pathophysiology

Hypokalaemia may develop as a consequence of potassium depletion or a shift of potassium into cells. In either case, there is an increase in the ratio of intracellular to extracellular potassium

Box 12.2.9 Causes of hypokalaemia

- Inadequate dietary intake
- Abnormal losses
  - Gastrointestinal
    - Vomiting, nasogastric aspiration
    - Diarrhoea, fistula loss
    - Villous adenoma of the colon
    - Laxative abuse
  - Renal
    - Mineralocorticoid excess
      - Conn's syndrome
      - Bartter syndrome
      - Ectopic ACTH syndrome
        - Small cell carcinoma of the lung

  - Barium poisoning
  - Hypothermia
  - Toluene intoxication
  - Hypokalaemic periodic paralysis

ACTH, Adrenocorticotropic hormone.

concentrations. This, in turn, produces hyperpolarization across excitable membranes and is responsible for the effects of hypokalaemia on striated muscle and the cardiac conducting system.

Aetiology

The causes of hypokalaemia are listed in Box 12.2.9.

Clinical presentation

Hypokalaemia commonly produces no symptoms in otherwise healthy subjects.

Clinical features may include weakness, constipation, ileus and ventilatory failure. Myopathy may develop, with weakness of the extremities, which characteristically worsens with exercise. If the hypokalaemia is severe and untreated, rhabdomyolysis may occur. Polyuria and polydipsia may result from the effect of hypokalaemia on the distal renal tubule (nephrogenic diabetes insipidus of hypokalaemia). Cardiac effects include ventricular tachycardias and atrial tachycardias, with or without block. Characteristic electrocardiogram (ECG) changes include PR prolongation, T-wave flattening and inversion and prominent U waves

Treatment

Oral replacement is safe for asymptomatic patients and 40 to 60 mmol of potassium every 1 to 4 hours is usually well tolerated.

Intravenous administration of potassium is recommended when hypokalaemia is associated with cardiac arrhythmias, familial periodic paralysis or severe myopathy. Usual infusion rates are 10 to 20 mmol/h. Rates greater than 40 mmol/h are not recommended. Potassium is a sclerosant and should, therefore, be given via a large peripheral or central vein. Serum potassium estimations every 1 to 4 hours and continuous cardiac monitoring are mandatory.

HYPERKALAEMIA

Introduction

Hyperkalaemia, defined as a serum potassium concentration greater than 5.5 mmol/L, is less common than hypokalaemia. Moderate (6.1 to 6.9 mmol/L) and severe (>7 mmol/L) hyperkalaemia can have grave consequences, particularly if acute.

Pathophysiology

Two homeostatic mechanisms are responsible for maintaining potassium balance. The renal system maintains external potassium balance by excreting 90% to 95% of the average daily potassium load (100 mmol/day); the gut excretes the remainder. This is a relatively slow process: only half the administered load of potassium will have been excreted in the urine after 3 to 6 hours. The extrarenal system involves hormonal and acid–base mechanisms that rapidly translocate potassium intracellularly. This system is critical in the management of acute hyperkalaemia.

Aetiology

The causes of hyperkalaemia are listed in Box 12.2.10.

Clinical features

The clinical features of hyperkalaemia are often non-specific. Diagnosis depends on clinical suspicion, measurement of potassium concentration in the plasma and the characteristic changes on the ECG.

Generalized muscle weakness, flaccid paralysis and paraesthesia of the hands and feet are common, but there is poor correlation between the degree of muscle weakness and serum potassium concentration.

Box 12.2.10 Causes of hyperkalaemia

- Pseudohyperkalaemia
  - Delay in separating red cells
  - Specimen haemolysis during or after venesection
  - Severe leucocytosis/thrombocytosis
- Excessive intake
  - Exogenous: IV or oral KCl, massive blood transfusion
  - Endogenous: tissue damage
  - Burns
  - Trauma
  - Rhabdomyolysis
  - Tumour lysis
- Decrease in renal excretion
  - Drugs
  - Spironolactone, triamterene, amiloride
  - Indomethacin
  - Captopril, enalapril
  - Renal failure
  - Addison disease
  - Hyporeninaemic hypoaldosteronism
- Compartmental shift
  - Acidosis
  - Insulin deficiency
  - Digoxin overdose
  - Succinylcholine
  - Fluoride poisoning
  - Hyperkalaemic periodic paralysis

IV, Intravenous.

The ECG changes (Table 12.2.1) are characteristic, but are an insensitive method of evaluating hyperkalaemia.

Serum biochemistry in almost all patients with hyperkalaemia shows some degree of renal impairment and metabolic acidosis. In dialysis patients, hyperkalaemia may develop without concomitant metabolic acidosis.

Treatment

Pseudohyperkalaemia is common due to release of potassium during or after venipuncture, so if hyperkalaemia is an unexpected finding, the serum potassium should be remeasured.

Hyperkalaemia with ECG changes requires urgent management. The priorities are as follows:

1. Antagonize potassium cardiac toxicity:
   - IV calcium chloride 10%, 5 to 10 mL or
   - IV calcium gluconate 10%, 15 to 30 mL. The effects of calcium should be evident within minutes and last for 30 to 60 minutes. A calcium infusion may be required. Calcium antagonizes the myocardial membrane excitability induced by hyperkalaemia. It does not lower serum potassium levels.

Table 12.2.1 Electrocardiogram changes of hyperkalaemia

Plasma potassium (mmol/L)	*Electrocardiogram characteristics*
6–7	Tall peaked T waves (>5 mm)
7–8	QRS widening, small-amplitude P waves
8–9	Fusion of QRS complex with T wave producing sine wave
>9	AV dissociation, ventricular tachycardia, ventricular fibrillation

AV, Atrioventricular.

2. Shift potassium into cells:
   - IV soluble insulin, 20 U with dextrose 50 g and/or
   - salbutamol nebulized (10 to 20 mg) or IV (0.5 mg diluted in 100 mL over 10 to 15 min) and or
   - IV sodium bicarbonate, 50 to 200 mmol
3. Enhance potassium excretion:
   - oral and/or rectal resonium A 50 g. This is a cation exchange resin; as the resin passes through the gastrointestinal tract, Na and K are exchanged and the cationically modified resin is then excreted in the faeces. This takes hours to have an effect.
   - furosemide diuresis
   - haemodialysis. This is usually reserved for cases of acute renal failure or end-stage renal disease. It is the most effective treatment for acutely lowering serum potassium, but there is usually a time delay in instituting dialysis and the temporizing measures outlined above must be employed in the interim.

The use of insulin and glucose is well supported in the literature. A response is usually seen within 20 to 30 min, with lowering of plasma potassium by up to 1 mmol/L and reversal of ECG changes. Transient hypoglycaemia may be observed within 15 minutes of insulin administration. In some patients, particularly those with end-stage renal failure, late hypoglycaemia may develop. For this reason, a 10% dextrose infusion at 50 L/hr is recommended and the blood glucose should be monitored closely. The exact mechanism by which insulin translocates potassium is not known; it is thought to be stimulation of Na-K-ATPase independent of cAMP.

β2-Agonists significantly lower plasma potassium when given intravenously or via a nebulizer. Potassium levels are reduced by up to 1.00 mmol/L within 30 minutes following 10 to 20 mg of nebulized salbutamol. The effect is sustained for up to 2 hours. Adverse effects of salbutamol administration include tachyarrhythmias and precipitation of angina in patients with coronary artery disease. Patients on non-selective β-blockers and with end-stage renal disease may not respond. Greater decreases in potassium have been observed when salbutamol treatment is combined with insulin and glucose. The additive effect is thought to be due to stimulation of Na-K-ATPase via different pathways.

Box 12.2.11 Causes of hypocalcaemia

EDTA, Ethylenediaminetetraacetic acid; *PTH*, Parathyroid hormone.

HYPOCALCAEMIA

Introduction

A reduction in serum calcium concentration manifests principally as abnormal neuromuscular function.

Pathophysiology

Calcium is involved in smooth and skeletal muscle contraction and relaxation, platelet aggregation, neurotransmission, hepatic and adipose glycogenolysis, thermogenesis and neutrophil function. In addition, most endocrine and exocrine gland function is calcium dependent.

Aetiology

The major cause of severe hypocalcaemia is hypoparathyroidism, as a result of surgery for thyroid disease, autoimmune destruction or from developmental abnormalities of the parathyroid glands. Other causes are listed in Box 12.2.11.

Clinical features

Patients with acute hypocalcaemia are more likely to be symptomatic than those with chronic hypocalcaemia. Symptomatic hypocalcaemia is characterized by abnormal neuromuscular excitability and neurological sensations. Early signs are perioral numbness and paraesthesia of distal extremities. Hyperreflexia, muscle cramps and carpopedal spasm follow. Chvostek sign (ipsilateral contraction of the facial muscles elicited by tapping the facial nerve just anterior to the ear) and Trousseau sign (carpopedal spasm with inflation of a blood pressure cuff for 3 to 5 minutes) are signs of neuromuscular irritability. If muscle contractions become uncontrollable, tetany results and this can prove fatal if laryngospasm occurs. Seizures may occur when there is CNS instability. Cardiovascular manifestations include hypotension, bradycardia, impaired cardiac contractility and arrhythmias. ECG evidence of hypocalcaemia includes prolonged QT interval and possibly ST prolongation and T-wave abnormalities.

Treatment

Acute symptomatic hypocalcaemia

In the emergency situation where seizures, tetany, life-threatening hypotension or arrhythmias are present, IV calcium is the treatment of choice. Infusion of 15 mg/kg of elemental calcium over 4 to 6 hours increases the total serum calcium by 0.5 to 0.75 mmol/L.

Administration of 10 to 20 mL of 10% calcium gluconate (89 mg elemental calcium per 10 mL) IV over 5 to 10 minutes is recommended. This should be followed by a continuous infusion because the effects of a single IV dose last only about 2 hours. The infusion rate should be adjusted according to serial calcium measurements obtained every 2 to 4 hours. Over-rapid infusion may cause facial flushing, headache and arrhythmias.

Calcium chloride 10% may also be used. This contains more calcium per ampoule (272 mg in 10 mL), resulting in a more rapid rise in serum calcium, but is more irritant to veins and can cause thrombophlebitis with extravasation.

Where hypocalcaemia and metabolic acidosis are present (usually in sepsis or renal failure), correction of the acidosis with bicarbonate may result in a rapid fall in ionized calcium as the number of calcium-binding sites is increased. Therefore hypocalcaemia must be corrected before the acidosis. Bicarbonate or phosphate should not be infused with calcium because of possible precipitation of calcium salts.

Cardiac monitoring is recommended during rapid calcium administration.

Chronic asymptomatic hypocalcaemia

These patients are usually managed with oral calcium supplements taken between meals. Calcitriol, the active hormonal form of vitamin D, 0.5 to 1.5 mg daily, can also be given.

HYPERCALCAEMIA

Introduction

Hypercalcaemia is a relatively common condition with a frequency estimated at 1:1000 to 1:10,000. The most frequent are malignancy and hyperparathyroidism.

Pathophysiology

Total serum calcium is made up of protein-bound calcium (40%, mostly albumin and not filterable by the kidneys), ion-bound complexes (13%, bound to anions such as bicarbonate, lactate, citrate and phosphate) and the unbound, ionized fraction (47%). The ionized fraction is the biologically active component of calcium and is closely regulated by parathyroid hormone (PTH). Total serum calcium is affected by albumin and does not necessarily reflect the level of plasma ionized calcium. Normal ionized calcium levels are 1.14 to 1.30 mmol/L. Protein binding, in turn, is influenced by ECF pH and alterations in serum albumin. Acidaemia decreases protein binding and increases the level of ionized calcium. To correct for pH: ionized calcium rises 0.05 mmol/L for each 0.1 decrease in pH.

To correct for serum albumin:

$$\text{Corrected } [Ca^+] = \text{measured } [Ca^+] + (40 - \text{albumin g/L}) \times 0.02 \text{ mmol/L}$$

Corrected calcium is used for all treatment decisions except where direct measurement of ionized calcium using an ion-specific electrode is available.

Three pathophysiological mechanisms may produce hypercalcaemia:

- Accelerated osteoclastic bone resorption. This is the most common cause of severe hypercalcaemia. Osteoclasts are activated by PTH and various humoral tumour products, the most common being parathyroid hormone-related protein (PTHRP).
- Increased gastrointestinal absorption (rarely important).
- Decreased renal excretion of calcium. PTH and PTHRP stimulate renal tubular reabsorption of calcium. Hypercalcaemia per se causes polyuria by interfering with renal mechanisms for the reabsorption of water and sodium. If there is inadequate fluid intake to compensate, extracellular volume depletion occurs, reducing glomerular filtration and exacerbating the hypercalcaemia.

Aetiology

The majority of cases of hypercalcaemia requiring urgent treatment are due to malignancy or, less commonly, primary hyperparathyroidism (parathyroid crisis). (Box 12.2.12).

Box 12.2.12 Causes of hypercalcaemia

- Factitious
  - Haemoconcentration
  - Postprandial
- Malignancy:
  - Lung and breast cancer, squamous cell carcinoma of the head and neck and cholangiocarcinoma and the haematological malignancies, multiple myeloma and lymphoma
- Primary hyperparathyroidism
- Drugs
  - Thiazides
  - Vitamin D
  - Lithium
  - Vitamin A
- Hormonal
  - Thyrotoxicosis
  - Acromegaly
  - Hypoadrenalism
  - Phaeochromocytoma
- Granulomas
  - Tuberculosis
  - Sarcoidosis
- Renal failure
- Milk alkali syndrome
- Immobilization

Clinical features

Hypercalcaemia causes disturbances of the gastrointestinal, cardiovascular and renal systems, and CNS.

Gastrointestinal manifestations include anorexia, nausea, vomiting and constipation. Cardiovascular manifestations include hypertension and a shortened QT interval on the ECG. Renal manifestations include polyuria, polydipsia and nephrocalcinosis (rare). CNS symptoms include psychotic behaviour, seizures, apathy, cognitive difficulties, obtundation and coma. Renal elimination of digoxin is also impaired.

Moderately elevated total serum calcium (3.00 to 3.50 mmol/L) is usually associated with symptoms. Markedly elevated total serum calcium (>3.5 mmol/L) mandates urgent treatment regardless of symptoms.

Treatment

Irrespective of the cause, the management of hypercalcaemic crisis is the same. There are three primary treatment goals:

- hydration of the patient ± enhancement of renal excretion of calcium
- inhibition of accelerated bone resorption
- treatment of the underlying problem.

Hydration and diuresis

Since hypercalcaemia invariably causes dehydration, volume expansion with intravenous fluids dilutes calcium and increases calcium clearance. Infusion rates of 200 to 300 mL/h of 0.9% saline, depending on the degree of hypovolaemia and the ability of the patient to tolerate fluid, may be required and, once adequate rehydration has been achieved, the infusion rate can be adjusted to maintain a urine output of 100 to 150 mL/h.

This treatment, although effective, results in a relatively modest reduction in serum calcium and patients with severe hypercalcaemia usually require additional treatment with bisphosphonates.

The routine use of loop diuretics is no longer recommended.

Enhancement of renal excretion

Haemodialysis is the treatment of choice to decrease rapidly serum calcium in patients with heart failure or renal insufficiency.

Inhibition of bone resorption

Pharmacological inhibition of osteoclastic bone resorption is the most effective treatment for hypercalcaemia, particularly hypercalcaemia of malignancy. Bisphosphonates, analogues of pyrophosphate, are the principal agents used. They inhibit osteoclast function and hydroxyapatite crystal dissolution. Unfortunately, normalization of calcium levels may take 3 to 6 days, which is too slow in critically ill patients.

Disodium pamidronate is currently one of the bisphosphonates of choice. The dose is 60 mg IV (in 500 mL 0.9% saline over 4 hours) if serum calcium is <3.5 mmol/L, and 80 mg IV if serum calcium is >3.5 mmol/L. Calcium levels normalize in up to 80% of patients within 7 days and this effect can persist for up to a month. Common adverse reactions include a mild transient elevation in temperature, local infusion site reactions, mild gastrointestinal symptoms and mild hypophosphataemia, hypokalaemia and hypomagnesaemia.

An alternative treatment to pamidronate is zoledronic acid 4 mg/100 mL (N saline or 5% dextrose) IV over 15 minutes. It is more potent and effective than pamidronate.

Glucocorticoids, after rehydration, are the treatment of choice in selected patient populations where there is inappropriately high production of 1.25-dihydroxyvitamin D as the mechanism for causing hypercalcaemia. Such conditions include vitamin D toxicity, sarcoidosis, other granulomatous diseases and haematological malignancies. The usual dose is 200 to 300 mg hydrocortisone IV for

3 to 5 days. However, the maximal calcium-lowering effect does not occur for several days and glucocorticoids should only be regarded as adjunctive therapy in hypercalcaemic crises.

Treat the underlying disorder

The definitive treatment for hypercalcaemia is to treat the underlying disease: surgery for hyperparathyroidism and tumour-specific therapy for hypercalcaemia of malignancy.

HYPOMAGNESAEMIA

Introduction

The diagnosis of magnesium deficiency is difficult and often overlooked largely because the symptoms are non-specific and do not usually appear until the patient is severely deficient.

Serum magnesium concentration (normal range: 0.76 to 0.96 mmol/L) is not a sensitive indicator of magnesium deficiency as it may not truly reflect total body stores. However, it is commonly used in the absence of other reliable methods to estimate the 'true' magnesium status. A low serum magnesium concentration is usually present in symptomatic magnesium deficiency, but it is important to remember that it may be normal in the presence of significant intracellular depletion.

Pathophysiology

Magnesium plays a critical role in metabolism: as an enzyme co-factor, in the maintenance of cell membranes and in electrolyte balance. It is the fourth most common cation in the body and is predominantly an intracellular ion with the majority found in bone (>50%) and soft tissue. Only 0.3% of total body magnesium is located extracellularly, of which 33% is protein bound, 12% is complexed to anions, such as citrate, bicarbonate and phosphate, and 55% is found in the free ionized form.

Hypokalaemia is present in 40% to 60% of cases of magnesium deficiency, due to renal wasting of potassium. The hypokalaemia is resistant to potassium replacement alone, as a result of a combination of factors, including impaired cellular cation pump activity and increased cellular permeability to potassium.

Hypocalcaemia is usually present at serum magnesium concentrations below 0.49 mmol/L. This may be due to impaired PTH synthesis or secretion or to PTH resistance as a result of magnesium deficiency.

Box 12.2.13 Causes of magnesium deficiency

Gastrointestinal losses
Acute and chronic diarrhoea
Acute pancreatitis
Severe malnutrition
Intestinal fistulae
Extensive bowel resection
Prolonged nasogastric suction

Renal losses
Osmotic diuresis—diabetes, urea, mannitol
Hypercalcaemia and hypercalciuria
Volume expanded states
Chronic parenteral fluid therapy

Drugs
ACE inhibitors
Alcohol
Aminoglycosides
Amphotericin B
Cisplatin
Ciclosporin

Diuretics—thiazide or loop
Other
Phosphate depletion

ACE, Angiotensin-converting enzyme.

(From Weisinger JR, Bellorin-Font E. Magnesium and phosphorus-electrolyte quintet. *Lancet*. 1998;352:391–396.)

Aetiology

From an emergency medicine perspective, hypomagnesaemia is most frequently encountered in the context of acute and chronic diarrhoea, acute pancreatitis, diuretic use, in alcoholics (in 30% of those admitted to hospital) and in diabetic ketoacidosis, secondary to glycosuria and osmotic diuresis (Box 12.2.13).

Clinical features

The clinical manifestations of severe magnesium deficiency include metabolic, neurological and cardiac effects (Box 12.2.14).

The presenting symptoms are non-specific and can be attributed to associated metabolic abnormalities, such as hypocalcaemia, hypokalaemia and metabolic alkalosis. In particular, patients may present with symptoms of hypocalcaemia: neuromuscular hyperexcitability, carpopedal spasm and positive Chvostek and Trousseau signs.

Early ECG changes of magnesium deficiency include prolongation of the PR and QT intervals, with progressive QRS widening and U-wave appearance as severity progresses. Changes in cardiac automaticity and conduction, atrial and ventricular arrhythmias, including torsades des pointes, can occur. Administration of a magnesium bolus can abolish torsades des pointes, even in the presence of normal serum magnesium levels. Magnesium is a co-factor in the Na-K-ATPase system, so magnesium deficiency enhances myocardial sensitivity to digitalis and may precipitate digitalis toxicity. Digitalis-toxic arrhythmias, in turn, can be terminated with intravenous magnesium.

Box 12.2.14 Clinical manifestations of severe magnesium deficiency

Cardiac effects	Metabolic effects	Neurological effects
Atrial fibrillation	Hypokalaemia	Grand mal seizures
Atrial flutter	Hypocalcaemia	Focal seizures
Supraventricular tachycardia	Hyponatraemia	Paraesthesias
Ventricular tachycardia	Hypophosphataemia	Dizziness
Torsades des pointes	Metabolic alkalosis	Vertigo
Coronary artery spasm	Hyperglycaemia	Ataxia
Hypertension	Hyperlipidaemia	Nystagmus
ECG changes		Tremor

Box 12.2.15 Magnesium doses (in mmol magnesium)

Emergency—IV route
  8–16 mmol *statim*
  40 mmol over next 5 h
Severely ill—IM route
  48 mmol on day 1
  17–25 mmol on days 2–5
Asymptomatic—oral route
  15 mmol/day

IM, Intramuscularly; *IV*, intravenously.

Treatment

Oral replacement is the preferred option in asymptomatic patients, although this route takes longer.

Symptomatic moderate-to-severe magnesium deficiency should be treated with parenteral magnesium salts. The patient should be closely monitored and therapy discontinued if deep tendon reflexes disappear or if serum magnesium exceeds 2.5 mmol/L. Suggested dosing regimens are outlined in Box 12.2.15.

HYPERMAGNESAEMIA

Hypermagnesaemia (serum magnesium above 0.95 mmol/L) is rare and usually iatrogenic.

The elderly and patients with renal impairment or chronic bowel disorders are particularly at risk, especially when IV magnesium or magnesium-containing cathartics or antacids are used.

Clinical manifestations include mental obtundation progressing to coma, cardiac arrhythmias, loss of deep tendon reflexes, refractory hypotension and respiratory arrest, nausea and vomiting, muscle paralysis and flushing.

Magnesium administration should be immediately discontinued. Further management is largely supportive. Maintain urine output at greater than 60 mL/h with fluid administration to enhance renal excretion. Frusemide (40 to 80 mg IV) may also be given once the patient is adequately hydrated. Haemodialysis may be of benefit in severe cases, particularly if there is impaired renal function.

CONTROVERSIES

- The safest and most effective ways of correcting hyponatraemia remain controversial because of the risk of inducing osmotic myelinolysis.
- The usefulness of bicarbonate for the acute therapy of hyperkalaemia has been questioned. A number of studies have shown that bicarbonate fails to lower potassium levels sufficiently in the acute, life-threatening situation to justify its use as first-line treatment. However, it is still recommended when hyperkalaemia is associated with severe metabolic acidosis (pH <7.20).

SECTION 13

HAEMATOLOGY EMERGENCIES

Edited by *Mark Little*

13.1 Anaemia

Mark Little

ESSENTIALS

1 **Anaemia is a condition in which the absolute number of red cells in the circulation is abnormally low.**

2 **Anaemia is not a diagnosis: it is a finding, which should prompt a search for an underlying cause.**

3 **The anaemic patient is doing at least one of three things: not producing enough red cells, destroying them too quickly or bleeding.**

4 **Bleeding is the most common cause of life-threatening anaemia encountered in the emergency department (ED).**

Introduction

Anaemia is a condition in which the absolute number of red cells in the circulation is abnormally low. The diagnosis is usually made on the basis of the full blood count (FBC). This, together with the blood film, offers qualitative as well as quantitative data on the blood components; a set of normal values is shown in Box 13.1.1.

The average life span of a normal red blood cell in the circulation is from 100 to 120 days. Aged red cells are removed by the reticuloendothelial system but, under normal conditions, are replaced by the marrow, such that a dynamic equilibrium is maintained. Anaemia develops when red cell loss exceeds red cell production. It follows that the anaemic patient is doing at least one of three things: not producing enough red cells, destroying them too quickly or bleeding.

The overriding functional importance of the red cell resides in its ability to transport oxygen, bound to the haemoglobin (Hb) molecule, from the lungs to the tissues. Functionally, anaemia may be regarded as an impairment in the supply of oxygen to the tissues, and the adverse effects of anaemia, from whatever cause, are a consequence of the resultant tissue hypoxia.

Anaemia is not a diagnosis: rather, it is a clinical or a laboratory finding that should prompt a search for an underlying cause (Box 13.1.2).

ANAEMIA SECONDARY TO HAEMORRHAGE

Aetiology

By far the most common cause of severe anaemia encountered in the ED is haemorrhage. Therefore assessment of the anaemic patient is often chiefly concerned with a search for a site of blood loss. The most common causes of haemorrhage are outlined in Box 13.1.3. However, the emergency physician must remain alert to the possibility that the patient who is not bleeding is manifesting a rarer pathological condition.

Box 13.1.1 Full blood count: normal parameters

Haemoglobin (Hb)	
Males	135–180 g/L
Females	115–165 g/L
Red blood cell count	
Males	4500–6500 × 10^9/L
Females	3900–5600 × 10^9/L
Haematocrit	
Males	42%–54%
Females	37%–47%
Other values	
MCH	27–32 pg
MCHC	32–36 g/dL
MCV	76–98 fL
Reticulocytes	0.2%–2%
White blood cells	4–11 × 10^9/L
Neutrophils	1.8–8 × 10^9/L
Eosinophils	0–0.6 × 10^9/L
Basophils	0–0.2 × 10^9/L
Lymphocytes	1–5 × 10^9/L
Monocytes	0–0.8 × 10^9/L
Platelets	150–400 × 10^9/L

MCH, Hb divided by RBC; *MCHC*, Hb divided by HCT; *MCV*, HCT divided by RBC. Most automated counting machines now give the red cell distribution width, a measure of degree of variation of cell size.

Peptic ulcer
Gastritis/Mallory-Weiss
Colonic/rectal bleeding

Obstetric/gynaecological bleeding
Ruptured ectopic pregnancy
Menorrhagia
Threatened miscarriage
Antepartum haemorrhage
Postpartum haemorrhage

Other
Epistaxis
Postoperative
Secondary to bleeding diathesis

Clinical features

Although it may be obvious on history and examination that a patient is bleeding, occasionally the source of blood loss is occult and the extent of the loss underestimated.

In the context of trauma, the history often gives clear pointers to both the sites and extent of blood loss. Consideration of the mechanism of injury may allow anticipation of occult pelvic, intraperitoneal or retroperitoneal bleeding. Intracranial bleeding is never an explanation for hypovolaemic shock in an adult.

In the absence of trauma, it is essential to obtain an obstetric and gynaecological history especially in women of childbearing age. The past medical history may point to a known haematological abnormality or a chronic disease process. A drug history is always relevant, as many drugs cause marrow suppression, haemolytic anaemia and bleeding. The family history may point to hereditary disease, and the social history may alert the clinician to an unusual occupational exposure in the patient's past or to recreational activities liable to exacerbate an ongoing disease process. The systems review is particularly relevant to the consultation with middle-aged or elderly male patients, who must be asked about symptoms of altered bowel habit and weight loss.

The symptomatology of anaemia proceeds from vague complaints of tiredness, lethargy and impaired performance through to more sharply defined entities such as shortness of breath on exertion, giddiness, restlessness, apprehension, confusion and collapse. Co-morbid conditions may be exacerbated (the dyspnoea of chronic obstructive airway disease) and occult pathologies unmasked (exertional angina in ischaemic heart disease).

Anaemia of insidious onset is generally better tolerated than that of rapid onset because of cardiovascular and other compensatory mechanisms. Acute loss of 40% of the blood volume may result in collapse, whereas—in some developing countries—it is not rare for patients with Hb concentrations only 10% of normal to be ambulant. Trauma superimposed on an already established anaemia can lead to rapid decompensation.

The cardinal sign of anaemia is pallor. This can be seen in the skin, lips, mucous membranes and conjunctival reflections. Yet not all anaemic patients are pallid and not all patients with a pale complexion are anaemic. Patients who have suffered an acute haemorrhage may show evidence of hypovolaemia: tachycardia, hypotension, cold peripheries and sluggish capillary refill. The detection of postural hypotension is an important pointer toward occult blood loss. Conversely, patients with anaemia of insidious onset are not hypovolaemic and may manifest high-output cardiac failure as a physiological response to hypoxia.

Other features of the physical examination may provide clues to the aetiology of anaemia. The glossitis, angular stomatitis, koilonychia and oesophageal web of iron deficiency anaemia are uncommon findings. Bone tenderness, lymphadenopathy, hepatomegaly and splenomegaly may point to an underlying haematological abnormality. The rectal and gynaecological examinations can sometimes be diagnostic.

Clinical investigations

The FBC often reveals an anaemia that has not been clinically suspected and that must be interpreted in the light of the history and examination. If the anaemia is mild, it may be a chance finding with little relevance to the patient's presenting complaint, but such a finding should never be ignored. At the very least a follow-up blood count should be arranged.

Anaemic patients have a low red cell count, a low haematocrit and a low Hb, but some caveats must be borne in mind:

- Patients who are bleeding acutely may initially have a normal FBC.
- Normal or high haematocrits may reflect haemoconcentration.
- Mixed pictures can be difficult to interpret (e.g. that of a polycythaemic patient who is bleeding).

Red cell morphology, particularly the mean corpuscular volume (MCV), can help to elucidate the cause of anaemia. The finding of a pancytopaenia suggests a problem in haematopoiesis rather than haemolysis or blood loss. In women of childbearing age, assay of blood or urine β-HCG is important.

Treatment

The principles of management of haemorrhage are as follows:

- Maintain the circulation.
- Identify the site of bleeding.
- Control the bleeding.
- Identify the underlying pathological process.
- Arrange for definitive treatment.
- Restore the blood volume.

The indications for red cell transfusion are discussed in Chapter 13.5. The faster the onset of the anaemia, the greater the need for urgent replacement. Patients who are tolerating their anaemia may require no more than an appropriate diet with or without the addition of haematinics. Elderly patients with severe bleeding often need red cells urgently. Excessive administration of colloid and/or crystalloid precipitates left ventricular failure, and it can then be difficult to administer red cells.

Chronic haemorrhage

The finding of a hypochromic microcytic anaemia on blood film is usually indicative of iron deficiency and, in the absence of an overt history of bleeding, should prompt a search for occult blood loss. Iron deficiency anaemia may be due to malnutrition, but inadequate dietary intake of iron is not usually the sole cause of anaemia in developed countries: much more commonly it is the result of chronic blood loss from the gastrointestinal (GI) tract, the uterus or the renal tract. More unusual causes are haemoptysis and recurrent epistaxis.

Patients present with insidious and rather vague symptoms. They may be unaware that they are bleeding and will probably show none of the trophic skin, nail and mucosal changes of iron deficiency. The automated cell count, in addition to showing a hypochromic, microcytic picture, may also show a raised red cell distribution width, which reflects anisocytosis on the blood film.

Iron studies may confirm the diagnosis of iron deficiency without pointing to the underlying cause. Serum iron and ferritin are low and total iron-binding capacity is high.

Disposition

If the source of blood loss is obvious—for example heavy menstrual bleeding—appropriate referral may be all that is indicated. If the source is not obvious, particularly in older patients, sequential investigation of the GI and renal tracts may be indicated. Decisions to admit or discharge these patients depend on the red cell reserves, the patient's cardiorespiratory status, his or her home circumstances and the likelihood of compliance with follow-up.

The anaemia itself can be corrected with oral or injectable iron supplementation. Intravenous ferric carboxymaltose over 20 minutes for the treatment of iron deficiency anaemia is now being used in EDs.

ANAEMIA SECONDARY TO DECREASED RED CELL PRODUCTION

Megaloblastic anaemia

The finding of a raised MCV is common in the presence or absence of anaemia. Alcohol abuse is a frequent underlying cause; other causes are listed in Box 13.1.4. MCVs greater than 115 fL are usually due to megaloblastic anaemia which, in turn, is usually due to either vitamin B12 or folate deficiency. Vitamin B12 and folate are essential to DNA synthesis in all cells. Deficiencies manifest principally in red cell production because of the sheer number of red cells that are produced. B12 deficiency is usually the result of a malabsorption syndrome, whereas folate deficiency is of dietary origin. Tetrahydrofolate is a co-factor in DNA synthesis; in turn, the formation of tetrahydrofolate from its methylated precursor is B12-dependent. Unabated cytoplasmic production of RNA in the context of impaired DNA synthesis appears to produce the enlarged nucleus and abundant cytoplasm of the megaloblast. When these cells are released to the periphery, they have poor function and poor survival.

Box 13.1.4 Some causes of a raised mass cell volume

- Alcohol
- Drugs
- Hypothyroidism
- Liver disease
- Megaloblastic anaemias (B12 and folate deficiency)
- Myelodysplasia
- Pregnancy
- Reticulocytosis

B12 deficiency due to pernicious anaemia is an autoimmune disorder in which autoantibodies to gastric parietal cells and the B12 transport factor (intrinsic factor) interfere with B12 absorption in the terminal ileum. Patients have achlorhydria, mucosal atrophy (a painful smooth tongue) and, sometimes, evidence of other autoimmune disorders, such as vitiligo, thyroid disease and Addison disease.

A rare but important manifestation of this disease is 'subacute combined degeneration of the spinal cord'. Demyelination of the posterior and lateral columns of the spinal cord manifests as a peripheral neuropathy and an abnormal gait. The central nervous system abnormalities worsen and become irreversible in the absence of B12 supplementation. Treatment of B12-deficient patients with folate alone may accelerate the onset of this condition.

Undiagnosed untreated pernicious anaemia is not a common finding in the ED, but the laboratory finding of anaemia and megaloblastosis should prompt haematological consultation. The investigative workup—which includes B12 and red cell folate levels, autoantibodies to parietal cells and intrinsic factor, a marrow aspirate, and Schilling's test of B12 absorption—may well necessitate hospital admission.

The workup for folate deficiency is similar to that for B12. Occasionally patients require investigation for a malabsorption syndrome (tropical sprue, coeliac disease), which includes jejunal biopsy. Folate deficiency is common in pregnancy because of the large folate requirements of the growing foetus. It can be difficult to diagnose because of the maternal physiological expansion of plasma volume and also of red cell mass, but diagnosis and treatment with oral folate supplements are important because of the risk of associated neural tube defects.

Both B12 and folate deficiency are usually manifestations of chronic disease processes. Rarely, an acute megaloblastic anaemia and pancytopaenia can develop over the course of days and nitrous oxide therapy has been identified as a principal cause of this condition.

Anaemia of chronic disorders

Patients with chronic infective, malignant or connective tissue disorders can develop a mild to moderate normochromic normocytic anaemia. Evidence of bleeding or haemolysis is absent and there is no response to haematinic therapy. The pathophysiology of this anaemia is complex and probably involves both decreased red cell production and red cell survival. Possible underlying mechanisms include reticuloendothelial overactivity in chronic inflammation and defects in iron metabolism mediated by a variety of acute-phase reactants and cytokines, such as interleukin-1, tumour necrosis factor and interferon γ, which impair renal erythropoietin production and function.

Anaemia of chronic disorders (ACD) is generally not so severe as to warrant emergency therapy. The importance of ACD in the ED lies in its recognition as a pointer toward an underlying chronic process. Difficulties can arise in distinguishing ACD from iron deficiency, and the two conditions may coexist—in rheumatoid arthritis, for example. Iron studies generally elucidate the nature of the anaemia. In iron deficiency, iron and ferritin are low and total iron binding is high, whereas in ACD iron and total iron binding are low and ferritin is normal or high.

Other causes of decreased red cell production

Bone marrow failure is rarely encountered in emergency medicine practice. The physician must be alert to the unusual, insidious or sinister presentation and be particularly attuned to the triad of decreased tissue oxygenation, immunocompromise and a bleeding diathesis that may herald a pancytopaenia. An FBC may dictate the need for haematological consultation, hospital admission and further investigation.

Among the entities to be considered are the aplastic anaemias, characterized by a pancytopaenia secondary to failure of pluripotent myeloid stem cells. Half of such cases are idiopathic, but important aetiologies are infections (e.g. non-A, non-B hepatitis), inherited diseases

Box 13.1.5 Classification of the myelodysplastic syndromes

Refractory anaemia
Refractory anaemia with ringed sideroblasts
Refractory anaemia with excess of blasts
Chronic myelomonocytic leukaemia

(e.g. Fanconi anaemia), irradiation therapeutic or otherwise and, most important in the emergency setting, drugs. Drugs that have been implicated in the development of aplastic anaemia include—in addition to antimetabolites and alkylating agents—chloramphenicol, chlorpromazine and streptomycin.

Characteristic of patients with a primary marrow failure is the absence of splenomegaly and of a reticulocyte response. There is a correlation between prognosis and the severity of the pancytopaenia. Platelet counts less than 20 × 10^9/L and neutrophil counts less than 500/mL equate to severe disease. Depending on the severity of the accompanying anaemia, patients may require red cell and sometimes platelet transfusion in the ED as well as broad-spectrum antibiotic cover. It is imperative to stop all medications that might be causing the marrow failure. Other forms of marrow failure include pure red cell aplasia, where marrow red cell precursors are absent or diminished. This can be a complication of haemolytic states in which a viral insult leads to an aplastic crisis (see The haemolytic anaemias, further on).

The myelodysplastic syndromes are a group of disorders primarily affecting the elderly. In these states there is no reduction in marrow cellularity but the mature red cells, granulocytes and platelets generated from an abnormal clone of stem cells are disordered and dysfunctional. There is peripheral pancytopaenia. These disorders are classified according to observed cellular morphology (Box 13.1.5). These conditions were once termed 'preleukaemia' and one-third of patients progress to acute myeloid leukaemia.

Two more causes of failure of erythropoiesis might be mentioned. One is invasion of the marrow and disruption of its architecture by extraneous tissue, the most common cause being metastatic cancer. Finally, but not at all uncommon, is the anaemia of chronic renal failure, where deficient erythropoiesis is attributed to decreased production of erythropoietin. Most patients with chronic renal failure on dialysis treatment tolerate a moderate degree of anaemia but occasionally require either transfusion or treatment with erythropoietin. Emergency physicians should recognize anaemia as a predictable entity in patients with chronic renal failure, which usually does not require any action.

ANAEMIA SECONDARY TO DECREASED RED CELL SURVIVAL: THE HAEMOLYTIC ANAEMIAS

Patients whose main problem is haemolysis are rarely encountered in the ED. The most fulminant haemolytic emergency imaginable is that following transfusion of ABO-incompatible blood (discussed in Chapter 13.5), a vanishingly rare event where proper procedures are followed. Haemolysis and haemolytic anaemia are occasionally encountered in decompensating patients with multisystem problems. Rarely, first presentations of unusual haematologic conditions occur.

Some of the haemolytic anaemias are hereditary conditions in which the inherited disorder is an abnormality intrinsic to the red cell, its membrane, its metabolic pathways or the structure of the Hb contained in the cells. Such red cells are liable to be dysfunctional and to have increased fragility and a shortened life span. Lysis in the circulation may lead to clinical jaundice as bilirubin is formed from the breakdown of Hb. Lysis in the reticuloendothelial system generally does not cause jaundice but may produce splenomegaly. The anaemia tends to be normochromic normocytic; sometimes a mildly raised MCV is due to an appropriate reticulocyte response from a normally functioning marrow. Serum bilirubin may be raised even in the absence of jaundice. Urinary urobilinogen and faecal stercobilinogen are detectable and serum haptoglobin is depleted. The antiglobulin (Coombs) test is important in the elucidation of some haemolytic anaemias. In this test, red cells coated in vivo (direct test) or in vitro (indirect test) with IgG antibodies are washed to remove unbound antibodies; they are then incubated with an anti-human globulin reagent. The resultant agglutination indicates a positive test.

Any chronic haemolytic process may be complicated by an 'aplastic crisis'. This is usually a transient marrow suppression brought on by a viral infection, which can result in a severe and life-threatening anaemia. Red cell transfusion in these circumstances may be lifesaving.

Hereditary spherocytosis

A deficiency of spectrin, the red cell wall protein, leads to loss of deformability and increased red cell fragility. These cells are destroyed prematurely in the spleen. The condition may present at any age with anaemia, intermittent jaundice and cholelithiasis. Patients are Coombs-negative and show normal red cell osmotic fragility. Splenectomy radically improves general health. Hereditary elliptocytosis is a similar disease with usually a milder course.

Glucose-6-phosphate dehydrogenase deficiency

Glucose-6-phosphate dehydrogenase (G6PD) generates reduced glutathione, which protects the red cell from oxidant stress. G6PD deficiency is an X-linked disorder present in heterozygous males and homozygous females. The disorder is commonly seen in West Africa, southern Europe, the Middle East and Southeast Asia. Oxidant stress leads to severe haemolytic anaemia. Precipitants include fava beans, antimalarial and analgesic drugs and infections. The enzyme deficiency can be demonstrated by direct assay and treatment is supportive.

Sickle cell anaemia

Whereas in the thalassaemias there is a deficiency in a given globin chain within the Hb molecule, in the haemoglobinopathies a given globin chain is present but structurally abnormal. HbS differs from normal HbA by one amino acid residue: valine replaces glutamic acid at the sixth amino acid from the N-terminus of the β-globin chain. Red cells containing HbS tend to 'sickle' at states of low oxygen tension. The deformed sickle-shaped red cell has increased rigidity, which causes it to lodge in the microcirculation and sequester in the reticuloendothelial system—thus causing a haemolytic anaemia.

Sickle cell disease is encountered in Afro-Caribbean people. The higher incidence in tropical areas is attributed to the survival value of the β-S gene against *falciparum* malaria. Heterozygous individuals have 'sickle trait' and are usually asymptomatic. Homozygous (HbSS) individuals manifest the disease in varying degrees. The haemolytic anaemia is usually in the range of 60 to 100 g/L and can be well tolerated because HbS offloads oxygen to the tissues more efficiently than HbA.

A patient with sickle cell disease may occasionally develop a rapidly worsening anaemia. This may be due to

- a production defect—reduced marrow erythropoiesis may be secondary to folate deficiency or to a parvovirus infection. This is an aplastic crisis.
- a survival defect—increased haemolysis is usually secondary to infection.
- splenic sequestration.

In any of these circumstances, transfusion may be lifesaving. However, these events are unusual. More commonly encountered is the vaso-occlusive crisis. A stressor—for example, infection, dehydration, or cold—causes sickle cells to lodge in the microcirculation. Bone marrow infarction is one well-recognized complication of the phenomenon, but virtually any body system can be affected. Common presenting

Box 13.1.6 Indications for exchange transfusion in sickle cell crisis

Neurological presentations: TIAs, stroke, seizures
Lung involvement (PaO_2 <65 mm Hg with FiO_2 60%)
Sequestration syndromes
Priapism

TIA, Transient ischaemic attack

complaints include acute spinal pain, abdominal pain (the mesenteric occlusion of 'girdle sequestration'), chest pain (pulmonary vascular occlusion), joint pain, fever (secondary to tissue necrosis), neurological involvement (transient ischaemic attacks, strokes, seizures, obtundation, coma), respiratory embarrassment and hypoxia, priapism, 'hand-foot syndrome' (dactylitis of infancy), haematuria (nephrotic syndrome, papillary necrosis), skin ulcers of the lower limbs, retinopathies, glaucoma and gallstones.

Most patients presenting with a vaso-occlusive crisis know they have the disease, but otherwise the differential diagnosis is difficult. Sickle cells may be seen on the blood film and can also be induced by deoxygenating the sample. Hb electrophoresis can establish the type of Hb present. Other investigations are dictated by the presentation and may include blood cultures, urinalysis and culture, chest x-ray, arterial blood gases and electrocardiography.

Pain relief should commence early. A morphine infusion may be required for patients with severe ongoing pain. Other supportive measures are dictated by the presentation. Intravenous fluids are particularly important for patients with renal involvement. Aim to establish a urine output in excess of 100 mL/h in adults. Antibiotic cover may be required in the case of febrile patients with lung involvement. It may be impossible to differentiate between pulmonary vaso-occlusion and pneumonia. Many patients with sickle cell disease are effectively splenectomized owing to chronic splenic sequestration with infarction and are prone to infection from encapsulated bacteria. The choice of antibiotic depends on the clinical presentation. Indications for exchange transfusion are shown in Box 13.1.6. The efficacy of exchange transfusion in painful crises remains unproven.

Haemoglobin S-C disease

Sickle cell trait or Hb S-C disease occurs in up to 10% of the African American population. The clinical presentation resembles that of sickle cell disease but is usually less severe.

Haemoglobin C disease

In HbC, lysine replaces glutamic acid in the sixth position from the N terminus of the β chain. Red cells containing HbC tend to be abnormally rigid, but the cells do not sickle. Homozygotes manifest a normocytic anaemia, but there is no specific treatment and transfusion is seldom required.

Thalassaemias

There is a high incidence of β-thalassaemia trait among people of Mediterranean origin; the region of high frequency extends in a broad band eastward to Southeast Asia.

Thalassaemias are disorders of Hb synthesis. In the Hb molecule, four haem molecules are attached to four long polypeptide globin chains. Four globin chain types (each with their own minor variations in amino acid order) are designated α, β γ and δ. Hb A comprises two α and two β chains; 97% of adult Hb is HbA. In thalassaemia, there is diminished or absent production of either the α chain (α thalassaemia) or the β chain (β thalassaemia). Most patients are heterozygous and have a mild asymptomatic anaemia, although the red cells are small. In fact, the finding of a marked microcytosis in conjunction with a mild anaemia suggests the diagnosis.

There are 4 genes on paired chromosomes 16 coding for α-globin and 2 genes on paired chromosomes 11 coding for β-globin. α-Thalassaemias are associated with patterns of gene deletion as follows: (−/−) is Hb-Barts hydrops syndrome, incompatible with life, and (α/−) is HbH disease.

Patients who are heterozygous for β thalassaemia have β thalassaemia minor or thalassaemia trait. They are usually symptomless. Homozygous patients have β thalassaemia major.

Diagnosis of the major clinical syndromes is usually possible through consideration of the presenting features in conjunction with an FBC, blood film and Hb electrophoresis.

Patients with HbH disease present with moderate haemolytic anaemia and splenomegaly. The HbH molecule is detectable on electrophoresis and comprises unstable β tetramers. α Trait occurs with the deletion of one or two genes. Hb, MCV and mean corpuscular Hb (MCH) are low but the patient is often asymptomatic.

β Thalassaemia major becomes apparent in the first 6 months of life with the decline of foetal Hb. There is a severe haemolytic anaemia, ineffective erythropoiesis, hepatosplenomegaly and failure to thrive. With improved care, many of these patients survive to adulthood and may possibly present to the ED, where transfusion can be lifesaving. Patients with β thalassaemia trait may be encountered in the ED relatively frequently. They are generally asymptomatic, with a mild hypochromic microcytic anaemia. It is important not to work up these patients for iron deficiency repeatedly and not to subject them to inappropriate haematinic therapy.

HELLP, Haemolysis, elevated liver enzymes and a low platelet count

Acquired haemolytic anaemias

Many of the acquired haemolytic anaemias are autoimmune in nature, a manifestation of a type II (cytotoxic) hypersensitivity reaction. Here, normal red cells are attacked by aberrant autoantibodies targeting antigens on the red cell membrane. These reactions may occur more readily at 37°C (warm autoimmune haemolytic anaemia, or AIHA), or at 4°C (cold AIHA). Warm AIHA is more common. Red cells are coated with IgG, complement or both. The cells are destroyed in the reticuloendothelial system. Fifty percent of cases are idiopathic, but other recognized causes include lymphoproliferative disorders, neoplasms, connective tissue disorders, infections and drugs (notably methyldopa and penicillin). Patients have haemolytic anaemia, splenomegaly and a positive Coombs test. In the ED setting, it is important to stop any potentially offending drugs and search for the underlying disease. The idiopathic group may respond to steroids, other immunosuppressive or cytotoxic drugs or splenectomy.

In cold AIHA, IgM attaches to the I red cell antigen in the cooler peripheries. Primary cold antibody AIHA is known as cold haemagglutinin disease. Other causes include lymphoproliferative disorders, infections such as those due to *Mycoplasma* and paroxysmal cold haemoglobinuria. Patients sometimes manifest Reynaud disease and other signs of circulatory obstruction. Symptoms worsen in winter. Red cell lysis leads to haemoglobinuria.

Microangiopathic haemolytic anaemia

In this important group of conditions, intravascular haemolysis occurs in conjunction with a disorder of microcirculation. Important causes are shown in Box 13.1.7.

Haemolytic uraemic syndrome and thrombotic thrombocytopaenic purpura

These are probably manifestations of the same pathological entity, with haemolytic uraemic syndrome occurring in children and thrombotic

thrombocytopaenic purpura most commonly in the fourth decade of life, especially in women. The primary lesion is likely to be in the vascular endothelium. Fibrin and platelet microthrombi are laid down in arterioles and capillaries, possibly as an autoimmune reaction. The clotting system is not activated. Haemolytic anaemia, thrombocytopaenia and acute renal failure are sometimes accompanied by fever and neurological deficits.

In adults, the presentation is usually one of a neurological disturbance (headache, confusion, obtundation, seizures or focal signs). The blood film reveals anaemia, thrombocytopaenia, reticulocytosis and schistocytes. The Coombs test is negative.

Patients require hospital admission. Adults with this condition may require aggressive therapy with prednisone, antiplatelet therapy, further immunosuppressive therapy and plasma exchange transfusions.

HELLP syndrome

HELLP stands for haemolysis, elevated liver enzymes and a low platelet count; it is seen in pregnant women in the context of pre-eclampsia. Treatment is as for pre-eclampsia, early delivery of the baby being of paramount importance.

Disseminated intravascular coagulation

The introduction of procoagulants into the circulation resulting in the overwhelming of anticoagulant control systems may occur as a consequence of a substantial number of pathophysiological insults—obstetric, infective, malignant and traumatic. Disseminated intravascular coagulation has an intimate association with shock of any cause. The widespread production of thrombin leads to deposition of microthrombi, bleeding secondary to thrombocytopaenia and a consumption coagulopathy as well as red cell damage within abnormal vasculature, leading to a haemolytic anaemia.

Recognition of this condition prompts intensive care admission and aggressive therapy. Principles of treatment include definitive management of the underlying cause and, from the haematological point of view, replacement therapy; this may involve the transfusion of red cells, platelets, fresh frozen plasma (FFP) and cryoprecipitate. There may be a role for heparin and other anticoagulant treatments if specific tissue and organ survival is threatened by thrombus.

Paroxysmal nocturnal haemoglobinuria

This entity is unusual in that an intrinsic red cell defect is seen in the context of an acquired haemolytic anaemia. A somatic stem cell mutation results in a clonal disorder. A family of membrane proteins (CD55, CD59 and C8 binding protein) is deficient and renders cells prone to complement-mediated lysis. The same proteins are deficient in white cells and platelets; therefore, in addition to being anaemic, patients are prone to infections and haemostatic abnormalities. They may go on to develop aplastic anaemia or leukaemia. Treatment is supportive. Marrow transplant can be curative.

Other causes of haemolysis

Haemolysis may be due to mechanical trauma, as in 'march haemoglobinuria'. Artificial heart valves can potentially traumatize red cells. Historically valves of the ball-and-cage type have been most likely to cause haemolysis, whereas disc valves are more thrombogenic. Improvements in design have made cardiac haemolytic anaemia very rare. Haemolysis is sometimes seen in association with a number of infectious diseases, notably malaria. Other infections that have been implicated are listed in Box 13.1.8. Certain drugs and toxins are associated with haemolytic anaemia (Box 13.1.9). The haemolytic anaemia that is commonly seen in patients with severe burns is attributed to direct damage to the red cells by heat.

Box 13.1.8 Infections associated with haemolysis

Babesiosis
Bartonella
Clostridia
Cytomegalovirus
Coxsackievirus
Epstein-Barr virus
Haemophilus

13.2 Neutropaenia

Mark Little

ESSENTIALS

1 **The risk of infection increases significantly as the absolute neutrophil count drops below 1.0 × 10^9/L.**

2 **Life-threatening neutropaenia is most likely due to impaired haematopoiesis.**

3 **A detailed medication history is vital to the 'workup' of neutropaenia.**

4 **Fever in the presence of severe neutropaenia constitutes a true emergency that mandates rapid assessment and aggressive management to prevent progression to overwhelming sepsis.**

5 **Strategies of early empiric broad-spectrum antibiotic administration have significantly reduced the overall mortality of febrile neutropaenia.**

Introduction

Neutropaenia is defined as a decrease in the number of circulating neutrophils. The neutrophil count varies with age, sex and racial grouping. The severity of neutropaenia is usually graded as follows:

- Mild: neutrophil count 1.0 to 1.5 × 10^9/L
- Moderate: neutrophil count 0.5 to 1.0 × 10^9/L
- Severe: neutrophil count <0.5 × 10^9/L.

The risk of infection rises as the neutrophil count falls; it becomes significant once the neutrophil count drops below 1.0 × 10^9/L. Australian guidelines have defined febrile neutropaenia as existing in a patient with a temperature above 38.4°C (or above 38°C on two occasions) with a neutrophil count less than 0.5 × 10^9/L or less than 1.0 × 10^9/L and likely to fall to less than 0.5 × 10^9/L. These patients must be examined for signs of systemic compromise (Box 13.2.1).

Box 13.2.1 Features of systemic compromise

Systolic BP ≤90 mm Hg or ≥30 mm Hg below patients usual BP or inotropic support
Room air arterial pO_2 ≤60 mm Hg, SpO_2 <90% or need for mechanical ventilation
Confusion or altered mental state
Disseminated intravascular coagulation or abnormal PT/aPTT
Cardiac failure or arrhythmia, renal failure, liver failure or any major organ failure (only if new or deteriorating and not atrial fibrillation or congestive heart failure)

(Reproduced with permission from Tam CS, OReilly M, Andersen D, et al. Use of empiric antimicrobial therapy in neutropenic fever. Australian Consensus Guidelines 2011 Steering Committee. *Intern Med J.* 2011;41:90–101.)

Neutropaenic patients are at greater risk of overwhelming infection if the onset of the neutropaenia is acute rather than chronic and, in the case of patients receiving cancer chemotherapy, if the absolute neutrophil count is in the process of falling rather than rising.

Signs or symptoms of infection in the presence of severe neutropaenia, especially with features of systemic compromise, constitute a true emergency that mandates rapid assessment and aggressive management to prevent progression to overwhelming sepsis. In the emergency department (ED) setting, this is most commonly encountered when a patient presents with fever in the context of chemotherapy for cancer.

Pathophysiology and aetiology

Polymorphonuclear neutrophils are formed in marrow from the myelogenous cell series. Pluripotent haematopoietic stem cells are committed to a particular cell lineage through the formation of colony forming units, which further differentiate to form given white cell precursors. The mature neutrophil has a multi-lobed nucleus and granules in the cytoplasm. The cells are termed 'neutrophilic' because of the lilac colour of the granules caused by the uptake of both acidic and basic dyes.

The neutrophils leave the marrow and enter the circulation, where they have a life span of only 6 to 10 hours before entering the tissues. Here they migrate by chemotaxis to sites of infection and injury, where they phagocytose and destroy foreign material. In health, about half of the available mature neutrophils are in the circulation. 'Marginal' cells are adherent to vascular endothelium or in the tissues and are not measured by the full blood count. Some individuals have fixed increased marginal neutrophil pools and decreased circulating pools; they are said to have benign idiopathic neutropaenia.

For a previously normal individual to become neutropaenic, there must be decreased production of neutrophils in the marrow, decreased survival of mature neutrophils or a redistribution of neutrophils from the circulating pool. The important causes are shown in Box 13.2.2.

It is a defect in neutrophil production that is most likely to prove life threatening. Consumption of neutrophils in the periphery, as occurs early in infectious processes, is likely to be rapidly compensated for by a functioning marrow. Fortunately, most of the primary diseases of haematopoiesis are rare and, in practice, many of the acquired neutropaenias are drug induced. Processes interfering with haematopoiesis, often involving autoimmune mechanisms, may affect neutrophils both in the marrow and in the periphery. Some drugs cause neutropaenia universally, but many more reactions are idiosyncratic, be they dose-related or independent of dose. Some commonly implicated drugs are listed in Box 13.2.3. Cancer chemotherapy drugs are now recognized as the commonest cause of neutropaenia.

Box 13.2.3 Drugs commonly associated with neutropaenia

Antibiotics: chloramphenicol, sulphonamides, isoniazid, rifampicin, β lactams, carbenicillin
Antidysrhythmic agents: quinidine, procainamide
Antiepileptics: phenytoin, carbamazepine
Antihypertensives: thiazides, ethacrynic acid, captopril, methyldopa, hydralazine
Antithyroid agents
Chemotherapeutic agents: especially methotrexate, cytosine arabinoside, 5-azacytidine, azathioprine, doxorubicin, daunorubicin, hydroxyurea, alkylating agents
Connective tissue disorder agents: phenylbutazone, penicillamine, gold
H_2-receptor antagonists
Phenothiazines, especially chlorpromazine
Miscellaneous: imipramine, allopurinol, clozapine, ticlopidine, tolbutamide

Clinical features

Neutropaenia is frequently anticipated based on the clinical presentation, such as fever developing in the context of cancer chemotherapy; this is by far the most common scenario in which severe neutropaenia is seen in the ED. Alternatively, it may be identified in the course of investigation for a likely infective illness, or it might be an incidental finding during investigation for an unrelated condition.

Chronic neutropaenia may be asymptomatic unless secondary or recurrent infections develop. Acute severe neutropaenia may present with fever, sore throat and mucosal ulceration or inflammation. Symptoms or signs of an associated disease process may also be present, such as pallor from anaemia or bleeding from thrombocytopaenia, as might occur in conditions causing pancytopaenia.

The history of the mode of onset and duration of the illness is important. Systems enquiry may reveal localizing infective symptoms. The past history may reveal a known haematological illness or previous evidence of immunosuppression, such as frequent and recurrent infections. A detailed drug history is vital. Most neutropaenic drug reactions occur within the first 3 months of taking a given drug.

In the ED, all observations should be performed at initial assessment and monitored regularly until disposition. Attention should be paid to identifying early signs of severe sepsis and the progression to septic shock.

Physical examination may reveal necrotizing mucosal lesions, pallor, petechial rashes, lymphadenopathy, bone tenderness, abnormal tonsillar or respiratory findings, spleno- or other organomegaly. Careful examination of the skin of the back, the lower limbs and the perineum for evidence of infection is important. The presence of indwelling venous access devices should be noted and insertion sites inspected for evidence of inflammation or infection.

Clinical investigations

Investigation in the ED is first aimed at confirming and quantifying the severity of neutropaenia, identifying the cause and then identifying the focus and severity of infection. An urgent full blood count and blood film should be ordered for any patient who is suspected of suffering febrile neutropaenia. A coagulation profile and full biochemistry are indicated once severe neutropaenia is confirmed. Anaemic patients may require a group-and-hold or cross-match.

Microbiological cultures aimed at isolating a causative organism should be taken, but antibiotics should not be unreasonably delayed in the presence of fever and confirmed significant neutropaenia. Blood cultures should be taken at the time of cannulation and, if possible, prior to the instigation of antibiotic therapy. Swabs of skin lesions; throat, nose and indwelling venous access device sites; sputum; urinalysis and urine culture; as well as stool cultures (including *Clostridium difficile* toxin) may be indicated depending on the clinical picture. Computed tomography scanning may be required to find an occult infection. Patients with apparent central nervous system infections might require a lumbar puncture provided that there are no contraindications.

Treatment

Management of the patient with confirmed febrile neutropaenia in the ED involves early recognition with a high-acuity triage, treatment of bacterial infection and institution of supportive care. Evolving or established haemodynamic instability requires immediate aggressive resuscitation.

For any patient with fever and suspected or confirmed significant neutropaenia, empiric broad-spectrum antibiotic therapy should be started in the ED after blood has been drawn for culture. Most protocols aim for antibiotic administration within 60 minutes of presentation or 30 minutes if there are signs of sepsis/septic shock. This strategy has played a pivotal role in reducing mortality rates in individuals with febrile neutropaenia. Australian consensus-based clinical recommendations for the management of neutropaenic fever in adults reinforce the need for the early administration of antibiotics. In general, antibiotics should provide good cover for both gram positive and gram negative organisms. With the increased use of indwelling venous access devices for cancer chemotherapy, there has been an increase in the incidence of sepsis due to gram-positive organisms, such as coagulase-negative staphylococci, *Staphylococcus aureus* and methicillin-resistant *S. aureus* (MRSA). Although it occurs infrequently, bacteraemia due to *Pseudomonas aeruginosa* is associated with a high morbidity and mortality; therefore it should also be covered.

Recent evidence suggests that antibiotic monotherapy is as efficacious as combined therapy. Therefore, for clinically stable patients, Australian consensus guidelines recommend a β-lactam monotherapy (such as pipperacillin-tazobactam 4.5 g q6h, cefepime 2 g q8h or ceftazidime 2 g q8h). These antibiotics should be administered within 1 hour of presentation and after at least one set of blood cultures has been ordered.

For patients with systemic compromise, the Australian consensus guidelines recommend the previously mentioned β-lactam antibiotics plus gentamicin (5–7 mg/kg daily) given within 30 minutes of presentation. If the clinicians believe that the shocked patient was colonized with gram positive organisms (e.g. MRSA, or if he or she has clinical evidence of a catheter-related infection in a unit with a high incidence of MRSA) and the patient has normal renal function), vancomycin (1.5 g q12h should be added. Empiric antifungal therapy is not generally required unless there is persistent fever in a high-risk patient beyond 96 hours of antibacterial therapy.

Disposition

The presence of significant neutropaenia with fever generally mandates admission to hospital. Patients with severe acute neutropaenia without an established aetiology will also generally require admission regardless of the presence or absence of fever. Both the haematological abnormality and the likely presence of infection require investigation. Sometimes the aetiology of the neutropaenia will be evident; in other cases marrow aspiration and biopsy will be required.

There is emerging evidence that a subset of febrile neutropaenic patients can be identified who are at low risk of life-threatening complications and in whom the duration of hospitalization and intensity of treatment may be safely reduced. Strategies that involve outpatient treatment of low-risk patients with oral antibiotics have also been evaluated. Such regimens rely on the accurate prediction of risk as well as the availability of structured programmes and resources.

Prognosis

The prognosis of the neutropaenic patient is largely dependent on the underlying aetiology of the condition. Improvements in therapy, such as rapid treatment with empiric broad-spectrum antibiotics, have significantly reduced mortality rates from this condition. Overall mortality rates for patients with febrile neutropaenia have declined from more than 20% to less than 4% in recent datasets.

CONTROVERSIES

- The prophylactic use of granulocyte colony-stimulating factors, such as filgrastim and pegfilgrastim, to reduce the incidence of febrile neutropaenia during cancer chemotherapy
- The indications for and efficacy of granulocyte transfusions in the management of febrile neutropaenia
- The development and validation of clinical decision rules to risk stratify patients with febrile neutropaenia and the use of these rules to determine suitability for oral antibiotic and/or outpatient therapy

13.3 Thrombocytopaenia

Mark Little

ESSENTIALS

1 **A low platelet count detected on automated blood count should always be confirmed by examination of the blood film prior to further investigation or treatment.**

2 **The cause of isolated thrombocytopaenia can often be determined by a careful history and physical examination in addition to assessment of the full blood count (FBC) and blood film.**

3 **Platelet transfusion is unnecessary in the management of the thrombocytopaenic patient unless the platelet count is extremely low or there is ongoing bleeding.**

4 **In the absence of other clotting disorders or abnormal platelet function, bleeding in the thrombocytopaenic patient is often amenable to local measures of haemostasis.**

Introduction

Thrombocytopaenia is defined as a reduction in the number of circulating platelets, the normal circulating platelet count being 150 to 400 × 10^9/L. It is the most common cause of abnormal bleeding. Like anaemia, thrombocytopaenia itself is not a diagnosis but rather a manifestation of another underlying disease process.

In the emergency department setting, thrombocytopaenia may present as an incidental finding on a routine blood count or may be diagnosed in the context of abnormal bleeding. In most cases the underlying aetiology can be determined by a careful history and physical examination combined with interpretation of the blood count.

Aetiology

The clinically important causes of thrombocytopaenia are outlined in Box 13.3.1. Diagnoses are classified by pathological process. It should be noted that more than one pathological process may be present. The causes can be divided into three different groups: pseudothrombocytopaenia, increased destruction of platelets and reduced production of platelets.

Pseudothrombocytopaenia

Pseudothrombocytopaenia results from an underestimation of the platelet count as measured by an automated particle counter. The most common mechanism is platelet clumping. Clumping is most often due to the anticoagulant ethylenediaminetetraacetic acid (EDTA) but may also result from autoantibodies, such as cold agglutinins. The presence of giant platelets and platelet satellitism may also yield falsely low automated platelet counts.

Any case of thrombocytopaenia found on an automated blood count should be confirmed by examination of the peripheral smear prior to further investigation or treatment.

Thrombocytopaenia due to increased platelet destruction

Immune-related thrombocytopaenia

Immune thrombocytopaenia

Immune thrombocytopaenia (ITP) is defined as an isolated thrombocytopaenia (low platelet count with an otherwise normal FBC and peripheral blood smear) in a patient with no clinically apparent associated conditions that can cause thrombocytopaenia. It is a common cause of a low platelet count and abnormal bleeding in both children and adults. ITP is thought to be caused by the development of autoantibodies to platelet membrane antigens.

In addition to the primary idiopathic form, ITP may also accompany autoimmune disorders, such as Graves disease and systemic lupus erythematosus. It is the main mechanism of the thrombocytopaenia related to HIV infection.

Drug-related thrombocytopaenia

A large number of drugs have been reported to cause immune-related thrombocytopaenia. By far the most commonly implicated are quinine,

Box 13.3.1 Causes of thrombocytopaenia

Pseudothrombocytopaenia
Platelet clumping
Collection into anticoagulant (ethylenediaminetetraacetic acid)

Abnormal distribution and dilution
- Splenic sequestration (hypersplenism)
- Splenic enlargement
- Hypothermia
- Massive blood transfusion

quinidine and heparin. Heparin is associated with a syndrome of thrombosis due to diffuse platelet activation accompanied by a consumptive thrombocytopaenia. Some platelet inhibitors, particularly ticlopidine and, less commonly, clopidogrel, are associated with severe thrombocytopaenia and other signs and symptoms of thrombotic thrombocytopaenic purpura (TTP). Recently developed monoclonal antibodies, such as infliximab (anti-tumour necrosis factor-α antibody), efalizumab (anti-CD11α antibody) and rituximab (anti-CD20 antibody) are also associated with an acute, severe, but usually self-limited thrombocytopaenia.

In most cases of drug-related thrombocytopenia, recovery occurs rapidly after withdrawal of the offending agent. The exception is patients with gold sensitivity, who may remain thrombocytopaenic for months due to the slow clearance of this drug.

Post-transfusion purpura

Post-transfusion purpura is clinically distinct from thrombocytopaenia due to dilution of platelets following massive transfusion. It is an acute, severe thrombocytopaenia occurring about 1 week after blood transfusion and is associated with a high titre of platelet-specific alloantibodies. It is most commonly reported in multiparous women following their first blood transfusion. The mechanism for alloantibody formation is unclear. Spontaneous recovery occurs within weeks, although fatalities from severe haemorrhage have been reported.

Non-immune platelet destruction

Thrombotic thrombocytopaenic purpura

TTP is considered to be the adult form of the haemolytic uraemic syndrome (HUS). Essentially a thrombotic microangiopathy, the classic pentad of clinical findings is (1) fever, (2) thrombocytopaenia, (3) microangiopathic haemolytic anaemia, (4) neurological abnormalities and (5) renal involvement.

TTP can occur sporadically as an idiopathic disorder or may be associated with pregnancy, epidemics of verotoxin-producing *Escherichia coli* and *Shigella dysenteriae*, malignancy, chemotherapy, marrow transplantation and drug-dependent antibodies. Treatment with plasma exchange has dramatically influenced the outcome of TTP. Mortality has fallen from more than 90% prior to introduction of plasma exchange to less than 20% with this treatment.

Thrombocytopaenia in pregnancy

Gestational thrombocytopaenia develops during an otherwise normal pregnancy and is clinically distinct from autoimmune thrombocytopaenias such as ITP. It is thought to be due to decreased platelet survival consequent to activation of the coagulation system. Thrombocytopaenia is usually mild and there is no corresponding thrombocytopaenia in the infant. The platelet count returns to normal after delivery, although thrombocytopaenia may recur in subsequent pregnancies.

Autoimmune thrombocytopaenias, on the other hand, are often associated with more severe reductions in the platelet count. Antiplatelet antibodies are capable of crossing the placenta and may result in significant thrombocytopaenia in the foetus and newborn. This can lead to complications, such as intracranial haemorrhage, during the delivery. Treatment of the mother with autoimmune thrombocytopaenia is similar in principle to the treatment of non-pregnant cases.

In the context of pregnancy, thrombocytopaenia may also be seen as part of the HELLP (haemolysis, elevated liver enzymes, low platelets) and pre-eclampsia syndromes. The two syndromes are thought to be related. Common to both is a process of microvascular endothelial damage and intravascular platelet activation. This leads to the release of thromboxane A and serotonin, which provoke vasospasm, platelet aggregation and further endothelial damage. In both syndromes, the process is terminated by delivery.

Disseminated intravascular coagulation

Thrombocytopaenia is one manifestation of the syndrome of disseminated intravascular coagulation (DIC). DIC is an acquired syndrome of diffuse intravascular coagulation up to the level of fibrin formation, accompanied by secondary fibrinolysis or inhibited fibrinolysis. It occurs in the course of severe systemic diseases or may be provoked by toxins, such as snake venoms.

Thrombocytopaenia due to impaired platelet production

Congenital disorders of impaired platelet production usually present in childhood and are not discussed here.

Of the acquired disorders of impaired platelet production, the most commonly seen in the emergency setting is the incidental finding of reduced platelet count in patients suffering viral illnesses. Causative viruses include Epstein-Barr virus, rubella and dengue fever. Thrombocytopaenia in these cases is reversible and requires no specific therapy other than monitoring of the platelet count to ensure normalization.

Disorders of bone marrow dysfunction, such as malignant infiltration and bone marrow suppression, cause thrombocytopaenia accompanied by reductions in numbers of other blood components. Examination of the FBC and blood film usually distinguishes these from other causes of isolated thrombocytopaenia. Further investigation is best referred to a haematologist.

Massive blood transfusion and thrombocytopenia

Massive blood transfusion is defined as the transfusion of a volume equivalent to the patient's normal blood volume within a 24-hour period. Thrombocytopaenia results from dilution of the patient's remaining platelets and, where whole blood is used, decreased survival of platelets in stored blood. It is possibly the most important factor contributing to the haemostatic abnormality seen in massively transfused patients. Platelet transfusion should be reserved for cases where the platelet count falls below 50×10^9/L.

Hypersplenism

Hypersplenism refers to the thrombocytopaenia due to pooling in patients with splenic enlargement. It is the primary cause of thrombocytopaenia in hepatic cirrhosis, portal venous hypertension and congestive splenomegaly. In these cases, thrombocytopaenia is rarely severe and not usually of clinical importance.

Transient thrombocytopaenia has been described in patients suffering severe hypothermia and is due to splenic sequestration. Platelet counts usually return to normal within days of rewarming.

Clinical features

There are distinct differences in the patterns of abnormal bleeding associated with disorders of platelet deficiency and disorders of impaired coagulation.

Spontaneous bleeding related to thrombocytopaenia typically manifests as cutaneous petechiae and/or purpura, most commonly in dependent areas such as the legs and buttocks. Other spontaneous manifestations include multiple small retinal haemorrhages, epistaxis and gingival/gastrointestinal bleeding. Bleeding following trauma or surgery in thrombocytopaenic patients is often immediate and may respond to local methods of haemostasis. In distinction to this, the bleeding associated with coagulation disorders is most commonly in the form of large haematomas or haemarthroses that occur spontaneously or develop hours to days following trauma.

In addition to the haemorrhagic manifestations of platelet insufficiency, patients with thrombocytopaenia may present with the clinical features of the underlying causative disorder. Splenic enlargement may be present in cases where thrombocytopaenia is due to hypersplenism, but it is not a feature of immune-related thrombocytopaenia.

The level of platelets associated with clinically significant abnormal bleeding is not precisely defined. It varies depending on the platelets' functional integrity and with the presence or absence of other risk factors, such as coagulation disorder, trauma, and surgery. There is evidence that platelet counts above 5×10^9/L are sufficient to prevent bleeding when the platelets are functionally normal and there are no other risk factors. Severe haemorrhage is uncommon at platelet counts above 20×10^9/L; in the setting of surgery, the risk of abnormal haemorrhage is reduced at counts above 50×10^9/L.

Clinical investigation

The FBC and examination of the blood film are diagnostic of thrombocytopaenia. *Isolated thrombocytopaenia* refers to a low platelet count in the presence of an otherwise normal FBC and blood film. In these cases, FBC combined with a careful clinical history and examination is often sufficient to lead to a final diagnosis. Co-existent anaemia and/or leucopaenia suggest bone marrow dysfunction as the primary aetiological process.

Other useful investigations may include coagulation studies and D-dimer (DIC, pre-eclampsia), electrolytes, urea and creatinine (TTP), liver function tests (HELLP and liver disease) and thyroid function tests (autoimmune thyroid disorders). Platelet antibody titres are indicated in the workup of pregnancy- related thrombocytopaenia, and bone marrow aspirate may be indicated in the investigation of thrombocytopaenia due to bone marrow dysfunction. However, neither of these tests is useful in the emergency department setting.

Treatment

Treatment is aimed at modulating the immune response and reducing the rate of platelet destruction and is indicated in all patients who have counts less than 20×10^9/L as well as those with counts less than 50×10^9/L accompanied by significant mucous membrane bleeding. First-phase treatment includes parenteral glucocorticoids (e.g. prednisolone 1 mg/kg/day for 4–6 weeks in tapered doses) and/or intravenous IgG. Splenectomy is usually reserved for patients who do not respond to medical therapy and have ongoing bleeding symptoms. There are a number of studies demonstrating benefit using of rituximab, a humanized monoclonal antibody against the CD20 antigen on B lymphocytes.

Bleeding in the face of a low platelet count may be responsive to local methods of haemostasis if the remaining platelets are functionally normal and there is no other disorder of coagulation.

The threshold for prophylactic transfusion in these patients is controversial.

Platelet transfusions may cause temporary increases in platelet count and may be used in cases of life-threatening haemorrhage but are otherwise not usually indicated.

Platelet transfusion is rarely indicated in immune-related thrombocytopaenias, as the transfused platelets are rapidly destroyed. Transfusion of platelets may aggravate TTP. In DIC, platelet transfusion has not been proven to be effective but may be indicated in bleeding patients. In cases of massive blood transfusion, platelets are not routinely indicated unless there is ongoing bleeding and the platelet count is below 50×10^9/L.

Raising the platelet count to 20 to 50×10^9/L is sufficient to prevent serious bleeding. In patients undergoing surgery or other invasive procedures, counts up to 60 to 100×10^9/L may be required. A useful rule of thumb is that in a 70-kg adult, transfusion of one unit of platelets will increase the platelet count by 11×10^9/L.

At present, platelet preparations for transfusion are stored in liquid at 22°C. Problems include the continued risk of febrile non-haemolytic reactions, transmission of infectious agents and graft-versus-host disease. Alternatives to conventional liquid storage include frozen storage, cold liquid storage, photochemical treatment and lyophilized platelets. None of these methods is currently widely available. Several platelet substitutes (fibrinogen-coated albumin microcapsules and liposome-based haemostatic agents) have been developed but remain untested in the clinical setting.

Disposition

Disposition will depend on the presence and extent of abnormal bleeding, the degree of thrombocytopaenia and the underlying aetiology. In general, patients who present with abnormal bleeding and a low platelet count should be admitted for further evaluation and treatment. In the absence of bleeding, patients who have isolated thrombocytopaenia with counts above 20×10^9/L may be investigated on an outpatient basis.

CONTROVERSIES

- The platelet count at which prophylactic platelet transfusion is indicated
- The development and clinical testing of alternative methods of platelet preparation and platelet substitutes
- Whether splenectomy is still the second-line therapy for adults with chronic ITP

13.4 Haemophilia

Sean Arendse

ESSENTIALS

1 Haemophilia is a disorder that should be managed by the emergency physician in consultation with the nearest haemophilia centre.

2 Patients should carry their treatment regimen cards with them. If they do not, they should be encouraged to do so.

Introduction

Haemophilia is a group of congenital disorders of blood coagulation that arise as a result of a deficiency of clotting factor proteins, which are essential to the normal intrinsic coagulation pathway. The classic form, haemophilia A, is attributable to deficiency of factor VIII, whereas haemophilia B (also known as Christmas disease) is attributable to deficiency of factor IX. Both these diseases have a classic X-linked pattern of inheritance and thus affect males, although female carriers may also have mild deficiency of the appropriate coagulation factor.

Haemophilia A is the commoner disease (80%), with an incidence of 1 in 8000 to 10,000 live male births, compared with an incidence of 1 in 25,000 to 30,000 for haemophilia B (20%).

Pathophysiology

The normal clotting system is activated in the presence of vascular injury to produce (1) vascular spasm, (2) platelet plug formation and (3) coagulation—factor activation and the production of fibrin. Normal coagulation of blood is dependent on the generation of adequate thrombin via the clotting cascade. Deficiency of factor VIII or IX reduces the amplification of the clotting cascade, thus causing haemophilia. The severity of the bleeding disorder is inversely related to the level of functional factor present and is categorized into mild, moderate and severe disease, as follows:

- Mild disease (6%–30% of normal factor level)—manifests with persistent bleeding after surgery, dental extractions and trauma. Spontaneous bleeds do not occur in this group of patients.
- Moderate disease (1%–5% of normal factor level)—manifests with bleeding into joints and muscles after minor trauma and excessive bleeding after surgery and dental extractions.
- Severe disease (<1% of normal factor level)—manifests with spontaneous joint and muscle bleeding and excessive bleeding following minor trauma, surgery or dental extractions.

Clinical features

Haemophilia A and B are clinically indistinguishable, and symptoms vary according to the severity of the inherited disorder. Mild disease may not present until adulthood, whereas moderate to severe disease usually presents in infancy or early childhood.

Bleeding in haemophilia tends to occur spontaneously or following minor trauma; it is typically delayed and persistent. This is because, although initial platelet 'plugging' function is normal, the subsequent coagulation 'cascade' response is abnormal. This delay is usually hours and occasionally days. Once bleeding occurs, it may persist for days or even weeks. Patients who are severely affected may present with bleeding episodes on a weekly basis.

The most common manifestations of haemophilia are as follows:

- Bleeding into joints (knees, elbows, ankles, shoulders, hips, wrists—in descending order of frequency)
- Bleeding into soft tissues and muscles (the iliopsoas muscle around the hip, calf, forearm, upper arm, Achilles tendon, buttocks)
- Bleeding in the mouth from a cut, bitten tongue or loss of a tooth
- Haematuria
- Superficial bruising
- Haemarthroses—bleeding from a synovial membrane appendicular structure with inflammation of the synovium, leading to degenerative arthritis, joint destruction and loss of joint mobility and function
- Bleeding into tissue planes—tense flexor haematomas in limbs, potentially causing compartment syndromes; haemorrhage into muscles, possibly leading to atrophy and contracture
- Bleeding into the neck (may cause airway compromise)
- Central nervous system bleeding
- Retroperitoneal bleeding

Patients may also present with a complication of therapy. Most haemophiliac patients treated before 1985 have been exposed to pathogenic viruses, of which the most important are hepatitis C, hepatitis B and HIV. Of those who received plasma prior to the mid-1980s, 90% are hepatitis B–positive, 85% to 100% are hepatitis C–positive and 60% to 90% are HIV-positive.

Clinical investigations

Investigations are tailored to the individual presentation. A full blood count, blood film and coagulation profiles are useful in the evaluation of first presentations or major bleed but unlikely to be helpful in patients with an established diagnosis. It is important to note that in an acute presentation, investigations and awaiting their results should not delay treatment with factor. The most important role for us in the emergency department (ED) is to administer factor as soon as is possible; blood results are not used to guide our use of factor in this group of patients. Generally we administer factor if we have any suspicion of a bleeding, regardless of how small we may think that bleed is.

Plain radiography of affected joints and computed tomography (CT) scanning of the head, chest, abdomen and pelvis may be essential to establish the presence or absence of bleeding complications.

The prothrombin time measures primarily factors II, VII, V and X; thus patients with either haemophilia A or B have a normal prothrombin time and a normal thrombin clotting time. The partial thromboplastin time measures activation of all factors other than factor VIII and is prolonged in haemophilia (although it can be normal if factor activity exceeds 30%). Specific factor assays are required to distinguish between haemophilias A and B.

Treatment

Treatment of haemophilia has evolved dramatically in the past 40 years with the discovery in the 1960s that coagulation factor VIII was concentrated in cryoprecipitate. More recently, highly purified concentrates of factor VIII and factor IX have been developed.

Box 13.4.1 RICES

- R = rest (in position of comfort)
- I = ice (cold pack to reduce bleeding and pain)
- C = gentle compression bandage
- E = elevation
- S = splint (severe/recurrent bleeds)

Products currently available for the treatment of haemophilia include the following:

- Recombinate (recombinant factor VIII)
- BeneFix (recombinant factor IX)
- Biostate (plasma-derived factor VIII, which includes von Willebrand factor [vWF])
- Monofix (plasma-derived factor IX)
- DDAVP (desmopressin)

Treatment of acute bleeding episodes primarily involves administration of factor replacement therapy. Complications of bleeding may require specific intervention. Adjunctive therapies include pain relief, rest and immobilization. Specific treatment is influenced by

- the type of haemophilia.
- the severity of haemophilia.
- the severity of the bleed.

Haemophilia patients presenting with suspected bleeds should be triaged to be seen within 30 minutes and receive prompt assessment by a senior doctor. For muscle and joint bleeds RICES (Box 13.4.1) should be initiated on arrival in order to limit bleeding and reduce pain, as should adequate analgesics.

Options for adequate analgesia include

- paracetamol
- inhaled nitrous oxide
- tramadol
- intravenous morphine
- possibly also patient-controlled analgesia (PCA)/opioid infusion
- **Avoid non-steroidal anti-inflammatory drugs (NSAIDs) and intramuscular (IM) injections**

In the context of pain relief, aspirin (or other platelet-modifying drugs) should be avoided and NSAIDs used with caution. IM injections should never be administered. In major bleeds, there may be a requirement for red cell transfusion. Developing limb compartment syndromes may require surgical decompression, and intracranial bleeds may require neurosurgical intervention. In all of these cases, factor replacement must commence as quickly as possible. Management of complex presentations requires a multidisciplinary approach and early consultation with the relevant state haemophilia centre, especially if the presentation is a major bleed or the patient has inhibitors.

Intravenous cannulation is best performed by a skilled practitioner to help ensure vein preservation. Invasive procedures, such as arterial puncture and lumbar puncture, must be performed only after the replacement of clotting factor.

Some patients with factor VIII levels higher than 10% may be successfully treated with 1-amino-8-D-arginine vasopressin (desmopressin, DDAVP), which acts by releasing vWF stored in the lining of the blood vessels. vWF is a protein that transports factor VIII in the bloodstream and, as such, plays an important role in blood clotting. Desmopressin appears to mobilize available factor VIII stores and may raise factor VIII activity by a factor of three. If the patient has previously had a documented good response to desmopressin, this can be used as first-line therapy for minor bleeding, such as haemarthroses.

Desmopressin can be administered intravenously, subcutaneously or by nasal spray. The intravenous dose is 0.3 µg/kg in 100 mL saline over no less than 45 minutes. A response should be evident within the first hour. More rapid administration can be associated with blood pressure changes. Side effects, including facial flushing and headache, are usually well tolerated. Tachyphylaxis tends to develop after three or four doses. The antidiuretic properties of desmopressin (which can last up to 24 hours after a dose) can produce fluid retention and hyponatraemia (leading to seizures), and the serum sodium levels should be measured before further doses are given. Desmopressin is useful in treating mild and very rarely moderate haemophilia A. It is not of value in severe haemophilia A or with any type of haemophilia B. In serious bleeds or major surgery, desmopressin alone will not control bleeding. In such a case, most patients should also receive factor VIII concentrate, recombinant factor VIII replacement and recombinant factor IX replacement.

Most haemophiliac patients are usually well known to their state haemophilia centres, which often have specialized treatment protocols for difficult or complex patients. Patients should have their treatment regimen cards with them. If not they should be encouraged to do so.

One unit of factor VIII concentrate provides the amount of factor VIII activity in 1 mL of normal plasma. Given that a 70-kg adult has a plasma volume of 3500 mL, we can expect that an infusion of 3500 units of factor VIII will produce 100% factor VIII activity in a haemophiliac individual with negligible activity prior to treatment. The half-life of factor VIII is approximately 12 hours. Accordingly, a further dose of 1750 units in 12 hours' time will again restore 100% activity.

It is not always necessary to provide 100% factor VIII activity in order to ensure haemostasis: levels of 30% to 50% may be sufficient in the context of haemarthrosis or dental extraction. Larger infusions should be reserved for life-threatening situations.

Treatment of bleeding

MINOR/MODERATE BLEED – Including, haemathrosis, minor trauma, epistaxis and suturing:

- Factor VIII (Advate®, Xyntha®)
- 30 IU/kg for the 1st dose, then 20 IU/kg at 12/12 and 24/24 post 1st dose
- DDAVP (Desmopressin)
- 0.3 microgram/kg in 100ml sodium chloride 0.9% over 45 mins
- Factor IX (BeneFIX)
- 60 IU/kg 1st dose, then 30 IU/kg at 24/24.
- Some injuries will require ongoing Factor treatment.

MAJOR BLEED – Intra cerebral, GIT, hip, throat, major muscle, e.g. Psoas or limb muscle bleeds with risk of compartment syndrome and fractures:

- Factor VIII (Advate, Xyntha)
- 45 IU/kg stat. Commence continuous Factor VIII infusion within 4 hours to maintain factor level >70%. Continuous infusion is initiated by HTH.
- Factor IX (BeneFIX)
- 90 IU/kg. Commence continuous Factor IX infusion within 4 hours to maintain factor level > 70%. Continuous infusion is initiated by HTH.

If Blood Bank unable to prepare infusion overnight, seek advice from haematology registrar rebolus regime

Many patients can administer factor VIII concentrate at home 'on demand'. Indeed, the availability of factor VIII and the ease of administration have revolutionized the care of haemophiliac patients in the community. However, the following are indications for hospital admission:

- Suspected intracranial haemorrhage
- A large bleed
- Ongoing bleed
- Suspected bleeding into the head, neck or throat
- Need for ongoing therapy, especially infusions
- Suspected compartment syndrome (especially of forearm and calf)
- Bleeding into hip or inguinal area, suspected iliopsoas haemorrhage
- Undiagnosed abdominal pain
- Persistent haematuria
- Ongoing analgesia requirements
- Inadequate social circumstances

Antifibrinolytic agents, such as tranexamic acid (Cyclokapron) and aminocaproic acid (Amicar), have been used as adjunctive therapy in episodes of gastrointestinal and mucosal bleeding—for example, following dental extraction. Fibrin tissue adhesives containing fibrinogen, thrombin and factor XIII have also been successfully placed in tooth sockets and similar surgical sites.

Tranexamic acid and aminocaproic acid are useful in treating both haemophilia A and B. These drugs help to hold a clot in place once it has formed. They act by stopping the activity of

plasmin, which dissolves blood clots. They do not actually help to form a clot, which means that they cannot be used instead of desmopressin or factor VIII or IX concentrate but can be used to hold a clot in place on mucous membranes, including in the oral cavity, nasal cavity, intestinal and uterine walls. Tranexamic acid and aminocaproic acid are associated with minor side effects including nausea, lethargy, vertigo, diarrhoea and abdominal pain.

Oral/dental bleeds

First-line therapy should be topical tranexamic acid mouthwash (5%). Patients hold 10 mL of the solution in the mouth near the site of bleeding (without gargling) for 2 minutes repeated five times a day for a week.

Haematuria

Factor replacement and antifibrinolytic therapy is not usually recommended in these cases due to the risk of clot retention and renal tract obstruction.

Head injury

Haemophiliac patients with even apparently minor head trauma need hospital assessment and CT head scanning. Beware of subtle signs of a developing subdural haematoma. If an intracranial bleed is suspected, replacement therapy should be initiated prior to radiological investigation.

Compartment syndrome

Compartment syndromes are relatively common in patients with hereditary and acquired bleeding disorders. As compartment syndrome is a clinical diagnosis, measuring compartment pressure is generally not needed to make the diagnosis.

Four of the classic signs of compartment syndrome—pallor, pulselessness, paraesthesia and paralysis—are all (very) late signs.

Pain is the earliest sign and has the following characteristics:

- Pain out of proportion to the expected
- Associated with a hard/tense compartment on clinical examination
- Severe pain on gentle passive stretch of that compartment (e.g. plantarflexion of ankle/toes, thus stretching the anterior compartment)
- Unremitting/increasing pain with increasing requirement of pain medications

The treatment for this condition is urgent fasciotomy.

Patients who present to the ED with bleeding disorders and suspected compartment syndrome should have the usual management for these conditions plus immediate referral to the orthopaedic unit and haematology unit.

Surgical decision making and indications for fasciotomy are the same as for patients without bleeding disorders and factor replacement dosage and frequency for these patients is the same as for any major surgery.

Antibodies to Factor VIII

Some patients develop antibodies to factor VIII, known as 'inhibitors'. Treatment has to be modified according to the titre of inhibitor present (measured by the Bethesda inhibitor assay). Patients are classified as high responders if their baseline inhibitor titre exceeds 10 Bethesda units (BU) or if the titre rises above 10 BU on exposure to factor VIII. Different management strategies are employed according to the severity of the bleed. These include increasing the dose of factor VIII or alternative therapies, such as activated prothrombin complex, porcine factor VIII or recombinant factor VIIa.

Most patients who develop inhibitors do so early in life and are known to have severe hereditary haemophilia, but inhibitors can also arise in previously normal individuals to produce an acquired haemophilia. The incidence of this phenomenon is from 0.2 to 1 per 1 million per year. Patients tend to be elderly and some have autoimmune disease, but there is also an association with pregnancy as well as with some drugs, notably penicillin. Patients haemorrhage into muscle and soft tissues and may present with haematemesis or with unusual postoperative bleeding. In the laboratory, the patient's blood shows a prolonged activated partial prothrombin time (APPT) that is not corrected by 'mixing'—that is, by the addition of normal plasma. Factor VIII levels are low. Management is directed towards control of the bleeding episode, replacement therapy and the prevention of further reactions using a variety of immunosuppressive remedies.

Disposition

- Patients with 'minor' bleeds and no other complicating issues may be discharged after treatment in the ED, but management should ideally be discussed first with the treating haemophilia unit and early review arranged.
- Patients with 'moderate' bleeds may need admission, preferably at the state treatment centre. These cases must be discussed with the treating unit before discharge from the ED.
- All patients with 'major' bleeds *must* be admitted and management discussed on an urgent basis with the treating haemophilia unit prior to transferring care.

von Willebrand disease

Factor VIII has an intimate association with vWF. This is an adhesive glycoprotein, secreted by endothelium and megakaryocytes, which is required for the normal instigation of platelet plug formation and for stabilization and transport of factor VIII within the circulation. Thus von Willebrand disease (vWD) is a result of dysfunction, reduction or a complete lack of the vWF and is often associated with low factor VIII activity. It is the most common inherited bleeding disorder, affecting 0.1% to 1% of the population and males and females equally.

Three types of vWD are recognized:

- Type I (common): reduced levels of vWF—clinically associated with mild bleeding
- Type II (uncommon): abnormally functioning vWF—clinically associated with a variable bleeding pattern
- Type III (rare): a near absence of vWF—clinical presentation is similar to that of moderate to severe haemophilia

Common symptoms of vWD include the following:

- Frequent nose bleeds
- Easy bruising
- Bleeding from gums following tooth extractions
- Menorrhagia
- Gastrointestinal bleeding

Treatment

If the patient has previously had a documented good response to DDAVP, this can be used as first-line treatment in type I vWD. It is occasionally also effective in type II vWD but never in type III vWD. The dose is the same as used in haemophilia (0.3 μg/kg). Antifibrinolytic agents, such as tranexamic acid, are often helpful for mucosal bleeding, epistaxis and menorrhagia. 'Biostate' (plasma-derived factor VIII, includes vWF) may be required in type I vWD if bleeding is severe or unresponsive to DDAVP; it can also be used to treat bleeding in patients with type II and type III vWD.

13.5 Blood and blood products

Sean Arendse • Biswadev Mitra

ESSENTIALS

1 **The decision to transfuse packed red cells should ultimately be based on the knowledge that the patient's oxygen carrying capacity has dropped to an unacceptably low level.**

2 **The administration of blood products carries substantial risk. The emergency physician should always ensure that potential benefits outweigh potential risks and communicate these risks and benefits in order to obtain informed consent where possible.**

3 **Rigorous risk management of administrative and clinical processes minimizes the risk of serious adverse reaction from the transfusion of blood products.**

Introduction

Blood is living tissue composed of blood cells suspended in plasma; it transports nutrients and oxygen and facilitates temperature control. An average 70-kg male has a blood volume of about 5 L. The cellular elements comprise red blood cells, white blood cells and platelets and make up about 45% of the volume of whole blood. Plasma, which is 92% water, makes up the remaining 55%.

Early attempts at blood transfusion were thwarted by adverse reactions. In 1900, Karl Landsteiner demonstrated the ABO blood group system and explained many of the observed severe incompatibility reactions (Table 13.5.1). He won the Nobel Prize for medicine in 1930 and went on to discover the rhesus factor in 1940. The next major advance in transfusion medicine occurred with the development of long-term anticoagulants, such as sodium citrate, which allowed extended preservation of blood. The development of refrigeration procedures enabled the storage of anticoagulated blood. The addition of a citrate-glucose solution extended the viability of collected blood to several days. The ability to preserve blood for longer than a few hours paved the way for the establishment of the first blood bank in a Leningrad hospital in 1932.

Table 13.5.1 The ABO group system

ABO blood group	*Antigens on red cells*	*Antibody in serum*
O	None	Anti-A, anti-B
A	A	Anti-B
B	B	Anti-A
AB	A, B	None

Transfusion of blood and blood products is now routine and vital to the practice of emergency medicine. As with any prescribed treatment, these products are associated with potential hazards as well as advantages. The hazards are more likely to be encountered with blood products used during emergencies. The blood products available in most Australian emergency departments (EDs) are packed red blood cells, platelets, fresh frozen plasma (FFP), cryoprecipitate, activated factor VII, prothrombin complex concentrates, and other factor concentrates.

In the Australian urban hospital setting, 50% of packed red cells are used for the treatment of anaemia, 22% pre- or perioperatively and 13% for abnormal, excessive or continued bleeding. Medical oncology uses 78% of all platelets. Approximately 41% of all FFP is used to correct coagulopathy associated with surgery, 27% to correct coagulopathy in bleeding, 16% to reverse haemostatic disorders in patients having massive blood transfusion, 11.5% for reversal of warfarin effect and the remaining 4.5% for a number of miscellaneous conditions, including liver disease and disseminated intravascular coagulation (DIC).

In the ED setting, blood products are most often administered to patients with acute rather than chronic blood loss. In trauma centres, severely injured patients are the major consumers of blood products; in non-trauma centres, patients with gastrointestinal haemorrhage account for the majority of transfusions. In these settings of acute blood loss, transfusion may be required rapidly and in large quantities. However, as short-stay units are developed, non–time critical transfusions of blood products for other medical indications are increasingly the responsibility of ED staff.

Packed red blood cells

Packed red blood cells are produced from whole blood collections by removing most of the plasma by centrifugation and then resuspending the red cells in citrate-based anticoagulant/preservative solution to prolong storage time. Each unit of packed cells contains approximately 200 mL of red cells. Transfusion of one unit can be expected to raise the haematocrit by 3% and the haemoglobin by 10 g/L provided that there is no ongoing blood loss.

Packed red cells are the blood product most commonly prescribed in the ED, the usual indication being the replacement of acute blood loss. Transfusion of packed red cells is indicated where the patient's oxygen-carrying capacity is so impaired that control of bleeding alone, if indeed it can be readily achieved, is regarded as insufficient to prevent tissue hypoxia. In patients with primary haematological conditions, failure of erythropoiesis or a haemolysis, the indication for transfusion is usually the same as for haemorrhage: a severe reduction in oxygen-carrying capacity. In patients with associated complex multi-system failure, such as DIC or septic shock, red cell transfusion may be lifesaving by improving the oxygen debt in tissues (Box 13.5.1).

The indication for transfusion in haemorrhagic shock has been traditionally defined as persistent haemodynamic instability despite a small volume fluid challenge. However, two further patient factors must be considered. First is the concept of hypotensive resuscitation, which states that prior to definitive cessation of bleeding, relative hypotension may stabilize clots and reduce

Box 13.5.1 Potential indications for red cell transfusion

Haemorrhage
Dilutional anaemia following severe burns
Iron deficiency anaemia
Megaloblastic anaemia
Anaemia of chronic disorders
Chronic renal failure
Failure of erythropoiesis
Sickle cell disease
Septic shock
Disseminated intravascular coagulopathy

further bleeding. Clinician must therefore alter their thresholds of haemodynamic instability. Patient factors must be borne in mind, including the cardiovascular co-morbidities and the presence of head injuries. Second, both high-volume crystalloid and blood transfusion have been associated with adverse outcomes. This suggests that both should be limited rather than focusing resuscitation efforts on the management of coagulopathy and early surgical management of haemorrhage.

Transfusion is not indicated when alternative haematinic therapy is deemed safe and appropriate. A moderately anaemic patient who is asymptomatic and not bleeding, with some reserve oxygen-carrying capacity, does not require blood transfusion. A haemoglobin of 7 g/dL is sometimes taken as the failsafe point in the decision regarding whether to transfuse, although of course the patient's unique circumstances must be taken into account: in other words, treat the patient, not the number. It should be also considered that, in an acutely bleeding patient, the initial haemoglobin result, measured at a time of volume contraction, may be an inaccurate representation of circulating oxygen-carrying capacity. The National Health and Medical Research Council together with the Australasian Society of Blood Transfusion have published transfusion guidelines for red blood cells and other products (Table 13.5.2).

Prior to any blood product transfusion, informed consent should be sought, obtained and documented except in emergent cases, where the delays may result in substantial adverse effects. The following sections discuss the risks of red cell transfusion.

Table 13.5.2 Guidelines for transfusion of blood components

Indications	*Considerations*
Red blood cells	
Hb	
<70 g/L	Lower thresholds may be acceptable in patients without symptoms and/or where specific therapy is available.
70–100 g/L	Likely to be appropriate during surgery associated with major blood loss or if there are signs or symptoms of impaired oxygen transport.
>80 g/L	May be appropriate to control anaemia-related symptoms in a patient on a chronic transfusion regimen or during marrow suppressive therapy.
>100 g/L	Not likely to be appropriate unless there are specific indications.
Platelets	
Bone marrow failure	At a platelet count of $<10 \times 10^9$/L in the absence of risk factors and $<20 \times 10^9$ in the presence of risk factors (e.g. fever, antibiotics, evidence of systemic haemostatic failure).
Surgery/invasive procedure	To maintain platelet count at $>50 \times 10^9$/L. For surgical procedures with high risk of bleeding (e.g. ocular or neurosurgery), it may be appropriate to maintain at 100×10^9/L.
Platelet function disorders	May be appropriate in inherited or acquired disorders, depending on clinical features and setting. In this situation, platelet count is not a reliable indicator.
Bleeding	May be appropriate in any patient in whom thrombocytopaenia is considered a major contributory factor.
Massive haemorrhage/ transfusion	Use should be confined to patients with thrombocytopaenia and/or functional abnormalities who have significant bleeding from this cause. May be appropriate when the platelet count is $<50 \times 10^9$/L ($<100 \times 10^9$/L in the presence of diffuse microvascular bleeding).
Fresh frozen plasma	
Single factor deficiencies Warfarin effect	Use specific factors if available. Use in the presence of life-threatening bleeding. Use in addition to vitamin K–dependent concentrates.
Acute DIC	Indicated where there is bleeding and abnormal coagulation; not indicated for chronic DIC.
TTP	Accepted treatment.
Coagulation inhibitor deficiencies	May be appropriate in patients undergoing high-risk procedures.
Following massive transfusion or cardiac bypass	Use specific factors if available May be appropriate in the presence of bleeding and abnormal coagulation.
Liver disease	May be appropriate in the presence of bleeding and abnormal coagulation
Cryoprecipitate	
Fibrinogen deficiency	May be appropriate where there is clinical bleeding, an invasive procedure, trauma or DIC.

DIC, Disseminated intravascular coagulation; *TTP*, thrombocytopaenia purpura.
(Modified from the National Health and Medical Research Council and Australasian Society Clinical Practice Guidelines on appropriate use of blood components. https://transfusion.com.au/transfusion_practice/patient_blood_management_guidelines.)

Effect of storage on red blood cells

Although it makes intuitive sense that blood loss should be replaced by blood products, there is evidence that the immediate observed benefit is from volume replacement rather than improved oxygen carriage. Red blood cells may not be fully functional until 2 to 6 hours after transfusion, because storage affects the oxygen-carrying capacity of blood. This is probably due to decreased intracellular 2,3-diphosphoglycerate (2,3-DPG), loss of red cell viability, decreased red cell deformability, relative acidosis and potassium leakage.

Storage reduces 2,3-DPG levels, leading to a leftward shift of the oxyhaemoglobin dissociation curve and increased affinity of oxygen binding. The transfused red cell does regenerate 2,3-DPG to normal levels, but this can take 6 to 24 hours post-transfusion. With increasing age of stored red cells, levels of 2,3-DPG progressively fall, such that by 5 to 6 weeks the level is only 10% of normal. It is still uncertain whether this abnormality is physiologically important, even in critically ill patients. In addition, hypocalcaemia, cell lysis, release of free haemoglobin, changes in nitric oxide levels, alterations in pH and increases in lipids, complement and cytokines are other effects of red cell storage. These changes are accompanied by increased membrane fragility, which can compromise microcirculatory flow and lead to increased red cell–endothelial cell interaction and inflammatory cytokine release. Such changes may explain recent findings associating the age of red blood cells with adverse outcomes and may be particularly disadvantageous to critically ill patients with a higher mortality risk.

When red cells are transfused, some of the cells are removed from the circulation within a few hours, with the rest surviving normally; as the storage time increases to 42 days, more cells are removed immediately after transfusion. This loss of viability is highly dependent on the anticoagulant/preservative solution used.

Potassium gradually leaks out of stored red cells, and this raises the plasma potassium by

approximately 1 mEq/L/day. Citrate toxicity results when the citrate in the transfused blood begins to bind calcium in the patient's body, resulting in hypocalcaemia. Clinically significant hypocalcaemia does not usually occur unless the rate of transfusion exceeds 1 unit every 5 minutes or so. Citrate metabolism is primarily hepatic; therefore hepatic disease or dysfunction can cause this effect to be more pronounced.

Choice of red cell product

The choice of red cell product is determined by time and safety considerations. O-negative red cells, the universal donor group, are readily available in most major hospitals. Supplies of O-negative blood are limited, and the product should be used with care. O-negative blood is generally reserved for transfusion immediately during patient reception and the initial stages of resuscitation, with a switch to cross-matched blood as soon as it is available. It is preferable that blood be collected prior to transfusion so as to characterize the recipient's blood group serology. Premenopausal female patients should be given group O Rh-negative, Kell-negative blood in an emergency situation in order to avoid sensitization and the possibility of haemolytic disease of the newborn in subsequent pregnancies. Male patients, however, can be transfused with either Rh-positive or negative blood. The incidence of adverse reaction using this type of blood is approximately 3%. By contrast, the provision of group-specific blood requires matching a blood sample to the major (ABO) and Rh-D compatibility groups only. Group-specific blood can be available for transfusion within 35 minutes, depending on the logistic support and staffing levels within the haematology laboratory. It has an incidence of adverse reactions similar to O-negative blood. As O-negative blood is usually in short supply, it is preferable, where possible, to infuse group-specific blood. A more comprehensive cross-match where there are no atypical antibodies identified in the initial screening can take 30 minutes or more and the incidence of adverse transfusion reaction is then reduced to 0.01%.

Precautions when cross-matching and transfusing blood

Although most patients do not require transfusion in the ED, it is often appropriate to 'group and hold' or cross-match the patient while in the department. Many hospitals have written protocols detailing the anticipated requirements for a given surgical procedure. Documentation should be meticulous. It should be mandated that the person drawing the blood for cross-matching should also fill in and sign the laboratory request form. Most severe incompatibility reactions to blood transfusion result not from exposure to unusual antigens but from administrative errors. Any systematic change in documentation protocols—for example, the adoption of an electronic record—must be accompanied by obsessive risk-management strategies.

The checking of the compatibility details of blood to be transfused must be meticulous. Blood products should not be left lying around workbenches. Universal precautions must be observed by staff setting up transfusions. Rapid or large transfusions should be given via a blood warmer. Blood should be transfused intravenously through sterile giving sets containing 170-μm filters. Alternative routes (arterial, intraperitoneal or intraosseous) should be used in exceptional circumstances. Lines for transfusion should be dedicated lines; drugs and other additives should be administered at separate sites. Normal saline is compatible with all blood components.

Pulse, blood pressure and temperature are measured at regular intervals and particular attention is paid to the patient during the first 25 minutes of the transfusion. The transfusion is started slowly. The rate at which it continues depends on clinical urgency. As a general rule, the faster the anaemia has developed, the more rapidly it must be corrected. Rapid infusion techniques may be indicated in patients who appear to be exsanguinating, but an overly rapid infusion may precipitate cardiac failure in the elderly. Hypothermia may be a problem if a blood warmer is not used.

Table 13.5.3 Adverse effects of blood transfusion

Immunological transfusion reactions	*Transmission of infection*
Immediate	Bacterial
Febrile non-haemolytic reactions	*Brucella*
Acute haemolytic transfusion reactions	*Pseudomonas*
Allergic reactions and anaphylaxis	*Salmonella*
Transfusion-related acute lung injury	*Treponema pallidum*
Delayed	Parasites
Delayed haemolytic transfusion reactions	*Babesia*
Alloimmunization	*Plasmodium*
Transfusion-associated graft-versus-host disease	*Toxoplasma*
Hypothermia	*Trypanosoma*
Dilutional coagulopathy	Viruses
Volume overload	Cytomegalovirus
	Hepatitis B and delta agent
	Hepatitis A
	Hepatitis C
	Other hepatitis, 'non-A, non-B'
	HIV-1 and HIV-2
	HTLV-1 and HTLV-2
	Parvovirus

HIV, Human immunodeficiency virus; *HTLV,* human T-cell lymphotropic virus.

Adverse reactions to transfusion

The principal adverse reactions to blood transfusion are listed in Table 13.5.3. Serious adverse reactions are relatively rare (Table 13.5.4), although some are more likely to occur when blood is administered urgently.

Immunological transfusion reactions

Immunological transfusion reactions may be immediate or delayed in onset.

Immediate

Febrile non-haemolytic reactions The most common transfusion reaction is a febrile, non-haemolytic transfusion reaction (FNHTR), which is defined as an increase in temperature of 1°C or more over baseline during a transfusion. It manifests as fever and occasionally shortness of breath 1 to 6 hours after transfusion. FNHTRs are benign, but their presentation is very similar to that of an acute

Table 13.5.4 Incidence of adverse transfusion reactions (per unit packed red cells transfused)

Adverse transfusion reaction	*Incidence*	*Mortality*
Bacterial sepsis	1 in 40,000–500,000	1 in 4–8 million
Acute haemolytic reaction	1 in 12,000–38,000	1 in 600,000–1.5 million
Delayed haemolytic reaction	1 in 1,000–12,000	1 in 2.5 million
Anaphylaxis	1 in 20,000–50,000	
Transfusion-related acute lung injury	1 in 5,000–100,000	1 in 5 million
Fluid overload	1 in 100–700	
Transfusion-associated graft-versus-host disease	Rare	90% fatality

(Modified from Australian Red Cross website: https://transfusion.com.au/adverse_events_overview. Accessed February 2017.)

Table 13.5.5 ABO and rhesus compatibility between donors and recipients

Donors	*O+*	*A+*	*B+*	*AB+*	*O–*	*A–*	*B–*	*AB–*

C, Compatible.

haemolytic transfusion reaction and infection, which have a higher rate of mortality and morbidity, mandating early clinical review to exclude more serious complications.

Acute haemolytic reactions Acute haemolytic transfusion reactions (AHTRs) result from the rapid destruction of donor red cells by preformed recipient antibodies and are medical emergencies. They are usually due to ABO incompatibility and most often the result of clerical or procedural errors. ABO and Rh compatibility between donors and recipients is presented in Table 13.5.5. Some acquired alloantibodies, such as anti-Rh or anti-Jka, are occasionally implicated, but AHTRs more typically occur when a group O recipient is transfused with non–group O red cells. This may lead to DIC, shock and acute tubular necrosis, precipitating acute renal failure. These reactions usually manifest with fever and rigors, lumbar pain, crushing chest pain, tachycardia, hypotension and haemoglobinaemia, with subsequent haemoglobinuria. The symptoms usually develop within the first 30 minutes of transfusion.

Anaphylactoid transfusion reactions Anaphylactoid reactions usually begin within 1 to 45 minutes of the start of transfusion of blood products, but less severe reactions can be delayed up to 2 to 3 hours. Generally a shorter time between commencement of the transfusion and onset of symptoms is associated with a more severe reaction. These reactions are manifested by the rapid onset of shock, hypotension, angio-oedema and respiratory distress. They are almost always due to the presence of class-specific immunoglobulin (Ig) G, anti-IgA antibodies in patients who are IgA-deficient. Selective IgA deficiency is not uncommon, occurring in about 1 in 300 to 500 people. The incidence of anaphylactic transfusion reactions can be reduced by the use of washed products (e.g. washed red cells) and by premedicating the patient with antipyretics and antihistamines.

Treatment of an anaphylactoid transfusion reaction consists of immediate cessation of transfusion and standard treatment of anaphylaxis, including oxygen fluids and adrenaline (see Chapter 2.8).

Transfusion-related acute lung injury Transfusion-related acute lung injury (TRALI) is a syndrome characterized by acute respiratory distress following transfusion. All plasma-containing blood products have been implicated including rare reports involving intravenous immunoglobulin (IVIG) and cryoprecipitate. It is a rare complication of allogeneic blood transfusion, but the incidence has not been well established due to difficulty in defining the syndrome and variable reporting mechanisms worldwide. Symptoms of TRALI typically develop during the transfusion or within 6 hours. Patients present with a rapid onset of dyspnoea and tachypnoea. There may be associated fever, cyanosis and hypotension. Clinical exam reveals respiratory distress, and pulmonary crackles may be present with no signs of congestive heart failure or volume overload. Chest x-ray (CXR) shows evidence of bilateral pulmonary oedema unassociated with heart failure (non-cardiogenic pulmonary oedema) with bilateral patchy infiltrates, which may rapidly progress to complete 'white out' indistinguishable from acute respiratory distress syndrome. The central venous pressure is normal, which helps to distinguish the condition from transfusion-associated circulatory overload. Treatment is supportive. There is no role for diuretics or corticosteroids. The blood bank must be notified, as reporting of TRALI allows better understanding of the true incidence of this reaction in addition to its clinical course and associated mortality.

Delayed

Delayed haemolytic transfusion reaction These reactions occur in patients who have developed antibodies from previous transfusions or pregnancy; however, at the time of pretransfusion testing, the antibody in question is too weak to be detected by standard procedures. Subsequent transfusion with red cells having the corresponding antigen results in an anamnestic antibody response and the haemolysis of transfused red cells. These delayed reactions are seen generally within 2 to 10 days after transfusion. Haemolysis is usually extravascular, gradual and less severe than with acute reactions, but rapid haemolysis can occur. A falling haematocrit, slight fever, mild increase in serum unconjugated bilirubin and spherocytosis on the blood smear may be noted.

Treatment of a delayed haemolytic transfusion reaction is usually not required unless anaemia is severe enough to require treatment. However, future transfusions containing the implicated red-cell antigen must be avoided. Alternatives to transfusion should be explored whenever possible.

Red-cell alloimmunization When antibodies are formed against foreign antigens from an individual's own species, the process is termed *alloimmunization* and the antibodies

are called *alloantibodies* (as opposed to forming autoantibodies to an individual's own antigens or forming xenoantibodies to antigens from a foreign species). Transfused (non–leucocyte depleted) red cells and platelets contain leucocytes to which antibodies can be made. This may cause patients to become resistant to subsequent platelet transfusions. Approximately 50% of patients undergoing multiple blood transfusions become alloimmunized and are refractory to further platelet transfusions. Refractory patients require platelets matched to their specific platelet/human leucocyte antigen (HLA) type. Patients receiving leucocyte-reduced blood products are at a much lower risk for refractoriness to platelet transfusion than are recipients of non–leucocyte reduced blood products. Although debate exists about its merits, for selected high-risk patients with transfusion-dependent diseases (e.g. sickle cell anaemia, thalassaemia), some transfusion services phenotype patients and provide phenotypically matched donor red blood cells (RBCs), even to those patients without alloantibodies (i.e. to prevent the formation of antibodies). There is general agreement that this is useful for Rh and Kell blood-group antigens in these groups of patients, but debate exists about its merits for more extensive phenotyping.

Transfusion-associated graft-versus-host disease Transfusion-associated graft-versus-host disease (TA-GVHD) results from the transfusion of viable T lymphocytes that proliferate and damage the recipient's tissue, particularly skin, gastrointestinal tract, liver, spleen and bone marrow. This is a rare and almost always fatal complication of transfusion. Clinical manifestations typically develop 10 to 14 days following transfusion and consist of fever, erythematous skin rash, pancytopaenia, diarrhoea and abnormal liver function. High-risk patients for this complication include bone marrow transplant recipients, patients receiving granulocyte transfusions, transfusions from a biologically related donor (directed donation), the fetus (intrauterine transfusion), exchange transfusion, patients with Hodgkin lymphoma and those with congenital cellular immune deficiency.

The investigation begins with the confirmation of the presence of GVHD. This is a pathological diagnosis requiring a skin or intestinal biopsy. Currently, the only method of preventing TA-GVHD is to γ-irradiate cellular components at risk of causing TA-GVHD or destined for at-risk recipients. Current techniques to leuco-reduce cellular blood components are not adequate to prevent TA-GVHD.

Transmission of infection

In Australia, blood is tested for ABO and Rh (D) blood groups, red-cell antibodies and the following infections:

- human immunodeficiency virus 1 and 2
- hepatitis B and C
- human T-cell lymphotropic virus I and II
- syphilis

In terms of viral safety, Australia has one of the safest blood supplies in the world (Table 13.5.6).

Hypothermia

Red blood cells are stored at 4°C. Rapid infusion of large volumes of stored blood can contribute to hypothermia. Blood warmers should be used during massive blood transfusion. In addition, other intravenous fluids should be warmed and other measures instituted to maintain the patient's body temperature (see Chapter 24.2).

Dilutional coagulopathies

Clinically significant depletion of coagulation proteins and platelets is a complication of massive transfusion, secondary to dilution and the consumptive coagulopathy of trauma. Stored red cells are deficient in platelets and clotting factors and the transfusion of large amounts can complicate bleeding when it is not accompanied by the assessment and correction of coagulation disturbances. Coagulation parameters including the prothrombin time (PT), activated partial thromboplastin time (APTT), platelet count and fibrinogen level should be monitored and corrected if deficiencies occur in the presence of abnormal bleeding. In actively bleeding patients, however, these parameters may not provide an accurate estimate of clot strength and results are often delayed by 30 to 60 minutes. Thromboelastography has the advantage of providing real-time assessment of clot strength and should be utilized where available.

Volume overload

This complication occurs when an excessive volume of fluid is administered. Pulmonary oedema is a particular risk in the elderly, infants and patients with chronic severe anaemia where the red-cell mass is decreased but the blood volume is normal. Abdominal compartment syndrome may result in bowel ischaemia and should be watched for.

Management of transfusion reactions

The first action to be taken in the management of any suspected transfusion reaction is to stop the transfusion immediately and assess the patient. The bag containing the transfused cells, along with all attached labels, should not be discarded so as to allow repeat typing and cross-matching of this unit by the blood bank. Management then proceeds as follows:

- Maintain the patient's airway, blood pressure and heart rate.
- From a different limb to the one transfused, obtain a sample for a direct antiglobulin test, plasma-free haemoglobin and repeat blood group and cross-match. Save a urine sample for haemoglobin testing.
- Culture the patient's blood.
- Commence broad-spectrum antibiotics to cover gram positive skin organisms and gram negative organisms.

The laboratory that tested and issued the blood should be alerted immediately and a search for any clerical error instituted. Every hospital has a protocol for evaluating transfusion reactions, which should be rigorously followed. The haematology unit should notify the local blood bank, which has a haematologist on call at all times and is responsible for the recall of any other implicated components from the same donor in the case of suspected infection or TRALI. If there is any suggestion (e.g. clerical mistake, hypotension, pink plasma or urine) that an AHTR is possible, oxygen should be applied to the patient and fluid resuscitation with saline to maintain a urine output of 2 to 3 mL/kg/h in an attempt to prevent acute oliguric renal failure. A vasopressor such as adrenaline may be required. If massive intravascular haemolysis has already occurred, hyperkalaemia is likely and cardiac monitoring and acute haemodialysis may be required.

Table 13.5.6 Risks of transfusion-transmitted infection (per unit tested blood transfused)

Infection	*Residual risk*
CMV	1 in 127,000
Hepatitis B	Approximately 1 in 660,000
Syphilis	Considerably <1 in a million
Hepatitis C	<1 in 10 million
HIV	<1 in 10 million
HTLV I and II	<1 in 10 million
Variant CJD	Possible and cannot be excluded

CJD, Creutzfeldt-Jakob disease; *CMV*, cytomegalovirus; *HIV*, human immunodeficiency virus; *HTLV*, human T-cell lymphotropic virus. (Modified from Australian Red Cross. http://www.transfusion.com.au/adverse_events. Accessed February 2017.)

Platelets

Platelets are among the main cellular components of blood and are central to haemostasis. Platelet products commonly available for transfusion are obtained by apheresis from a single donor or from donated blood using buff-coat or platelet-rich

plasma techniques. Modifications to reduce the risk of viral transmission and prevent GVHD include leucocyte reduction, irradiation, plasma depletion and the use of platelet additive solutions.

Platelets are transfused to prevent or treat haemorrhage in patients with thrombocytopaenia or defects in platelet function. Specific indications for platelet transfusion are shown in Table 13.5.2. The use of platelets is not generally considered appropriate in the treatment of immune-mediated platelet destruction, thrombotic thrombocytopaenic purpura, haemolytic uraemic syndrome or drug-induced or cardiac bypass thrombocytopaenia without haemorrhage.

In general one platelet unit will raise the platelet count about 5 to 10 × 10^9/L in an average adult. Depending on the method of manufacture, the volume of each unit of platelets varies from 100 to 160 mL, with a storage life of about 5 days at 20 to 24°C.

Compatibility testing is not necessary in routine platelet transfusion, although platelet components should preferably be compatible with the recipient's ABO and Rh type. ABO-incompatible platelets may be used if ABO-compatible platelets are not available. The usual dose in an adult patient is 4 units, which is equivalent to 1 unit of apheresis platelets or 1 unit of pooled platelets.

Fresh frozen plasma

FFP is prepared from anticoagulated blood by separating the plasma from the blood cells through centrifugation of whole blood or apheresis. It is stored frozen until used. It contains all coagulation factors including small amounts of factor V and approximately 200 units of factor VIII. FFP can be stored at below 25°C for up to 12 months. Indications for use of FFP are shown in Table 13.5.2.

The appropriate dose depends on the clinical indication, patient size and results of laboratory tests. A general guide is 10 to 15 mL/kg per dose, but in some situations dosages greater than this may be required (e.g. dilutional coagulopathy in the context of massive transfusion). On average 1 mL of FFP/kg patient weight will raise most coagulation factors by 1%; therefore a dose of 10 to 15 mL/kg would be expected to increase levels by 10% to 15%. Compatibility testing is not required; however, ABO-compatible plasma should be used wherever possible. Group AB plasma can be used for all patients in an emergency.

Cryoprecipitate

Cryoprecipitate is prepared by thawing FFP to between 1°C and 6°C and recovering the precipitable protein fraction. It contains most of the factor VIII, fibrinogen, factor XIII, von Willebrand factor and fibronectin from the FFP. It may be stored for up to 12 months at 25°C or below. Once thawed, it must be used immediately or stored at 2°C to 6°C for up to 24 hours. Cryoprecipitate is indicated in fibrinogen deficiency with clinical bleeding or prior to an invasive procedure and in DIC. Cryoprecipitate is transfused to keep fibrinogen levels above 1.0 g/L in the acutely bleeding patient. Compatibility tests before transfusion are not necessary. It is preferable to use an ABO group compatible with the recipient's red cells; however, ABO-incompatible blood can be used with caution. Up to 4 units/10 kg body weight may be required to raise the fibrinogen concentration by approximately 0.5 g/L in the absence of continued haemorrhage.

The use of cryoprecipitate is not generally considered appropriate in the treatment of haemophilia, von Willebrand disease or deficiencies of factor XIII or fibronectin unless alternative therapies are unavailable.

Refusal of blood and blood product transfusion

Patients with certain religious beliefs may refuse blood and blood product transfusion (e.g. Jehovah's witnesses). Healthy volunteers can tolerate Hb levels of 50 g/L without evidence of end-organ hypoxia. However, it is estimated that the median Hb concentration associated with mortality is about 25 g/L. The patient's wishes must be rigorously protected and blood products avoided. Several strategies may be used to manage the anaemia. Sedation should be instituted to minimize metabolic demand. A ventilation cycle of 2 hours of 90% FiO_2, followed by 2 hours of 90% SpO_2 and then 20 hours of 95% SpO_2 may be employed to maximize oxygen delivery while minimizing shunt from absorption atelectasis and to promote erythropoiesis. Recombinant erythropoietin (36,000 units/day), folic acid (5 mg qd), vitamin B12 (1 mg qd) and iron infusions are options to maximize haematopoiesis. In female patients, where applicable, menses should be inhibited with progesterone. Blood testing should be rationalized and performed using paediatric-size samples.

A few case studies on the use of synthetic haemoglobin have been published. HBOC-201 is the commonest product used and is a modified lactated Ringer solution containing 130 g/L of polymerized Hb of bovine origin. It is compatible with all blood types, stable for 3 years when stored at 2°C to 30°C and stable for 2 years when stored at 40°C. When fully saturated, HBOC-201 has the same oxygen-carrying capacity as whole blood, with the same Hb concentration. The partial pressure of oxygen at which HBOC-201 is 50% saturated (40 mm Hg) is higher than that for cellular Hb (27 mm Hg), which facilitates oxygen delivery to tissues. The half-life of HBOC-201 is approximately 20 hours. Polymerization of the Hb reduces its glomerular diffusion and nephrotoxicity. The use of synthetic haemoglobin remains experimental at this stage and further trials are needed to determine the efficacy and safety profile of such products.

CONTROVERSIES

- Although the changes observed during red-cell storage affect overall red-cell viability and function, there are no randomized controlled studies examining the effect of storage duration on recipient morbidity and mortality.
- Acute coagulopathy has been observed in up to 40% of cases of massive acute haemorrhage associated with tissue injury and shock. Best practice guidelines for the use of platelets, cryoprecipitate or FFP in the shocked patient are determined primarily from observational studies and expert opinion. Prospective randomized controlled trials are required to determine optimal management strategies in the acutely haemorrhaging and coagulopathic patient.
- The potential for prions, thought to be the infective molecules in the variant form of Creutzfeldt-Jakob disease, to be transmitted by blood transfusion has become a subject of intense scrutiny in transfusion medicine.

SECTION 14

RHEUMATOLOGY AND MUSCULOSKELETAL EMERGENCIES

Edited by *Conor Deasy*

14.1 Rheumatological emergencies

Michelle C. Papandony • Michael J. Gingold • Flavia M. Cicuttini

ESSENTIALS

1 **Rheumatological emergencies relate to the disease, extra-articular manifestations of the disease or toxicity from treatment.**

2 **Infection must be considered and promptly treated in patients on antirheumatic and immunosuppressive medication, including those on biological therapies.**

Introduction

Rheumatological conditions are common and encompass (1) inflammatory diseases, such as rheumatoid arthritis (RA); (2) connective tissue diseases, such as systemic lupus erythematosus (SLE); and (3) mechanical/musculoskeletal conditions. Life-threatening emergencies are rare and relate to either the underlying condition or a complication from its treatment. The most common rheumatological emergency seen in the emergency department (ED) is acute monoarthritis (see Chapter 14.2). This chapter discusses the important general emergencies associated with rheumatological conditions.

Many of these conditions are autoimmune; thus immunosuppression is usually central to their management, making infection a frequent complication. More targeted, so-called biological therapies, which inhibit proinflammatory cytokines including tumour necrosis factor-α (TNF-α) and interleukin-6 (IL-6), as well as B- and T-cell activity, have been developed. They carry their own set of potential complications, again including infection.

RHEUMATOID ARTHRITIS

RA affects 1% to 2% of the population across most ethnic subgroups and is two to three times more common in females than males. RA is a systemic inflammatory condition of unknown aetiology characterized by widespread synovitis, resulting in joint erosions and destruction. It may also produce extra-articular manifestations, including vasculitis and visceral involvement.

Management typically involves symptom relief with non-steroidal anti-inflammatory drugs (NSAIDs) and/or corticosteroids and early initiation of conventional disease-modifying antirheumatic drugs (DMARDs). These include methotrexate, leflunomide, sulfasalazine and hydroxychloroquine, and if these agents fail to control disease progression, biological agents are commenced. The latter act by inhibiting TNF-α (infliximab, etanercept, adalimumab, golimumab, certolizumab pegol), IL-6 (tocilizumab), T-cell co-stimulation (abatacept), janus kinase 1 (JAK1) (tofacitinib) or by depleting B cells (rituximab). With increasing medical evidence suggesting that early and aggressive use of biological and non-biological DMARDS prevents joint destruction and disease progression, such agents are used increasingly more frequently in rheumatology patients.

ARTICULAR MANIFESTATIONS OF RHEUMATOID ARTHRITIS

Acute monoarthritis

Although a patient with established RA may present with an acutely painful, hot, swollen joint that is due to the underlying condition, consideration of septic arthritis is important. Patients with RA are two to three times more susceptible to septic arthritis than matched controls.[1] The risk is approximately twofold higher again in RA patients on TNF-α inhibitors compared with RA patients on conventional DMARDs.[2] Septic arthritis must be considered in a patient with RA who has acute monoarthritis out of keeping with their disease activity.

Cervical spine involvement

Cervical spine involvement in RA is common with a prevalence of up to 80%.[3] Cervical spine involvement may manifest as atlanto-axial subluxation (most commonly anterior movement on the axis) or subluxation of lower cervical vertebrae.[4] Either of these can result in cervical myelopathy.

Cervical spine subluxation is often asymptomatic.[3] The most common symptom is neck pain that may radiate towards the occiput. Other

Box 14.1.1 Symptoms and signs of cervical myelopathy

Symptoms
Pain
Weakness
Peripheral paraesthesia
Gait disturbance
Sphincter dysfunction
Changes in consciousness
Respiratory dysfunction
Lhermitte phenomenon

Signs
Spasticity
Weakness
Hyperreflexia of deep tendon reflexes
Extensor plantar response
Gait ataxia
Respiratory irregularity

suggestive symptoms include sensory loss in hands or feet, paraesthesia or weakness in the distribution of cervical nerve roots, and slowly progressive spastic quadriparesis.

Important 'red flags' suggesting cervical myelopathy are listed in Box 14.1.1.

Imaging

Plain x-rays of the cervical spine (lateral view) may demonstrate an increase in separation between the odontoid and arch of C1. Prior to taking flexion–extension films, perform plain 'peg' x-rays to exclude odontoid fracture or severe atlanto-axial subluxation. Computed tomography (CT) can provide additional useful information; magnetic resonance imaging (MRI) is more sensitive for myelopathy.

Management

An important consideration with RA of the cervical spine in the ED is avoiding excessive manipulation when endotracheal intubation is required.

Patients with subluxation and signs of spinal cord compression represent a neurosurgical emergency.

EXTRA-ARTICULAR MANIFESTATIONS OF RHEUMATOID ARTHRITIS

Rheumatoid vasculitis

Vasculitis in RA can occur in both small- and medium-sized vessels. Patients typically have long-standing, aggressive joint disease. This presentation, although important, is becoming less frequent due to the development of effective RA treatment.

Clinical features

Rheumatoid vasculitis presentations are varied and non-specific. Patients frequently have constitutional symptoms and fatigue. One of the most common manifestation of medium vessel RA vasculitis includes deep skin ulcers on the lower limbs,[5] digital ischaemia and gangrene. Palpable purpura is a manifestation of small vessel RA vasculitis. Mononeuritis multiplex is another frequent presentation resulting from vasculitic infarction of the vasa nervorum, which typically has an acute onset.

Medium vessel rheumatoid vasculitis may also cause organ infarction and necrosis and mimics polyarteritis nodosa (PAN) with vasculitis of the renal arteries and, less commonly, the mesenteric circulation. Pericarditis may accompany rheumatoid vasculitis, but coronary vasculitis is rare. Ocular manifestations include episcleritis and peripheral ulcerative keratitis. Central nervous system (CNS) involvement is rare.

Investigations and diagnosis

Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are elevated in rheumatoid vasculitis. Rheumatoid factor titre is typically elevated in rheumatoid vasculitis, although this is a non-specific finding. Rheumatoid vasculitis in the absence of rheumatoid factor is rare. Anti-citrullinated protein antibody (anti-CCP) may be positive in rheumatoid vasculitis, but once again, is a non-specific finding. Check a full blood count, urea and electrolytes, and a midstream urine specimen for active urinary sediment, including abnormal red cells or casts, proteinuria, as well as infection. In the work-up of vasculitis, it is also important to exclude infections that may mimic vasculitis. These include hepatitis B and C, human immunodeficiency virus (HIV) and syphilis, as well as a basic infection screen.

Further investigations are directed at the relevant organ system involved usually after specialist consultation:

- skin biopsy for cutaneous involvement
- nerve conduction studies/electromyography (EMG) for mononeuritis multiplex
- sural nerve biopsy for mononeuritis multiplex
- renal biopsy for deranged renal function or active urinary sediment

Angiography findings are non-specific and not always diagnostic.

Management

Systemic rheumatoid vasculitis has a poor prognosis without immune-suppressive therapy. Urgent rheumatology consultation is required, as treatment usually consists of high-dose corticosteroids as well as cyclophosphamide or, a DMARD, often necessitating hospital admission.

Other extra-articular manifestations of rheumatoid arthritis

Pulmonary disease

Pulmonary manifestations include pleural-based disease, such as pleurisy or pleural effusions, or parenchymal disease, such as interstitial lung disease (the most common manifestation), organizing pneumonia and rheumatoid nodules. Caplan's syndrome occurs when RA is associated with pneumoconiosis. Important differential diagnoses include infection due to immune suppression, treatment-related toxicity, such as methotrexate-induced pneumonitis, and other medical co-morbidities, including chronic obstructive pulmonary disease.

Parenchymal disease documented on chest x-ray or high-resolution CT requires specialist treatment.

Cardiac disease

Pericarditis occurs in 30% of RA patients based on electrocardiogram and/or echocardiography, but less than 10% have clinical features. It generally presents when there is active joint and other extra-articular disease, and management consists of NSAIDs or prednisolone.

Myocarditis is a rare manifestation of RA. It may be granulomatous and, depending on its location, can produce valvular (especially mitral) incompetence or conduction defects. It is investigated with troponin, cardiac MRI and/or cardiac biopsy.

Sjögren syndrome

Sjögren syndrome may present in a primary form as a systemic disease, but can also occur secondary to RA and other connective tissue disorders. The classic symptoms are dry gritty eyes, dry mouth or both. Treatment is usually symptomatic in patients with no other features.

Felty syndrome

Felty syndrome is characterized by seropositive RA, splenomegaly and neutropaenia. There may be other cytopaenias, as well as leg ulcers, and infection is a risk.

Renal disease

Renal involvement with RA is rare and includes vasculitis and glomerulonephritis. Secondary amyloidosis can occur in patients with long-standing active disease. However, many medications used in RA are nephrotoxic, in particular NSAIDs and cyclosporin. Medication induced nephrotoxicity should not cause an active sediment.

Neurological disease

Vasculitis may produce mononeuritis multiplex, otherwise CNS involvement is rare.

Ischaemic heart disease in rheumatoid arthritis and other connective tissue diseases

Patients with RA and other connective tissue diseases, such as SLE, have an increased risk of ischaemic heart disease (IHD), independent of traditional cardiac risk factors.[6] The higher incidence of IHD appears related to disease factors, such as widespread inflammation, extra-articular disease[7] and medications, such as NSAIDs (including selective COX-2 inhibitors) and corticosteroids, may also play a role.

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is a multisystem, autoimmune disease. It is the prototype disease of immune complex deposition resulting in tissue damage across a wide range of organ systems and one of the most common autoimmune conditions in women of childbearing age.

Clinical features

Common presenting features of SLE include general constitutional symptoms, such as fatigue, malaise and weight loss. There are a variety of skin manifestations in SLE that are lupus-specific (malar rash, discoid lupus, subacute cutaneous lupus erythematosus) or non-specific (panniculitis, alopecia, oral ulceration). Arthralgia or an acute non-erosive arthritis are the most common presenting symptoms of SLE.

Another common manifestation is serositis, causing pleurisy, pericarditis or peritonitis. SLE also causes renal and CNS disease (discussed later) and, rarely, can involve the lung (pneumonitis, pulmonary hypertension) and heart (myocarditis, endocarditis). Myositis may also occur.

Investigations

FBC often reveals cytopaenias, in particular leukopenia and thrombocytopenia, which are a common feature of active SLE. Biochemistry may indicate renal impairment. ESR and CRP may be raised in acute disease.

Clotting abnormalities can include a prolonged activated partial thromboplastin time due to the lupus anticoagulant (LA), one of the antiphospholipid antibodies, along with anticardiolipin antibody (aCL) and others. Paradoxically, there is an associated predisposition to both venous and arterial blood clots when these are positive.

Serological abnormalities

The antinuclear antibody (ANA) is present in 95% of patients with SLE, but may also occur in other connective tissue and inflammatory diseases, as well as at low levels in healthy adults. The anti-Smith (Sm) and anti-dsDNA (double-stranded DNA) antibodies are more specific but less sensitive for SLE. Anti-Sm is obtained as part of a panel of antibody tests for extractable nuclear antigens (anti-ENA). Serological abnormalities also include decreased levels of complement components C3 and C4, in particular when SLE is active.

Other tests are directed towards the organ system involved, for example, midstream urine specimen looking for proteinuria or glomerular haematuria (>70% dysmorphic red blood cells or red-cell casts) and chest x-ray in the patient with serositis.

Assessing systemic lupus erythematosus disease activity

Useful symptoms of disease activity include mouth ulcers, alopecia and constitutional symptoms, as well as organ-specific symptoms, such as arthralgia or pleuritic chest pain.

Investigations used to assess disease activity include complement levels (low C3 and C4 in active SLE), CRP and ESR (elevated), as well as anti-dsDNA titre (rising in active SLE). These are not diagnostic and many people with quiescent SLE may also have hypocomplementaemia or elevated anti-dsDNA titres.

A midstream urine for urinary sediment or proteinuria is an essential marker of renal involvement.

Management

Management of SLE is directed by the organ system involved and includes topical therapies for cutaneous lupus and NSAIDs for arthralgias and mild serositis. Most patients with SLE will be on an antimalarial, such as hydroxychloroquine, helpful for skin and musculoskeletal manifestations as well as organ involvement. Many patients will also be on corticosteroids. Those with major organ involvement will also be taking other immunosuppressants, such as methotrexate, cyclophosphamide or azathioprine. Mycophenolate mofetil is frequently now used as an alternative to cyclophosphamide for lupus nephritis. Rituximab may also be used for severe SLE, including cerebral and gastrointestinal manifestations.

Lupus nephritis

Early diagnosis of lupus nephritis is essential to prompt management and prevent progression of renal damage. Patients may be asymptomatic or present with nocturia, haematuria or proteinuria. Other presentations include hypertension, rapidly progressive glomerulonephritis and the nephrotic syndrome.

Urinalysis is the most useful investigation in detecting lupus nephritis, and proteinuria is the most common abnormality detected. The fresh urine specimen should be sent for phase contrast microscopy in order to detect the presence of dysmorphic erythrocytes (>70% indicates glomerular disease) or cellular casts.

Urinalysis can expedite the investigation and further management of this potentially organ-threatening condition. Prompt referral for consideration of renal biopsy and further management is indicated.

Neuropsychiatric systemic lupus erythematosus

There is a myriad of neuropsychiatric manifestations of neuropsychiatric SLE. Neurological presentations include:

- stroke (due to vasculitis, emboli, atherosclerosis or antiphospholipid antibodies)
- seizure
- migraine
- aseptic meningitis

Psychiatric presentations include:

- headache and mood disturbance, including anxiety
- cognitive dysfunction 'lupus fog'
- dementia
- psychosis

These presentations are non-specific and have a broad differential diagnosis; the role of the ED is first to exclude the more common non-SLE presentations, such as meningitis or intracranial haemorrhage.

Investigations

Brain imaging studies are needed as well as tests for SLE activity (discussed previously).

Cerebrospinal fluid (CSF) analysis is essential to exclude infection, but may be normal in SLE. Changes, such as elevated protein, low glucose or even a positive ANA, are non-specific and do not always reflect active SLE.

GIANT CELL (TEMPORAL) ARTERITIS AND OTHER VASCULITIDES

Giant cell (temporal) arteritis

Giant cell arteritis (GCA) is the most frequent vasculitis and most commonly affects Caucasians. It is a large and medium vessel vasculitis of unknown aetiology, which predominantly

affects the cranial branches of arteries originating from the aortic arch and, commonly though not exclusively, the temporal artery.

Polymyalgia rheumatica (PMR) is a syndrome of inflammatory pain and stiffness in the neck, shoulder and pelvic girdles, worse in the morning or after exercise, that occurs alone or frequently in association with GCA.

Epidemiology

GCA and PMR rarely occur before the age of 50 years,[8] with a mean age at diagnosis of approximately 72 years. The incidence of GCA is roughly 1 in 500 of people over the age of 50 years, although the incidence and prevalence of PMR are less well studied.

Clinical features

The most common symptom of GCA is new headache, usually localizing to the temporal region, although it can be more diffuse. The area is often tender and associated with scalp sensitivity, worsened by brushing the hair. Most patients complain of constitutional symptoms, such as malaise, fatigue, anorexia and weight loss. Jaw claudication (pain after a period of chewing) is the most specific symptom for GCA, although not sensitive, as it is present in only 34%.[8] On examination, the temporal arteries may be thickened, 'ropey' and tender with a reduced or absent pulse.

The most serious complication of GCA is anterior ischaemic optic neuropathy (AION) resulting in sudden painless loss of vision which can be bilateral, particularly if untreated. Less commonly, other branches of the aorta may be involved resulting in hemiparesis, arm claudication, aortic dissection or myocardial infarction.

Polymyalgia rheumatica

The relationship between onset of symptoms of GCA and PMR is highly variable. PMR symptoms may occur before, after or with GCA symptoms. Five percent to 15% of patients with PMR will have a diagnosis of GCA, and about 50% of patients with GCA have symptoms of PMR.

Differential diagnosis of giant cell arteritis and polymyalgia rheumatica

GCA can mimic any of the other vasculitides. Non-arteritic AION can also mimic GCA. The differential diagnosis of PMR includes late-onset RA, polmyositis and other myopathies, fibromyalgia, malignancy and hypothyroidism.

Investigations

The classic non-specific laboratory finding in GCA and/or PMR is a markedly elevated ESR (often >100 mm/h). CRP is also usually elevated, and a full blood count often shows a mild normochromic normocytic anaemia.

A temporal artery biopsy confirms the diagnosis of GCA and is particularly useful when the diagnosis is doubtful or the presentation atypical. However, as GCA can cause isolated foci of arteritis ('skip lesions'), there is a false negative rate of 10% to 30%. As such, a negative biopsy does not exclude GCA.

Criteria for diagnosis

The ACR classification criteria for GCA are helpful in differentiating GCA from other forms of vasculitis.[9] They include:

- age at onset >50 years
- a new headache
- temporal artery tenderness or decreased pulsation
- ESR >50

An abnormal artery biopsy showing vasculitis with mononuclear infiltrate or granulomatous inflammation with multinucleated giant cells also confirms the diagnosis.

Although various classification criteria for PMR have been published, having excluded other diagnoses (except GCA), the presence of all three of the following clinical and laboratory criteria defines the diagnosis[9]:

- age ≥50 at onset of symptoms
- bilateral aching and stiffness for over 30 minutes after waking, in two of the following three areas; neck and torso, shoulder girdle, hips/pelvic girdle
- ESR >40

In practice, rapid response to prednisolone ≤20 mg daily is also used as an additional criterion with 50% to 70% improvement within 72 hours.

Management

Corticosteroids are essential for GCA and should not be withheld to perform a biopsy. The initial dose for GCA is unclear, but prednisone 40 to 60 mg daily (or 1 mg/kg/day) is generally recommended for uncomplicated disease. A new onset of clinical manifestations suggesting an unstable blood supply to the eyes or the CNS (e.g. arteritic optic neuropathy) is typically managed with intravenous pulse therapy (e.g. 1000 mg of methylprednisolone per day for 3 consecutive days).[10]

The dose of prednisone for PMR uncomplicated by GCA is lower at 10 to 20 mg/day; 15 mg is generally agreed as an appropriate standard dose.[10] Most GCA patients do not require hospital admission, provided a temporal artery biopsy can be organized within 2 weeks. After 2 weeks, corticosteroid treatment may affect diagnostic yield of a temporal artery biopsy. Patients with visual loss at diagnosis require urgent treatment often with pulsed parenteral corticosteroids and inpatient admission. Patients with GCA should also be commenced on aspirin.

Approach to the other systemic vasculitides

The systemic vasculitides are a group of disorders characterized by an inflammatory infiltrate in the walls of blood vessels resulting in damage to the vessel wall. Table 14.1.1 classifies vasculitic syndromes according to vessel size. (There is much overlap.)

Clinical features

An underlying vasculitis should be considered in patients who present with one or more of the following:

- unexplained systemic illness—fatigue, fevers, night sweats, malaise
- unexplained ischaemia of an organ or limb
- rash with palpable purpura
- chronic inflammatory sinusitis and chronic discharge or bleeding from the nose or ears
- mononeuritis multiplex
- pulmonary infiltrates
- microscopic haematuria, especially if dysmorphic glomerular erythrocytes
- any of the above in the setting of atopy and peripheral blood eosinophilia

Investigations and diagnosis

Baseline investigations include Full Blood Count (FBC), Urea and Electrolytes (U&E), Liver Function Tests (LFTs) and clotting studies, as well as CRP and ESR. A panel of autoimmune serological tests is carried out, including ANA, ENA, dsDNA rheumatoid factor, anticyclic citrullinated peptides (anti-CCP), complement levels (C_3, C_4), antineutrophil cytoplasmic antibodies (ANCA) and cryoglobulins. PAN is associated with hepatitis B and cryoglobulinaemic vasculitis with hepatitis C infection. HIV infection should also be excluded.

Collection of a midstream urine specimen to look for glomerular haematuria and proteinuria is mandatory when vasculitis is suspected. Imaging is indicated, such as chest x-ray, CT scan of the chest or sinuses or other areas, depending

Table 14.1.1 Classification of systemic vasculitis according to vessel size

Vessel size	*Vasculitis*
Large	Takayasu arteritis Temporal (giant cell) arteritis
Medium	Polyarteritis nodosa Kawasaki disease
Small	Wegener granulomatosis (ANCA+) Microscopic polyangiitis (ANCA+) Churg–Strauss syndrome (ANCA+/−) Henoch–Schönlein purpura Cryoglobulinaemic vasculitis Leucocytoclastic cutaneous vasculitis

on the suspected organ involved. The definitive diagnosis of vasculitis requires biopsy of affected tissue or angiography.

Differential diagnosis of systemic vasculitis

Other conditions that may mimic systemic vasculitis include:

- infections, such as infective endocarditis, meningococcaemia, gonococcaemia, hepatitis B, hepatitis C, HIV and syphilis
- disorders of haemostasis and thrombosis, such as thrombotic thrombocytopaenic purpura (TTP), antiphospholipid syndrome
- malignancy, such as lymphoma, myxoma
- sarcoidosis.

Management of systemic vasculitis

Treatment is usually with high-dose corticosteroids and, depending on the condition, additional immunosuppression, such as cyclophosphamide or rituximab. Urgent specialist referral is essential.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) is an inflammatory arthritis of the axial skeleton, which can result in progressive spinal fusion. It affects <1% of the general population, and its prevalence is linked to the prevalence of HLA-B27.

The hallmark pathological feature of AS is new bone formation and spinal fusion, which makes spinal injury a particular risk. Reduced mobility and muscle atrophy lead to a higher falls risk.

Spinal fractures are up to four times more common in AS patients than in the general population, and the risk of spinal cord injury is even higher. Fractures can occur at any point in the spine and do not have the classical appearance of wedge or endplate compression. There is also a higher rate of atlanto-axial subluxation, with similar precautions required, as in those with RA. Patients with advanced fusion may also develop cauda equina syndrome in the absence of a fracture.

Fractures in AS can be missed by plain x-ray, and the onset of new spinal pain or a change in spinal pain necessitates further imaging with either CT or MRI.

Systemic sclerosis

Systemic sclerosis, or scleroderma, is a chronic connective tissue disorder. The hallmark of this disease is thickening or hardening of the skin. Scleroderma can cause serious damage to internal organs, including the lungs, heart, kidneys, oesophagus and gastrointestinal tract.

Classification

Scleroderma can be classified as localized or systemic. Localized scleroderma presents with purely dermatological manifestations, including morphea and linear scleroderma. There is no internal organ involvement associated with localized scleroderma. Systemic scleroderma can be classified into limited and diffuse. There is often overlap between the manifestations of limited and diffuse scleroderma. Some of the manifestations include:

- Skin thickening of the fingers of both hands, extending above the elbow in diffuse disease
- Sclerodactyly
- Telangiectasia
- Raynaud phenomenon
- Digital tip ulcers
- Pulmonary arterial hypertension
- Interstitial lung disease
- Scleroderma renal crisis

Investigations

Inflammatory markers (CRP and ESR) may not be elevated in scleroderma. A full blood examination may reveal microcytic anaemia, due to slow GI bleeding from telangiectasia. Biochemistry may indicate renal impairment, as a result of current or past scleroderma renal crisis. Anti Scl-70 antibodies (also called anti-topoisomerase I, which constitutes part of the ENA panel) may be positive in diffuse scleroderma. Anti-centromere antibodies may be positive in limited scleroderma. Anti-RNA polymerase III antibodies are useful for the diagnosis and risk stratification of severe manifestations, such as renal crisis and severe skin sclerosis.

Scleroderma renal crisis

Severe and life-threatening renal disease develops in approximately 10% to 15% of patients. Scleroderma renal crisis is characterized by:

- Acute onset renal failure
- Abrupt onset of moderate to marked hypertension (some patients may remain normotensive)
- A urinary sediment that is normal or has mild proteinuria

Scleroderma renal crisis requires prompt clinical identification and management. Renal biopsy does not definitively establish the diagnosis, as indistinguishable changes can occur in other conditions such as transplantation rejection and haemolytic-uraemic syndrome.

The cornerstone of treatment for scleroderma renal crisis is blood pressure control with angiotensin-converting enzyme (ACE) inhibitors. This is one of the few cases in rheumatology where corticosteroids are not used, as they may potentiate hypertension and renal crisis.

RHEUMATOLOGICAL THERAPY EMERGENCIES

Non-steroidal anti-inflammatory drugs

NSAIDs are commonly used for relief of arthralgia in both inflammatory and non-inflammatory conditions. They are of equal efficacy, although those with shorter half-lives appear to have less gastrointestinal toxicity.[11] NSAIDs should be used in the lowest possible dose for the shortest duration and combinations of NSAIDs (except aspirin) should be avoided.[11] The COX-2 selective inhibitors, such as celecoxib, have a reduced incidence of peptic ulcer disease, but a similar incidence of other adverse effects including hypertension, peripheral oedema and cardiac failure. There is an increased risk of cardiovascular deaths with prolonged courses and higher doses.

Corticosteroids

Corticosteroids are the mainstay of treatment for most inflammatory rheumatological conditions. At high doses, they provide rapid control of inflammatory disease and are often required for long-term management at low doses. Long-term use is associated with numerous adverse effects.

Although there is concern about infection among patients on DMARDs, prednisolone contributes considerably (possibly more) to the immune-suppressed patient's overall infection risk.

Immunosuppressants/disease-modifying antirheumatic drugs

This heterogeneous group of medications is used to prevent joint destruction in the inflammatory arthritides and as steroid-sparing therapy in many connective tissue diseases. They include methotrexate, leflunomide, hydroxychloroquine, sulphasalazine, ciclosporin, azathioprine and cyclophosphamide. Each drug has its own range of adverse effects, but common adverse effects include cytopaenias, rashes including Stevens–Johnson syndrome, abnormal liver function tests, GI toxicity and heightened susceptibility to infections (Table 14.1.2).

Biological disease-modifying antirheumatic drugs

The so-called biological DMARDs are a newer and expanding collection of therapies directed against molecules and cells that mediate joint destruction and help drive the inflammatory process. These therapies are being increasingly used for those who fail conventional DMARD therapy for RA. Some of the biological DMARDS

Table 14.1.2 Adverse effects of disease-modifying antirheumatic drugs

DMARD	*Adverse effects*
Methotrexate	Nausea and other GI upset, mouth ulcers, abnormal liver function (transaminases), bone marrow suppression, rash, alopecia, pneumonitis Increased bone marrow toxicity in renal impairment—withhold in acute renal failure Teratogenic
Leflunomide	Abnormal liver function (transaminases), diarrhoea, rash, alopecia, hypertension, peripheral neuropathy Teratogenic
Hydroxychloroquine	Nausea, rash, dizziness ('cinchonism'), retinal toxicity at higher doses (all uncommon)
Sulphasalazine	GI upset, uncommonly abnormal liver function and bone marrow suppression, rashes (rarely, Stevens–Johnson syndrome)
Ciclosporin	Renal impairment, hypertension, electrolyte disturbance, hyperuricaemia and gout, gingival hyperplasia, hirsutism
Cyclophosphamide	Bone marrow suppression especially neutropaenia, GI upset, bladder toxicity, including haemorrhagic cystitis (acute) and bladder cancer (chronic), opportunistic infections Teratogenic
Azathioprine	GI upset, rash, systemic symptoms, abnormal liver function, bone marrow suppression, skin cancers, infections

DMARDs, Disease-modifying antirheumatic drugs; *GI,* gastrointestinal.

are also used for treatment-resistant psoriatic arthritis and ankylosing spondylitis, as well as other non-rheumatological conditions.

Adverse effects associated with biological DMARDs include an increased risk of infections, particularly soft-tissue and joint infections, as well as reactivation of tuberculosis (in particular, with TNF inhibitor treatment) and varicella (in particular, with JAK1 inhibitor treatment). Other opportunistic infections appear more common, such as listeriosis. Patients may also develop local injection site reactions and infusion-related reactions, which can be delayed in nature. Less common adverse effects include a form of drug-induced lupus and demyelination.

Presentations of treatment-related emergencies

Infections

As treatment of rheumatological conditions is directed at immunosuppression, infections are a common and expected adverse effect of therapy. Although most of the larger studies have focused on TNF inhibitors, which have been available the longest, there is an increased risk of serious infections compared with the general RA population. This risk may be highest in the first 6 months of therapy.[12]

Patients on biological therapy who develop an infection are advised temporarily to cease their treatment and to commence antibiotics. If in doubt, they should be admitted to hospital to receive parenteral antibiotics. There is also an increased risk of reactivation of tuberculosis and infections such as *Varicella, Listeria* and *Salmonella*.[12] Rigorous tuberculosis screening prior to commencement of anti-TNF therapy should now be universal.

Special mention must be made of the biological agent tocilizumab directed against IL-6. Tocilizumab causes marked suppression of acute phase reactants, particularly CRP, and even in the presence of active infection, a patient on this medication may have a normal CRP. Thus if there is a clinical suspicion of infection, appropriate antibiotic therapy must be instituted.

Bone marrow suppression

Anaemia, leucopaenia and thrombocytopaenia all may occur in patients taking DMARDs, such as methotrexate, cyclophosphamide, sulphasalazine and azathioprine, with neutropaenic sepsis presenting a particular danger.

Cytopaenia in a patient taking methotrexate is uncommon, but those at increased risk include the elderly and those with renal impairment, related to the drug's mechanism of action as an inhibitor of dihydrofolate reductase. Management includes temporary cessation of treatment and administration of folinic acid, the active form of folic acid.

The most common adverse effect of cyclophosphamide is myelosuppression, particularly leucopaenia. The white cell nadir occurs at 2 weeks post-infusion following intravenous therapy. Patients on oral therapy may experience a gradual decrease in white cell count, which is typically less predictable than on intravenous therapy.

Bone marrow suppression may also occur as a side effect of azathioprine treatment, especially if given in combination with allopurinol, which inhibits its metabolism, thus potentiating bone marrow toxicity. Cytopaenias are also more common in patients with deficient thiopurine methyltransferase enzyme, which should be checked prior to the commencement of azathioprine. Sulphasalazine therapy is uncommonly complicated by bone marrow suppression.

Disease-modifying antirheumatic drug-related pneumonitis

Methotrexate and leflunomide may both result in lung toxicity. The most frequent is a hypersensitivity pneumonitis, but other forms of lung injury may occur. Clinical features are non-specific and include constitutional symptoms, cough and progressive dyspnoea. Subacute presentations are more common.

Imaging reveals interstitial opacities and patchy consolidation. High-resolution CT scanning typically shows a ground-glass appearance. The main differential diagnosis is of a respiratory infection which may be due to typical pathogens or opportunistic infections, such as *Pneumocystis jirovecii*.

Management is supportive, with empiric antibiotic therapy in case of infection. Corticosteroids are also used. Patients may become seriously ill and require intensive care, but mortality is still low (1%).

Leflunomide may also cause lung injury, typically in the first few months of therapy and usually when given in combination with methotrexate.

Allopurinol hypersensitivity syndrome

Minor hypersensitivity reactions to allopurinol occur in about 2% of patients and usually consist of a mild rash. Rarely, a severe hypersensitivity syndrome may present in an unwell patient with fever, rash, abnormalities of liver function, peripheral blood eosinophilia and acute renal failure due to interstitial nephritis. It is more common in those with renal impairment who do not have an appropriate dose reduction. Treatment is supportive.

14.2 Monoarthritis

Michelle C. Papandony • Michael J. Gingold • Flavia M. Cicuttini

ESSENTIALS

1 Presenting features alone, including absence of fever, do not reliably exclude a septic arthritis, especially in older people and those who are immunosuppressed.

2 Synovial aspirate in appropriate pathology transport media should be performed prior to commencing antibiotics when septic arthritis is being considered.

3 Acute monoarthritis affecting a prosthetic joint or the hip should *not* be aspirated in the emergency department. It requires urgent orthopaedic assessment.

SEPTIC ARTHRITIS

The assessment of a patient with acute monoarthritis is focused on excluding a septic arthritis. Septic arthritis can cause rapid joint destruction, morbidity and mortality.[1]

Pathogenesis and pathology

Non-gonococcal bacterial arthritis occurs when bacteria enter the synovial lining of a joint via the haematogenous route, local spread from nearby soft-tissue infections or following penetrating trauma or injury to a joint. Bacteria reach the synovium, cause swelling and destruction of articular cartilage, which may extend to subchondral bone, and produce irreversible damage within days. The commonest causative organisms are staphylococci and streptococci.

Epidemiology and risk factors

The prevalence of septic arthritis ranges between 4 and 10 per 100,000 patients per year and appears to be rising. It is also almost seven times more common in Indigenous Australians.[2]

Risk factors for septic arthritis include inflammatory arthritis (especially rheumatoid arthritis), diabetes mellitus and systemic factors, such as age greater than 80 years, as well as local factors, such as recent joint surgery, joint prosthesis and overlying skin infection. These individual risk factors increase the risk of septic arthritis by two- to threefold.[3] Skin infection overlying a prosthetic joint increases the risk of infection by 15-fold.[3] Immunosuppressants heighten susceptibility to septic arthritis. The risk of septic arthritis depends on the potency of immunosuppression that is used.

Clinical features

Septic arthritis presents with joint pain and swelling in more than 80% of cases, which may be associated with systemic symptoms, such as sweats and rigors.[3] The hip and knee joints are the most commonly involved joints.

The patient may be febrile and the affected joint is usually swollen, warm, erythematous and tender. Classically there is reduced ability to actively move the joint and marked pain on passive movement. Unfortunately, the symptoms and signs are not sensitive, and a patient with septic arthritis may present with only some of these features. Thus septic arthritis cannot be excluded with confidence on the history and examination alone, and so must be considered in any presentation of monoarthrtis.

Differential diagnosis

The differential diagnosis of acute monoarthritis is shown in Table 14.2.1. Risk factors include a history of rheumatoid arthritis, connective tissue disease, gout or other inflammatory arthritis, as well as risk factors for infection, such as immunosuppression (which patients may neglect to mention), diabetes and corticosteroids. Recent trauma or history of a bleeding diathesis or anticoagulation are also relevant. Recent sexually transmitted infections, including gonococcal infection or non-specific urethritis, or any systemic features including uveitis and/or gastrointestinal infection, may point toward a reactive arthritis.

Clinical investigations

Blood tests

Perform a full blood count (FBC), C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR). ESR and CRP are non-specific and not sensitive

Table 14.2.1 Common presentations with acute monoarthritis to an emergency department

Gout
Reactive arthritis such as post-viral
Acute exacerbation of pre-existing inflammatory arthritis
Rheumatoid arthritis
Septic arthritis

Note: Orthopaedic-related joint problems, such as trauma and/or haemarthrosis, plus osteoarthritis (OA) were not included in this series.[4]

for septic arthritis, but may help in the differential diagnosis. Blood cultures should be taken prior to antibiotic administration. Serum urate may be elevated, but can be normal in acute gout and should not be used to diagnose acute gout.

Imaging

X-ray may be normal in septic arthritis, as it takes at least 1 week for destructive changes to appear on plain x-ray. Magnetic Resonance Imaging (MRI) is helpful to determine if the pathology is in the joint or juxta-articular bone.

Joint aspiration

The single most important investigation is synovial fluid aspiration and analysis. Send the aspirate in a sterile container for Gram stain and culture, as well as for polarizing light microscopy to look for the presence of urate (strongly negative birefringent) crystals or calcium pyrophosphate crystals (weakly positive birefringent crystals). Using blood culture bottles does not appear to increase the yield of a positive culture.

Place some of the aspirate in an Ethylendiaminetetraacetic Acid (EDTA) tube for a cell count to be performed. The likelihood of septic arthritis increases from 2.9% with a synovial white cell count above 25,000/μL up to 28% with a synovial white cell count of greater than 100,000/μL. Synovial glucose and protein levels are unhelpful.

Criteria for diagnosis of septic arthritis

There is no 'gold standard' test for the diagnosis of septic arthritis. Synovial fluid Gram stain has a sensitivity of up to 50% only, while culture has a sensitivity up to 85%.[3] Combined with an appropriate clinical presentation, the presence of microorganisms in synovial fluid on Gram stain and/or a positive synovial fluid culture with high synovial white cell count are diagnostic. New molecular techniques for diagnosis of infection in synovial fluid are promising but not yet readily available (e.g. 16S rRNA polymerase chain reaction [PCR]).

Treatment

Treatment of septic arthritis requires an urgent referral to orthopaedics for surgical drainage with admission to hospital. Antibiotic use should follow local guidelines and be discussed with the orthopaedic and infectious disease units. Empirical antibiotic therapy pending microbiology results should cover against *Staphylococcus*; administer dicloxacillin or flucloxacillin 2 g IV 6 hourly or cephazolin 2 g IV 6 hourly if the patient is allergic to penicillin. The patient with suspected hip or prosthetic joint sepsis must be referred to orthopaedics urgently without attempting joint aspiration.

GOUT

Gout is an intra-articular inflammatory response to monosodium urate crystal deposition usually related to hyperuricaemia. It is more common in males than females, but is extremely rare in the premenopausal female.

Aetiology and pathogenesis

Uric acid is derived from purine metabolism. Hyperuricaemia is the strongest predictor for gout and relates to either overproduction or under excretion of uric acid. Hyperuricaemia may also cause radiolucent renal calculi.

Overproduction of uric acid is due to dietary factors or endogenous factors associated with high cell turnover, such as a haematological malignancy. Reduced excretion is related to chronic kidney disease, hypovolaemia, metabolic acidosis and medications, such as diuretics, cyclosporin, pyrazinamide and ethambutol. There is also frequently a family history of gout.

Epidemiology

The peak incidence of acute gout occurs in men between the ages of 30 and 60 years and in women between 55 and 70 years. The presentation of gout in younger patients should prompt a search for a secondary cause (including lifestyle factors). Gout is more common in Maori and Polynesian populations.

Clinical features

The classic presentation is of acute onset of a hot, swollen and painful first metatarsophalangeal joint (75% of cases) known as podagra. Other commonly affected joints include joints in the foot, the ankle, knee and small joints of the hand.

Common triggers of an acute attack are binges of alcohol or purine-rich foods, dehydration, severe illness such as sepsis, acute renal failure, trauma and surgery. Sudden cessation or the introduction (especially in an acute attack) of hypouricaemic agents, such as allopurinol or febuxostat, may also precipitate gouty arthritis, as can the introduction or a dose change of a diuretic.

Untreated, the symptoms will abate over the course of several days to 2 weeks. Occasionally, the patient may appear systemically unwell during an acute attack with malaise and systemic inflammatory response features. The patient may also be febrile, however, should not have rigors. Examination reveals a tender, warm and erythematous joint with severely restricted range of movement. Presentations of acute gout may also be polyarticular (see Chapter 14.3).

Recurrent untreated acute gout and hyperuricaemia results in chronic tophaceous gout, where the patient is no longer pain-free between attacks. Examination reveals tophus formation on the first metacarpophalangeal joint, ears, around the elbows and in the fingers with marked joint deformity.

Investigations and diagnosis

Synovial fluid aspiration

Synovial fluid aspirate to identify monosodium urate crystals is diagnostic of acute gout. The crystals may be phagocytosed (intracellular) and the synovial fluid will have a high white cell count. A delay in crystal analysis in the laboratory, as well as concurrent use of local anaesthetic with joint aspiration, may result in the crystals being dissolved and a negative aspirate. Send fluid for Gram stain and culture to rule out septic arthritis, which may coexist with gout. Podagra with a typical clinical scenario has a sensitivity of 96% and specificity of 95% for acute gout, so aspiration is not indicated.[4]

Blood tests

Hyperuricaemia on blood testing is not diagnostic of gout; although up to 5% of adults may have a raised serum uric acid at some point, only one-fifth (1% overall) will ever have an attack of gout. Conversely, in about one-third of patients with gout, the serum uric acid level is normal during an acute attack. Other blood tests, such as FBE, ESR, and CRP, are sent and may be abnormally elevated. Check renal function to identify a potential aetiology and help guide treatment, such as avoidance or reduced doses of non-steroidal anti-inflammatory drugs (NSAIDs) or colchicine.

Imaging

Plain x-ray is performed to exclude injury, but should be normal in the acute attack other than soft-tissue swelling. Punched-out periarticular erosions are seen in chronic gouty arthritis, which, when associated with calcium deposition, deforming arthritis and soft-tissue swelling, are characteristic of chronic tophaceous gout.

Management

Treat acute pain and then prevent chronic relapse with hypouricaemic drugs. Educate all patients to correct lifestyle factors where appropriate.

Acute attack

Colchicine

When NSAIDs are contraindicated, colchicine may be used. A loading dose of 1 mg of colchicine, followed by 0.5 mg 6 hours later and 0.5 mg once or twice daily 12 hours later, is recommended until the gout attack resolves.[4,5] Higher doses are no longer recommended, due to increased toxicity

with nausea, vomiting, diarrhoea and the risk of renal impairment. Colchicine doses should be lowered in patients with renal impairment and/or patients on statins; this combination may increase the risk of neuromyopathy, myopathy and rhabdomyolysis.

Non-steroidal anti-inflammatory drugs

After excluding infection, give either an NSAID, corticosteroid and/or colchicine in the absence of contraindications. Corticosteroids, such as prednisolone 30 to 35 mg daily for 3 days, then tapered over 1 to 2 weeks,[4] are used in gout refractory to NSAIDs. An alternative approach is intra-articular corticosteroid for monoarticular gout, provided sepsis has been excluded.

Recurrent attacks

Urate lowering therapy

A second attack of gout usually requires urate lowering therapy, although this is not commenced in the emergency setting, as treatment should be delayed until the acute flare has settled; commencing treatment during an acute attack may prolong and worsen the severity of the acute episode. Allopurinol, a xanthine oxidase inhibitor, prevents the production of uric acid from xanthine. It is introduced at a low dose (100 mg daily) once the acute attack has settled and gradually titrated up to 300 mg daily.[4] Typically the patient will remain on a low-dose NSAID (or prednisolone/low-dose colchicine) as prophylaxis against precipitating further acute attacks. For patients with gouty tophi, a target uric acid level of <0.36 mmol/L is recommended; continue flare prophylaxis for 3 months after the target uric acid level is achieved, then cease.

Febuxostat is a new orally administered selective xanthine oxidase inhibitor that may be used to reduce urate levels, particularly in patients with poor kidney function or intolerant of allopurinol; a Phase III trial is currently being conducted to evaluate the cardiovascular safety.

An alternative uricosuric agent to allopurinol is probenecid. However, it should be avoided in renal impairment (eGFR <30), as it is ineffective.

ACUTE PSEUDOGOUT

Acute pseudogout causes an acute monoarthritis and is one of the several potential presentations of calcium pyrophosphate dihydrate (CPPD) deposition disease. It is more common in females and patients over 65 years old.

Aetiology and pathogenesis

Calcium pyrophosphate disease is characterized by deposition of CPPD crystals in cartilage causing chondrocalcinosis. When released, there may be uptake in other synovial structures and an inflammatory response producing acute synovitis, tenosynovitis or bursitis.

Advanced age is the strongest risk factor. Other associations are a family history, metabolic diseases such as haemochromatosis, Wilson disease, hyperparathyroidism, hypophosphataemia or hypomagnesaemia and mechanical factors, such as previous injury or osteoarthritis (OA).

Clinical features

CPPD deposition disease presents in a variety of ways. The two most common are acute pseudogout and chronic pyrophosphate arthropathy, which may mimic OA. Other presentations include tenosynovitis, bursitis or as an incidental radiographic finding of chondrocalcinosis. CPPD deposition disease may also mimic rheumatoid arthritis or ankylosing spondylitis, as well as the neuropathic joint.

Acute pseudogout typically presents in older patients, and the knee is the most commonly affected joint. Other common sites include the wrist, shoulder, elbow and ankle. Occasionally, there may be an oligo-articular presentation. Presentation is with a hot, red and swollen joint. There may be systemic inflammatory response features and the patient may be febrile. Once again, the patient should not have rigors. Triggers include trauma, surgery or illness, but most cases are spontaneous.

Investigations and clinical diagnosis

Joint aspiration

Diagnosis of pseudogout depends on the demonstration of CPPD crystals in synovial fluid, which is frequently blood stained. Polarizing light microscopy demonstrates weakly positive birefringent rhomboid-shaped crystals.

Laboratory studies and imaging

Younger patients presenting with polyarticular chondrocalcinosis should be screened for an underlying metabolic cause, checking serum calcium, magnesium, phosphate, alkaline phosphatase, parathyroid hormone, thyroid function and iron studies.

Plain x-rays of the joint may reveal chondrocalcinosis seen in fibrocartilage, such as the knee menisci, triangular cartilage of the wrist and pubic symphysis. Other characteristic findings are of marked degenerative change in joints that are not usually affected by OA.

Management

Symptoms of acute pseudogout frequently improve once the joint has been aspirated. Intra-articular injection of corticosteroid is also appropriate for acute monoarthritis, once infection has been excluded. In addition, rest and splintage for 48 to 72 hours is beneficial.

Give oral analgesics and NSAIDs similar to acute gout, particularly for polyarticular pseudogout, as performing multiple joint injections is impractical and painful.

In many patients, NSAIDs are contraindicated due to comorbidities such as renal impairment and cardiovascular disease, so an intra-articular or a tapering course of oral corticosteroids is needed (1/2 mg/kg).

HAEMARTHROSIS

Haemarthrosis is bleeding into a joint which may be traumatic and related to intra-articular injury or non-traumatic related to an underlying bleeding diathesis.

Aetiology

The causes of haemarthrosis are listed in Table 14.2.2.

Clinical features

A haemarthrosis causes a painful swollen, often warm, joint with a reduced range of movement. Ask about a history of trauma and, if minimal or absent, consider a bleeding disorder, such as haemophilia or anticoagulant use. Also ask about troublesome bleeding during a previous operation or following dental instrumentation, and about a family history.

Investigations

Perform plain radiography to exclude a fracture. Consider a computed tomography scan if there is a high index of clinical suspicion for a fracture but normal plain imaging. Send a FBC and a coagulation screen if there is no history of significant trauma.

Haemarthrosis is diagnosed on aspiration of synovial fluid. An intra-articular fracture is indicated by observing fat globules floating on the surface of the blood.

Table 14.2.2 Causes of haemarthrosis

Traumatic
• Fracture
• Ligamentous (e.g. anterior cruciate or peripheral meniscal tear in the knee)
Non-traumatic
• Bleeding diathesis, e.g. haemophilia, von Willebrand disease
• Anticoagulation
• Neuropathic joint
• Acute pseudogout
• Septic arthritis
• Pigmented villonodular synovitis
• Vascular abnormalities, such arteriovenous malformation, haemangioma

Management

Management includes rest, immobilization, ice and compression as well as analgesia. Aspiration frequently provides pain relief if performed within 24 hours of onset. NSAIDs should be avoided in patients with a bleeding diathesis.

Haemophilia or other bleeding diathesis

Haemarthrosis due to haemophilia or other disorders of clotting factor deficiency requires *immediate* factor replacement therapy to a level of 40% to 50% of normal. This should be performed as soon as possible after the presentation, in consultation with a haematology specialist.

Often the patient will be able to advise on his or her normal treatment (and usually knows what factor he or she is deficient in, his or her usual basal level and how much replacement is necessary in an acute bleed).

Vitamin K and administration of fresh frozen plasma may be required in patients with elevated International Normalised Ratio (INR) related to warfarin toxicity. Obtain advice from the haematology specialist for patients that are on novel oral anticoagulants (NOACs).

SPONDYLOARTHRITIS

Monoarthritis is occasionally a presentation of a spondyloarthritis, such as reactive arthritis, psoriatic arthritis or inflammatory bowel disease-associated arthritis.

Clinical features suggesting a reactive arthritis include a recent history of infective diarrhoea, uveitis or sexually transmitted infection, such as urethritis. The patient may appear ill and be febrile with a tachycardia. The patient should be asked about a history of psoriasis or inflammatory bowel disease in the past.

Check for sites of enthesitis with inflammation at a tendon insertion points, such as the Achilles tendon or plantar fascia around the heel, or dactylitis causing 'sausage-shaped' digits.

GUIDELINE APPROACH TO THE MANAGEMENT OF ACUTE MONOARTHRITIS

The British Society for Rheumatology guidelines[6] regarding the approach to the hot swollen joint include the following:

- The hot, swollen and tender joint should be considered as septic arthritis until proven otherwise. This may occur in the absence of fever.
- Synovial fluid must be obtained and sent for appropriate investigations prior to commencement of antibiotics. In situations of high clinical suspicion, a negative Gram stain or culture does not exclude septic arthritis.
- Other investigations should include blood cultures, CRP, ESR and FBC.
- X-ray of the affected joint should be performed as a baseline.
- Septic joints require aspiration to dryness in addition to parenteral antibiotics.
- Prosthetic joints and suspected hip sepsis require an urgent orthopaedic opinion.
- The presentation of a hot and swollen first metatarso-phalangeal joint is almost always gout, and is diagnosed clinically.

14.3 Polyarthritis

Michelle C. Papandony • Shom Bhattacharjee • Flavia M. Cicuttini

ESSENTIALS

1 **Polyarthritis is a common adult rheumatological presentation with a wide differential diagnosis.**

2 **Recording articular and extra-articular involvement facilitates decision making, particularly with regards to patient admission.**

3 **Joint aspiration is paramount for both diagnosis and excluding a septic arthritis.**

4 **Early rheumatological consultation is essential to ensure appropriate and timely diagnosis and treatment for inflammatory arthritis to prevent joint damage and maintain joint function.**

5 **Early rheumatological consultation or admission is essential in the presence of extra-articular or systemic inflammatory response features.**

6 **Emergency management is with anti-inflammatory medication that may include systemic or intra-articular corticosteroids.**

Introduction

Polyarthritis is a frequent rheumatological presentation to the emergency department in adults. This chapter focuses on the initial assessment, management and most appropriate follow-up of the more common conditions encountered. These include rheumatoid arthritis (RA), seronegative spondyloarthritis including psoriatic arthritis, reactive arthritis with reference to arthritides occurring in association with enteric and urogenital infections, and infectious arthritis including viral arthritis and rheumatic fever. Management principles include establishing the diagnosis, treating the acute problem and arranging appropriate follow-up.

Box 14.3.1 Differential diagnosis of polyarthritis syndromes

Inflammatory
Rheumatoid arthritis
Inflammatory osteoarthritis
Systemic connective tissue disease, including SLE, vasculitis, Behçet disease, relapsing polychondritis
Seronegative spondyloarthropathies, commonly psoriatic arthropathy
Gout
Pseudogout (calcium pyrophosphate arthropathy)
Drug induced, including lupus syndromes
Infectious arthritis—bacterial including mycobacteria, endocarditis, protozoal, viral
Reactive or post-infectious arthritis including rheumatic fever

Non-inflammatory
Neoplastic/paraneoplastic disease, including hypertrophic pulmonary osteoarthropathy
Sarcoidosis
Endocrine disease, such as haemochromatosis, acromegaly
Haematological disease, such as haemophilia, leukaemia

SLE, Systemic lupus erythematosus.

ACUTE POLYARTHRITIS

Polyarthritis syndromes may be difficult to diagnose accurately due to the wide range of differential diagnoses, as seen in Box 14.3.1. Important principles include:

1. Exclude infection.
2. Consider relevant differential diagnosis, such as early presentation of inflammatory arthritis.
3. Document extra-articular involvement.

Clinical features and diagnosis

History

Take a focused history to include the following:

Mode of onset
- Acute (less than 6 weeks): gonococcal, viral including human immunodeficiency virus (HIV), reactive arthritis, rheumatic fever, crystal arthritis (gout or pseudogout)
- Chronic (longer than 6 weeks): RA, psoriatic arthropathy, systemic lupus erythematosus (SLE), systemic sclerosis, dermatomyositis, other autoimmune diseases, crystal arthritis (gout or pseudogout)

Distribution
- Symmetric or asymmetric
- Large or small joint involvement

Course
- Progressive, intermittent or migratory

Constitutional symptoms
- Fever, night sweats, fatigue, significant weight loss >10%

Rheumatological systems review
- Symptoms suggestive of an inflammatory arthritis: early morning stiffness, joint swelling, uveitis, scleritis, urethritis, cervicitis, chronic bowel symptoms
- Symptoms suggestive of a connective tissue disorder: Raynaud phenomenon, sclerodactyly, sicca syndrome, oral, nasal, digital or genital ulcers, rash, alopecia, and serositis with pleuritis or pericarditis
- Symptoms suggestive of vasculitis: haemoptysis, haematuria, hypertension, symptomatic peripheral neuropathy
- Many of these symptoms may overlap in rheumatological conditions.

Extra-articular organ involvement
- Cough, dyspnoea, hypertension, haematuria, symptomatic peripheral neuropathy

Other history

History of recent sore throat, febrile illness, new sexual contact, features of a sexually transmitted disease, diarrhoea, rash or uveitis, suggesting reactive arthritis

Past medical history of psoriasis, gout, rheumatic fever, inflammatory bowel disease (IBD), malignancy and juvenile polyarthritis

Family history of gout, psoriasis, IBD, uveitis or chronic back pain suggesting ankylosing spondylitis (AS) and other seronegative arthritis

Examination

Perform a detailed physical examination[1] and document:
- vital signs
- painful joints and soft-tissue swelling and their distribution
- cutaneous stigmata of underlying diseases, such as nail changes (psoriatic), rash and subcutaneous nodules, oral, genital or digital ulceration
- features of organ involvement, such as a pleural or pericardial rub, cardiac murmur or pulmonary crackles
- lumbosacral spine and pelvis including sacroiliac joints

Investigations

Laboratory studies

Send blood for full blood count (FBC), urea, electrolytes and liver function tests (ELFTs) and inflammatory markers, including erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).

Exclude infection by sending blood cultures, urine microscopy and chest x-ray.

Send serum antibody or antigen tests as indicated by the history for infectious exposure, such as hepatitis B and C serology, HIV serology, syphilis serology, chlamydia and gonorrhoea urine polymerase chain reaction (PCR), streptococcal antigen test (ASO titre) and an autoantibody panel including antinuclear antibody (ANA), extractable nuclear antigen antibodies (ENA), double stranded DNA, rheumatoid factor (RF) and antibodies against citrullinated peptides (ACPA), usually ordered as anticyclic citrullinated peptide (anti-CCP). Antibody tests in particular should be interpreted with caution and in the context of each individual patient, due to their varying sensitivity and specificity.

Joint aspiration

Joint aspiration and analysis of synovial fluid are essential to diagnose septic arthritis and crystal arthropathy (see Chapter 14.2).

Imaging studies

Imaging studies, such as plain x-rays, may demonstrate diagnostic features in erosive arthropathy, but these do not occur for some time after the acute onset. They may also demonstrate chondrocalcinosis, which may suggest a diagnosis of pseudogout.

RHEUMATOID ARTHRITIS

RA is a chronic systemic inflammatory disorder characterized by symmetric synovitis, erosive polyarthritis and numerous extra-articular manifestations. The onset is often indolent and may lack the characteristic symmetrical joint involvement. Joint destruction may begin within a few weeks of symptom onset and is irreversible. A window of opportunity exists to initiate early treatment that will alter the course of the disease; early referral to rheumatology is important.

Diagnosis

The diagnosis in adults is guided by the American College of Rheumatology/European League Against Rheumatism Criteria. These criteria were revised in 2010[2] to identify features predictive of erosive disease earlier in the illness. Constitutional features, such as malaise and fatigue, are common.

'Definite RA' is based on the confirmed presence of:
- synovitis in at least one joint
- absence of an alternative diagnosis that better explains the synovitis

- a total score of 6 or greater (of a possible 10) from individual scores in four domains: number and site of involved joints (score range 0 to 5); serological abnormality (score range 0 to 3); elevated acute-phase response (score range 0 to 1) and symptom duration (2 levels; range 0 to 1) (Box 14.3.2

Morning stiffness, symmetric involvement and radiographic erosions are no longer included in the diagnostic criteria; however, they are also suggestive of RA.

Clinical features

Characteristic presentations in RA include the following:

Cervical spine

Degeneration of the transverse ligament of the C1 vertebra produces C1 to C2 instability in patients and can result in cervical cord compression or vertebral artery insufficiency. In addition, decreased motion and myelopathy may result from long-standing joint involvement (see Chapter 14.1).

Upper limb

The wrist, metacarpophalangeal and proximal interphalangeal joints are typically affected, with sparing of the distal interphalangeal joints.

Box 14.3.2 Classification criteria for rheumatoid arthritis

A. Joint involvement
- 1 large joint—0 pts
- 2–10 large joints—1 pt
- 1–3 small joints (with or without involvement of large joints)—2 pts
- 4–10 small joints (with or without involvement of large joints)—3 pts
- >10 joints (at least 1 small joint)—5 pts

B. Serology (at least 1 test result is needed for classification)
- Negative RF and negative ACPA—0 pts
- Low-positive (<3 × ULN) RF or low-positive ACPA—2 pts
- High-positive (≥3 × ULN) RF or high-positive ACPA—3 pts

C. Acute-phase reactants (at least 1 test result is needed for classification)
- Normal CRP and normal ESR—0 pts
- Abnormal CRP or abnormal ESR—1 pt

D. Duration of symptoms
- <6 weeks—0 pts
- ≥6 weeks—1 pt
- Add score of categories A–D: a score of >6/10 classifies a patient as having definite RA

ACPA, Antibodies against citrullinated peptides; *CRP*, C-reactive protein; *ESR*, erythrocyte sedimentation rate; *RA*, rheumatoid arthritis; *RF*, rheumatoid factor; *ULN*, upper limit normal. (Adapted from Kay J, Upchurch KS. ACR/EULAR 2010 rheumatoid arthritis classification criteria. *Rheumatology (Oxford).* 2012;51(6):vi5–vi9.)

Swan-necking and boutonnière deformities are common, together with ulnar deviation at the metacarpophalangeal joints. Fixed flexion deformities may result in entrapment neuropathies, in particular, carpal tunnel syndrome with median nerve involvement. Tenosynovitis may lead to tendon rupture, particularly of the extensor pollicis longus, or degenerative changes in the long extensors of the middle, ring and the little fingers with rupture of these tendons.

Lower limb

The hip and knee are frequently involved. Metatarsophalangeal joint subluxation may occur. Talonavicular joint inflammation causes pronation and eversion deformity, with overlying muscle spasm. A Baker cyst due to posterior herniation of the joint capsule of the knee joint may occur and require differentiation from a deep vein thrombosis by Doppler ultrasound. Entrapment of the posterior tibial nerve causes burning paraesthesiae on the sole of the foot.

Extra-articular manifestations

The extra-articular manifestations of RA are protean and may involve any organ system due to local inflammation causing functional or neurological deficits, rheumatoid vasculitis or distant inflammation (see Chapter 14.1). Patients may also present with the side effects of the treatment, including sepsis related to immunosuppression. Sepsis with encapsulated organisms is of particular concern in patients with the Felty syndrome of RA with splenomegaly and neutropenia.

Investigations

Laboratory studies

Send blood for FBC, UEC and LFTs and non-specific markers of inflammation, such as ESR, and CRP, with assays for serum RF and anti-CCP. Anti-CCP is as sensitive but more specific than RF for RA and is more frequently positive early in the disease process. It is also thought to identify individuals at higher risk of erosive disease.[3] Some patients with RA may be classified as 'seronegative', meaning that RF and anti-CCP are negative despite their clinical presentation being consistent with RA. Send blood cultures as well as midstream urine for suspected sepsis.

Joint aspiration

Joint aspiration is essential to exclude coexistent or primary sepsis in any sudden hot, swollen joint.

Imaging

Initial plain imaging of affected joints at first presentation does not usually demonstrate erosive changes, but is useful in patients with long-standing disease. However, always request x-rays of the cervical spine in any patient with cervical or neurological features to look for an atlanto-dens interval of greater than 2.5 mm, which is diagnostic of instability. Include a chest x-ray if there is a fever and/or any respiratory features. Request an ultrasound examination to differentiate deep vein thrombosis from a Baker cyst.

Emergency management

Emergency therapy aims to exclude infection and relieve acute pain. Rheumatology referral enables early and appropriate intervention with disease-modifying antirheumatic drugs (DMARDs), reducing joint damage and disability. Admit patients if there is evidence of multisystem involvement, severe symptoms requiring nursing or allied health management, or if they are unable to tolerate oral therapy.

Medication falls broadly under the categories of non-steroidal anti-inflammatory drugs (NSAIDs) and DMARD therapy, including biological DMARDs. Readers are referred to Chapter 14.1 for a brief overview of these medications and common adverse effects. If arthritis is not well controlled on DMARDs such as Methotrexate and Sulfasalazine, patients are quickly escalated to biological DMARDs in order to achieve the two primary management goals: (1) prevent joint damage, and (2) maintain joint function. In addition to medication, important principles include education and exercise. Other long-term measures include orthopaedic and orthotic intervention. Surgery involving joint fusion, synovectomy, total joint arthroplasty and reconstruction may be required.

Prognosis

The spontaneous remission rate in RA is approximately 13%.[4] High titres of anti-CCP or RF, which are present in up to 75% of patients with RA, the presence of nodules and human leucocyte antigen (HLA)-DR4 haplotype are markers of severity. A patient's life expectancy is shortened by 10 to 15 years by accelerated cardiovascular disease, infection, pulmonary and renal disease, and gastrointestinal bleeding.

SERONEGATIVE ARTHRITIS

The seronegative spondyloarthritis disorders are characterized by inflammation of the axial spine with sacroiliitis and spondylitis, in particular, enthesitis, which is inflammation at the attachments of tendons and ligaments to bones, dactylitis, asymmetric polyarthritis often of the lower limb, eye inflammation and varied mucocutaneous features. They are labelled 'seronegative', as the serum RF is negative.

Epidemiology

The term 'seronegative spondyloarthritis' covers conditions such as AS, reactive arthritis occurring in the setting of viral or bacterial infection, psoriatic arthritis and arthritis associated with IBD. It is further differentiated into *axial* and *peripheral* spondyloarthritis.

The prevalence of the seronegative spondyloarthritis disorders varies widely and may parallel the prevalence of the HLA-B27 gene.

However, the exact role of HLA-B27 in the pathogenesis of these disorders has not been clearly defined; however, patients with HLA-B27 positivity have a 20-fold risk of developing spondyloarthropathy.[5]

The Assessment of Spondyloarthritis International Society (ASAS) advanced classification criteria for axial and peripheral spondyloarthritis (Fig. 14.3.1). These criteria have better sensitivity and comparable specificity to previous criteria and are well validated.[6]

PSORIATIC ARTHRITIS

Psoriatic arthritis is a heterogeneous disease distinct from other inflammatory arthritides. It occurs in up to 30% of patients with psoriasis, but may affect up to 40% of hospitalized psoriasis patients with widespread skin involvement.[7] It occurs between the ages of 30 and 60 years, with an equal prevalence in males and females. It is thought to be inherited in a polygenic pattern significantly influenced by environmental factors, including trauma and infectious agents. The arthropathy pattern may be pauci-articular, but more than five peripheral joints are usually involved.

Clinical features and diagnosis

The diagnosis of psoriatic arthritis is essentially clinical, requiring the demonstration of coexisting synovitis and psoriasis.

Classification criteria for psoriatic arthritis (CASPAR) diagnostic criteria[8]

Established inflammatory joint disease and at least three points from the following features:

- current psoriasis (2 points)
- history of psoriasis (in the absence of current psoriasis) (1 point)
- family history of psoriasis (in the absence of current or past history) (1 point)
- dactylitis (1 point)
- juxta-articular new bone formation (1 point)
- RF negativity (1 point)
- nail dystrophy (1 point)

Five clinical subtypes are recognized, including asymmetric oligoarthritis, symmetric small joint polyarthritis, predominant distal interphalangeal joint involvement, psoriatic spondyloarthropathy and arthritis mutilans. Major extra-articular organ manifestations, such as aortic insufficiency and pulmonary fibrosis, occur rarely. However, up to 30% of patients have mild inflammation at the eye, most commonly conjunctivitis.

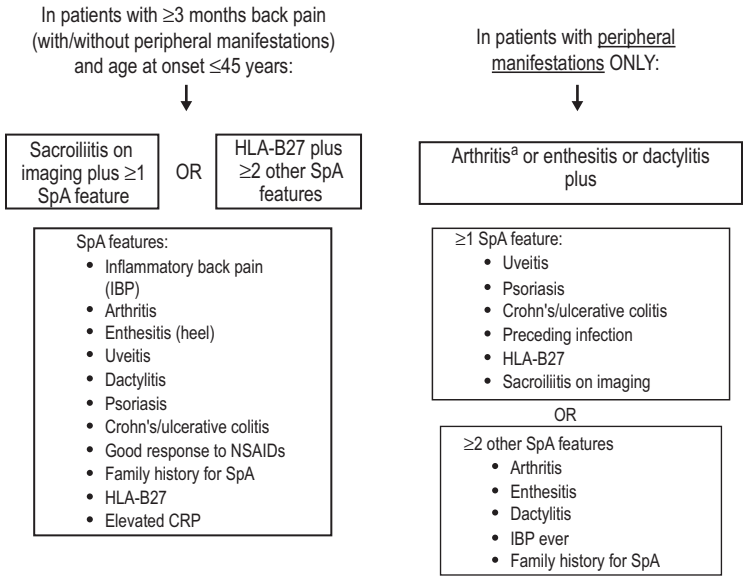

FIG. 14.3.1 Combined use of the Assessment of Spondyloarthritis International Society (ASAS) criteria for axial spondyloarthritis and the ASAS criteria for peripheral SpA in the entire SpA population. [a]Peripheral arthritis: usually predominantly lower limb author asymmetric arthritis combined sensitivity 79.5% and combined specificity 83.3% *n*=975. *CRP*, C-reactive protein; *HLA*, human leucocyte antigen; *NSAIDs*, non-steroidal anti-inflammatory drugs. (Reproduced with permission from Rudwaleit M, van der Heijde D, Landewé R, et al. The Assessment of SpondyloArthritis International Society classification criteria for peripheral spondyloarthritis and for spondyloarthritis in general. *Ann Rheum Dis.* 2011;70:25–31.)

Asymmetric oligoarthritis

This occurs in 30% to 50% of patients.[9] It presents as an oligoarthritis involving a single large joint, in association with a 'sausage-shaped' or dactylitic digit or toe. Dactylitis occurs due to a combination of arthritis and tenosynovitis. Distal interphalangeal joint involvement is typical, almost invariably associated with psoriatic nail changes of pitting, ridging and onycholysis. Enthesitis occurs most frequently with this form of the disease and commonly manifests as plantar fasciitis or epicondylitis at the elbow.

Symmetric small joint polyarthritis

This occurs in 30% of patients, in a pattern strongly resembling RA, but with distal interphalangeal joint involvement[9].

Psoriatic spondyloarthritis

This occurs in 5% of patients.[9] It is often asymptomatic, but may present with inflammatory low back pain due to sacroiliitis in up to 30% of cases.

Arthritis mutilans

'Arthritis mutilans' is a rare (<5% of patients) but well-characterized feature of psoriatic arthritis with severely deforming arthritis including telescoping of the fingers or toes from osteolysis of the metacarpal or metatarsal bones and phalanges.[9].

Dermatological features

Dermatological features include typical erythematous, scaling plaques on the extensor surfaces of the elbows and knees, scalp and ears and nail pitting, ridging and onycholysis with separation of the nail from the underlying nail bed. Nodules and vasculitic features such as digital ulcers are not seen.

Psoriatic arthritis can be difficult to distinguish from the other seronegative spondylarthritides in the absence of dermatological features or a positive family history.

Investigations

ESR and CRP are raised, but the RF and autoantibody screen are negative. Plain x-rays of affected joints may reveal typical radiographic features including soft-tissue swelling, bone proliferation at the base of digital phalanges coupled with resorption of the distal tufts (the 'pencil-in-cup'

deformity) and fluffy periostitis.[10] Chest radiographs are useful as a baseline when clinical examination suggests cardiac or pulmonary involvement.

Emergency management

Emergency treatment involves the exclusion of infection and relief of pain. Prompt rheumatology referral for early institution of DMARDs to prevent joint destruction and maintain joint function. Education, exercise and referral to a multidisciplinary allied health team are also part of the mainstay of ongoing management. Admit patients if their symptoms are severe enough to preclude oral therapy or safe discharge, pending outpatient specialist follow-up.

NSAIDs are useful for acute symptomatic relief. Intra- or peri-articular corticosteroids may be used for short-term relief of painful arthritis or enthesitis; however, exclusion of active infection is paramount. Long-term therapy with DMARDs, such as sulphasalazine or methotrexate, is instituted at specialist review. Oral corticosteroids are usually avoided as their cessation often exacerbates the psoriasis. Therapy with tumour necrosis factor-α (TNF-α) antagonists; interleukin-17A (IL-17A) 12 and 23 antagonists have been approved for rheumatologists under strict access criteria for severe disease resistant to other DMARD therapy.

Emergency management of skin disease includes topical treatments, such as emollients and keratolytic agents.[11] Phototherapy and photo-chemotherapy may be instituted on early dermatological consultation.

Prognosis

Psoriatic arthritis generally runs a more benign course than RA; adverse prognostic factors include onset before 20 years of age, erosive disease and extensive skin involvement.[9]

REACTIVE ARTHRITIS

Reactive arthritis is an aseptic peripheral arthritis following certain infections, which include bacterial infections of the urogenital tract usually by *Chlamydia trachomatis* or *Neisseria gonorrhoeae*, or of the gastrointestinal tract with organisms, such as *Shigella*, *Salmonella* and *Campylobacter*. It may also follow bacterial infections such as *Treponema pallidum* and viral infections, such as HIV. The seroconversion illness of HIV has its own constellation of articular symptoms and is considered to be a separate entity.

Epidemiology

The prevalence of reactive arthritis is difficult to define. The male preponderance is up to 9:1 following sexually transmitted infection, but males and females are equally affected following gastrointestinal tract infection.[12] The peak incidence is around age 35 years and up to 75% of patients are HLA-B27 positive.[12] An important exception is with the reactive peripheral arthritis that occurs in 20% of patients with idiopathic IBD, a condition that may mimic gastrointestinal tract infection, but where patients are usually HLA-B27 negative.

Clinical features and diagnosis

The diagnosis of reactive arthritis is clinical. It typically manifests within a month of gastrointestinal or genitourinary infection. Musculoskeletal manifestations include myalgias and asymmetric polyarthritis affecting the knees, ankles and small joints of the feet in particular, although peripheral upper limb involvement is seen. Affected joints demonstrate marked inflammatory features with erythema, swelling, warmth and exquisite pain on active or passive movement. Fever and malaise are common. Exclusion of a septic joint is paramount.

Arthritis and extra-articular manifestations

Symptomatic spondylitis and sacroiliitis cause low back and buttock pain and occur frequently. Dactylitis and enthesitis are characteristic features of this disease with heel pain from plantar fasciitis or Achilles tendinitis.

Extra-articular features include keratoderma blennorrhagica, the scattered, thickened, hyperkeratotic skin lesions with pustules and crusts seen in reactive arthritis and circinate balanitis. Keratoderma blennorrhagica on the soles or palms may coalesce to form plaques virtually indistinguishable from those of psoriasis.[13] Circinate balanitis causes shallow meatal ulcers that are moist in uncircumcised men or hyperkeratotic and plaque-like in circumcised men.[13] An inflammatory aortitis occurs in 1% of patients and may result in aortic valvular incompetence and/or heart block.

The peripheral arthritis associated with IBD can be migratory and occurs in a similar distribution. Common features include joint effusions, particularly involving the knee, and sacroiliitis or spondylitis. Unlike peripheral arthritis following genitourinary infection, the spondylitis of IBD-associated arthritis may not settle with treatment of the bowel inflammation. Cutaneous manifestations associated with this form of arthritis occur mainly on the lower limbs and include erythema nodosum and pyoderma gangrenosum.

Investigations

Laboratory

An active inflammatory response is seen in the acute phase with a neutrophil leucocytosis and thrombocytosis and raised ESR and CRP. The presence of a mild normochromic, normocytic anaemia suggests chronic disease. Send blood for HLA-B27.

Document the preceding gastrointestinal or genitourinary organism by stool culture or cervical/urethral swabs. RF and ANA are often negative.

Joint aspiration

Joint aspiration is vital to exclude intra-articular sepsis (see Chapter 14.2). The synovial fluid may be turbid, viscous and with a neutrophil leucocytosis up to 50,000/mm^3, but Gram stain and bacterial culture are negative, and unlike true septic arthritis, the synovial glucose level is not significantly reduced compared to serum levels.[14] Macrophages with intracytoplasmic vacuoles containing ingested neutrophils are occasionally seen.

Imaging

X-ray changes are unusual with acute arthritis, but are seen after several months. As with psoriatic arthritis, a common finding is a 'fluffy' periosteal reaction, particularly at the calcaneus, and evidence of sacroiliitis or spondylitis with bridging syndesmophytes in long-standing disease.

Emergency management

Exclude infection by synovial aspiration and culture with a markedly inflamed joint and consult early with a rheumatologist, particularly in a patient with a first presentation. Admit patients with suspected septic arthritis until it is excluded or if they are unable to tolerate simple oral therapies. Request a cardiology opinion for major cardiac involvement with valvular disease or a conduction abnormality and a gastroenterology opinion when IBD is suspected, although the role of treatment and the effect on the arthropathy is unclear.

Otherwise, provide symptom relief with NSAIDs as the mainstay of treatment. Corticosteroids may be given after rheumatological consultation, either systemic, intra-articular, topically for the skin manifestations. Disease modifying therapy is initiated at specialist follow-up if NSAID therapy fails to control symptoms. Multidisciplinary physical therapy is essential on an outpatient basis.

Give antibiotics, such as doxycycline 100 mg orally bd for 7 days or azithromycin 1 g orally once for documented urethritis or cervicitis, and remember partner contact tracing and treatment involving infectious diseases service.[14]

Prognosis

Signs and symptoms usually remit within 6 months. However, up to 50% of patients suffer from recurrent arthritis and up to 30% develop chronic arthritis.[15] Post-dysenteric cases have a better prognosis than post-chlamydial cases. Poor prognostic signs include early onset under the age of 16 years, hip involvement and the presence of dactylitis.

POLYARTICULAR CRYSTAL ARTHRITIS

Crystal-induced arthritis disorders result from the deposition of crystal in joint spaces, such as in gout or pseudogout. Both diseases cause debilitating joint inflammation resulting from the lysis of neutrophil polymorphs that have ingested monosodium urate in the case of gout, or calcium pyrophosphate crystals in pseudogout. Although usually monoarticular, polyarticular involvement can occur in up to 5% of cases. Exclusion of septic arthritis via joint aspiration is paramount. See Chapter 14.2.

INFECTIOUS POLYARTHRITIS

Septic bacterial arthritis is most often monoarticular, although it can present with polyarticular involvement. Septic screen should be performed, including blood cultures, urine microscopy and culture and chest radiograph. Cardiac echocardiogram is essential to look for vegetations in the presence of a cardiac murmur. Joint aspiration for cell count, gram stain and culture is essential for diagnosis. Infectious polyarthritis may also occur as aseptic manifestation of certain viral infections and following streptococcal infection in acute rheumatic fever (ARF).

Viral arthritis

Arthralgia affecting several joints is common in many viral infections, but few cause frank polyarthritis. In general, these are self-limiting and managed symptomatically. Viruses involved include alphaviruses, such as the Ross River virus (RRV), parvovirus B19, and hepatitis A, B and C viruses.

Alphaviruses

Alphaviruses are a mosquito-borne genus of the Togaviridae family. They are responsible for epidemics of febrile polyarthritis, including RRV, Barmah Forest and Sindbis viruses (SINV) in Australia and West Nile virus in the United States; Chikungunya virus in East Africa, South and Southeast Asia; O'nyong-nyong virus in East Africa and the Mayaro virus in South America.[16,17]

Ross River virus

RRV is endemic to Australia, New Zealand and South Pacific islands and is the most common arboviral disease in Australia. RRV is transmitted by the *Ochlerotatus* (formerly *Aedes*) *vigilex* mosquito via a marsupial reservoir.[18] Epidemics of acute febrile polyarthritis are most common between January and May, but can occur after periods of heavy rains.

Clinical features and diagnosis

A detailed travel and sexual history is essential. There is usually low-grade fever and other constitutional symptoms. A rash varying in distribution, character and duration occurs up to 2 weeks before, during or after the other features. Polyarticular symptoms are present in most patients with a symmetric arthritis or arthralgia primarily affecting the wrist, knee, ankle and small joints of the extremities. Cervical lymphadenopathy occurs frequently, and paraesthesiae and tenderness of the palms and soles occur in a small percentage of cases.[19]

The diagnosis is predominantly clinical, particularly in endemic areas in the event of a local outbreak, and confirmed by serology.

Investigations

Serology testing distinguishes RRV from other causes of febrile polyarthritis, such as Barmah Forest virus. A significant rise in IgM antibody titre to RRV indicates acute infection or the virus itself may be isolated from the serum of acutely unwell patients. Radiographs are unremarkable and unnecessary, as the disease is largely self-limiting.[20]

Emergency management

Patients with RRV require symptomatic treatment with simple analgesics or NSAIDs. Occasionally, a brief course of low-dose prednisolone may be used. RRV is a notifiable disease.[18] Refer to a rheumatologist if symptoms are severe or refractory to simple treatment measures.

Conventional personal preventative measures, such as protective clothing, effective mosquito repellent and avoidance of mosquito-prone areas should be recommended, as no vaccine currently exists.

Prognosis

RRV is usually self-limiting, but prolonged symptoms may occur and there may be relapses of decreasing intensity, separated by remissions for up to a year or more.

Parvovirus B19

Human parvovirus B19 infection is caused by a small, single-stranded DNA virus that has a predilection for erythroid precursor cells and is transmitted by respiratory secretions. It causes the self-limiting illness *erythema infectiosum* known as 'slapped cheek disease' or 'fifth disease' in children. In adults, however, parvovirus B19 manifests with severe flu-like symptoms, and as many as 75% develop joint symptoms. It may be responsible for up to 12% of adult patients presenting with acute polyarthritis, most notably in those who have frequent exposure to children.[21]

Clinical features and diagnosis

The characteristic 'slapped cheek' rash is usually absent in adults. An acute polyarthritis improves over 2 weeks, with symmetric involvement of peripheral small joints, including the hands (proximal interphalangeal and metacarpophalangeal joints in particular), wrists, knees and ankle joints. Morning stiffness is prominent. These features are similar to those seen in patients with RA.

Uncommon but important extra-articular features of parvovirus B19 infection include[22]:

- development of an aplastic crisis in patients with chronic haemolytic anaemia
- bone marrow suppression in immunocompromised patients
- *hydrops fetalis* in women infected during pregnancy
- Henoch–Schönlein purpura
- thrombotic thrombocytopaenic purpura
- granulomatosis with polyangiitis (GPA, formerly known as Wegener granulomatosis) or polyarteritis nodosa (rare).

Investigations

Send an FBC, given the potential for an aplastic crisis and bone marrow suppression. Non-specific markers of inflammation are likely to be elevated. Specific serological diagnosis is made by a high IgM antibody titre specific to the virus and by isolation of the viral DNA by PCR. IgG antibodies to parvovirus B19 indicate past infection. Radiographs of the affected joints are normal.

Emergency management

Rest and NSAIDs are the mainstay of emergency treatment, except in pregnant women when NSAIDs are contraindicated in the third trimester. A short course of prednisolone may be required. Significant extra-articular manifestations may require admission and consultation with the appropriate specialist. Blood transfusion or intravenous immunoglobulin infusions may be necessary.

Prognosis

Joint symptoms are self-limited in the majority of adult patients, but up to 10% may have prolonged relapsing and remitting symptoms lasting up to 9 years.[23]

Hepatitis A, B and C viruses

The hepatitis viruses A, B and C all cause viral polyarthritis. Hepatitis B virus (HBV) is responsible for 20% to 25%, and hepatitis A virus (HAV) up to 14% of causes in patients with viral polyarthritis.[24] The polyarthritis of HAV tends to occur during the infectious phase and is self-limiting. The polyarthritis of HBV and HCV occurs in early infection during a period of significant viraemia and is thought to be due to immune complexes.

Clinical features and diagnosis

HBV polyarthritis is acute and severe and manifests in a symmetric, migratory or additive fashion.[25] Other large axial joints, in addition to hand joints, may be involved, and significant early morning stiffness is often present. The arthritis may precede the development of jaundice and persist for several weeks after jaundice has developed.

Hepatitis C virus (HCV) polyarthritis is rapidly progressive and symmetrical, involving the hands, wrists, shoulders, knees and hips.[25] Carpal tunnel syndrome and tenosynovitis may occur. It is unusual for polyarthritis to be the first manifestation of the underlying disease in either HBV or HCV. Nonetheless, ask about exposure risk factors for these viruses, such as intravenous drug abuse, unprotected sexual intercourse, past blood transfusions, tattoos, as well as about previous jaundice.

Both hepatitis B and hepatitis C disease are associated with a number of important extra-articular, extra-hepatic manifestations that include

- HBV: polyarteritis nodosa, systemic necrotizing vasculitis, membranous glomerulonephritis
- HCV: mixed cryoglobulinaemia causing palpable purpura, arthritis and serum cryoglobulinaemia with cutaneous phenomena, such as Raynaud syndrome and digital ulcers, membranous glomerulonephritis and lymphoma

Laboratory investigations and imaging

Send blood for LFTs for raised transaminases with elevated bilirubin, hepatitis B surface antigen, surface antibody and core antibody. If core hepatitis B core antibody is positive, perform viral DNA quantification by PCR. Check also for anti-HCV IgM and for viral DNA quantification by PCR.

Also check FBC and for ESR, CRP, complement C3 and C4, cryoglobulins and RF in the presence of a rash, ulcers or other vasculitic phenomena.

Radiographs are normal other than showing soft-tissue swelling.

Emergency management

Commence symptomatic treatment with NSAIDs and refer refractory HBV- or HCV-associated polyarthritis to a rheumatology specialist and/or combined hepatology clinic. Disease-modifying agents, such as prednisolone and sulphasalazine, may be used cautiously with careful monitoring of the liver function tests and for increasing viraemia. Refer patients to a gastroenterologist for ongoing management of hepatitis infection and assessment of liver function. Patients with HCV should be commenced on direct acting antivirals.

Prognosis

This varies depending on the underlying disease and on the presence of vasculitic phenomena. The polyarthritis of HBV is usually limited to the pre-icteric phase, but patients with chronic active hepatitis or chronic HBV viraemia may have recurrent arthritis.

RHEUMATIC FEVER

ARF refers to the constellation of non-infectious symptoms occurring after a pharyngeal infection with group A streptococci (GAS). Evidence suggests that it may also occur in high-risk populations following skin infections with GAS.[26]

Epidemiology

ARF is characterized by inflammation of connective tissue including the joints, subcutaneous tissue, heart and blood vessels. Its prevalence has declined over time in developed countries, but it remains a major public health problem in Indigenous populations in the more socially isolated parts of Australasia and in developing countries. In fact, the highest documented rates in the world occur in the Aboriginal Australian population and Torres Strait Islander populations of New Zealand and the Pacific Islands.[27]

ARF is primarily a disease of children aged 5 to 14 years. The annual incidence may reach up to 1.2 per 1000 Aboriginal children.[28] However, the polyarthritis of ARF is most common in adolescents and young adults.

Diagnosis and clinical features

The diagnosis of ARF worldwide is made using the 1944 Jones, or more recent World Health Organization major and minor criteria. However, these criteria appear too restrictive for diagnosing ARF in Australian Indigenous populations. Therefore new criteria for use in high- and low-risk populations in Australia have been proposed (Table 14.3.1).[28]

The polyarthritis of ARF is usually the earliest symptom of the disease and is classically described as migratory, affecting several joints in quick succession for a short time, commencing with the large joints of the lower limb then the large joints of the upper limb.[29] Affected joints are painful, but objective signs of inflammation, such as erythema and swelling, are not prominent.

Fever and constitutional symptoms are common. Other important extra-articular major criteria (with polyarthritis) of the disease include the following[28]:

- carditis: symptomatic pericarditis with pain and/or congestive cardiac failure with breathlessness, new murmurs, cardiomegaly, electrocardiographic evidence of heart block
- Sydenham chorea (St Vitus dance): choreiform movements particularly of the face and upper limbs, emotional lability, rarely transient psychosis

Table 14.3.1 2012 Australian guideline for the diagnosis of acute rheumatic fever

	High-risk groups	*All other groups*
Initial episode of ARF	Two major **or** one major and two minor manifestations plus evidence of a preceding GAS infection	Two major **or** one major and two minor manifestations plus evidence of a preceding GAS infection
Recurrent attack of ARF in a patient with known past ARF or RHD	Two major **or** one major and two minor **or** three minor manifestations plus evidence of a preceding GAS infection	Two major **or** one major and two minor **or** three minor manifestations plus evidence of a preceding GAS infection
Major manifestations	• Carditis, including subclinical evidence of rheumatic valve disease on echocardiogram • Polyarthritis **or** aseptic monoarthritis **or** polyarthralgia • Chorea • Erythema marginatum • Subcutaneous nodules	• Carditis, excluding subclinical evidence of rheumatic valve disease on echocardiogram • Polyarthritis • Chorea • *Erythema marginatum* • Subcutaneous nodules
Minor manifestations	• Fever • ESR ≥30 mm/h or CRP ≥30 mg/L • Prolonged P-R interval on ECG	• Fever • Polyarthralgia or aseptic mono-arthritis • ESR ≥30 mm/h or CRP ≥ 30 mg/L • Prolonged P-R interval on ECG

ARF, Acute rheumatic fever; *CRP,* C-reactive protein; *ESR,* erythrocyte sedimentation rate; *GAS,* group A streptococci; *RHD,* rheumatic heart disease.

- subcutaneous Aschoff nodules: firm, painless, mobile nodules near bony prominences on the extensor surfaces of wrists, elbows and knees
- rash (*erythema marginatum*): occurs in around 5% of ARF

Laboratory investigations and imaging

Measure antistreptolysin O and antideoxyribunuclease B (anti-DNase B) titres.[29] As these titres can take 6 weeks after infection to peak, interpretation in the acute phase should be cautious and serial tests should be performed.

Send a throat swab for culture and rapid antigen testing, although the sensitivity and specificity of these tests vary. Other important tests include:

- ESR and CRP, which are almost invariably elevated
- FBC, which may demonstrate a leucocytosis and, less commonly, a normochromic, normocytic anaemia
- ECG to document the P-R interval
- chest x-ray to look for cardiomegaly or symptomatic cardiac failure

Synovial fluid aspirate is usually inflammatory with an elevated white cell count and sterile on microscopy and culture. Radiographs of affected joints generally demonstrate soft-tissue swelling only.

Emergency management

This depends on establishing the diagnosis and treating the manifestations. Patients are markedly symptomatic and often require admission for initial observation and management. Request rheumatology and infectious disease opinions, and a neurology opinion if chorea is troublesome. The presence of heart block or, more importantly, frank cardiac failure or acute valvular regurgitation mandate cardiology admission.

The polyarthritis of rheumatic fever is exquisitely responsive to NSAID therapy, particularly aspirin, so much so that failure of NSAID therapy rapidly to relieve symptoms should prompt consideration of an alternative diagnosis.[28] Give high-dose aspirin at 80 to 100 mg/kg/day in 4 to 5 divided doses in adults, usually for 1 to 2 weeks.[28]

Commence antibiotic therapy with phenoxymethylpenicillin 10 mg/kg up to 500 mg orally 12-hourly for 10 days to eradicate streptococcal pharyngitis, after obtaining appropriate diagnostic investigations as detailed previously. Commence prophylaxis following resolution of the acute episode in high-risk indigenous communities.

Ongoing rheumatology and infectious diseases specialist follow-up is recommended. Note that penicillin reduces the frequency and severity of post-streptococcal rheumatic fever, but has little effect on the course of the immune-complex mediated post-streptococcal glomerulonephritis (PSGN).

Prognosis

Recurrence of ARF commonly occurs within 2 years of the initial attack, despite prophylactic therapy. Most affected connective tissues do not sustain long-lasting damage, with the exception of the heart, which is prone to additive subclinical damage resulting in rheumatic heart disease.

14.4 Musculoskeletal and soft-tissue emergencies

Anthony Tzannes

ESSENTIALS

1 The mechanism of injury and biomechanics predict the soft-tissue damage caused.

2 Soft-tissue injuries can be as debilitating and painful as fractures in the same area, and may take longer to heal.

3 The so-called 'minor injury' can be associated with significant and prolonged morbidity that could be permanent if managed incorrectly. Adopting a careful, consistent approach that considers potential pitfalls is important to patient outcome.

4 Exclude potentially serious causes of back pain by assessing for 'red flags' in every patient presenting with this complaint.

COMMON CAUSES OF SOFT-TISSUE INJURIES

All injuries have a soft-tissue component. The simplest way of dividing their causes is into 'acute' (specific event that exceeds tissue tolerance) and 'chronic' (repetitive minor damage in excess of ability to heal). Both types may be further subdivided by the tissue affected (bone, tendon, muscle, etc.).

Acute soft-tissue trauma can also be subdivided by the mechanism:

- Penetrating:
  - puncture versus incised
  - solid object versus fluid stream (high pressure hose, etc.).
- Blunt:
  - crush injury±laceration
  - shear/degloving (open or closed).

Many of the types of trauma above are covered in other chapters.

General evaluation of a soft-tissue injury

Assessment

History

Obtain a history of:

- the nature of the injury: when, where and how it was sustained with specific attention to the forces involved, especially any potential crush or shear injury with devitalized tissue
- the possibility of a foreign body, wound contamination and/or damage to deeper structures
- patient function pre and post injury
- pain associated with the injury, including time course, nature and aggravating factors
- co-morbidities and drug therapy
- allergies and tetanus immunization status.

Therapeutic Guidelines. *Therapeutic Guidelines: Rheumatology, Version 3*. Melbourne: Therapeutics Guidelines Ltd; 2017.

Examination

The extent of any nerve damage should be determined *before* using local anaesthetic.

Examination should potentially be delayed until after an x-ray if a radiopaque foreign body (metal or glass) is suspected, after giving analgesia.

Tendon damage may be best elucidated after adequate analgesia is obtained so the wound can be adequately explored.

PUNCTURE INJURY

Management

Refer immediately to the appropriate surgical team all high-pressure gun injuries, such as from grease, paint or oil where the skin has been broken, even if no damage is apparent initially. They require extensive wound debridement and tissue plane cleaning, however innocuous they may seem.[1]

Otherwise, clean the wound and evaluate the need for tetanus prophylaxis and antibiotics. A puncture wound to the sole of the foot will require exploration if it has occurred through the sole of footwear, or potentially has a foreign body.

Prophylactic antibiotics are controversial. If prophylaxis is chosen, give amoxicillin/clavulanate 875/125 mg bd for 5 days, add pseudomonal cover (e.g. ciprofloxacin 500 mg bd) if it is an at-risk injury such as through footwear.[2] As these wounds are at a high risk of infection, instruct the patient to return if increasing pain, redness or swelling occurs.

ACUTE MECHANICAL OVERLOAD INJURIES

These include fractures, ligament sprains, muscle strains or tears, and tendon ruptures. Many are covered in Section 4.

See Table 14.4.1 for a classification system for ligamentous sprains.

Table 14.4.1 Classification of ligament sprains/muscle strains

Grade	*Features*
I	Small number of fibres injured, pain on loading, but no laxity or loss of strength
II	Significant number of fibres injured, with laxity and/or weakness and pain on loading
III	Complete tear with gross laxity and no strength

Management

General principles

The initial management principles are the same for both ligament sprains and muscular strains. This includes protection, rest, ice, compression and elevation (PRICE) with analgesia, usually a combination of paracetamol 1 g orally qid, plus a non-steroidal anti-inflammatory drug (NSAID), such as ibuprofen 400 mg orally tds (in the absence of NSAID-sensitive asthma, peptic ulcer disease and renal impairment).

Ligament sprain

Ligament sprains that are grade I or II (see Table 14.4.1) are managed with a protective brace or strapping and reduction in, but not cessation of, physical activity. Consider immobilizing grade III sprains with a splint or plaster of Paris (POP) cast and/or operative repair if there is gross instability and warn the patient that he or she can take up to 3 months or longer to heal. This is of particular relevance to the manual labourer and high-level athlete. Proprioception retraining at physiotherapy has been shown to prevent recurrence in the long term (>1 year) but not mid-term (6 to 9 months)[3] in lateral ankle sprains.

Muscle strain

Muscle strains require initial PRICE to minimize bruising and haematoma formation followed by a graded return to activity. Physiotherapy may aid in return of function and prevent re-injury. [4]

Assess the functional limitations imposed by these injuries, particularly in patients who live alone and/or who are elderly and infirm, as loss of independence is likely. A complete muscle tear, especially in an active individual, may benefit from operative repair following referral to an orthopaedic specialist. Consider the need for community services, respite care or admission for those who are initially unable to care for themselves.

Tendon rupture

Evaluation

Acute rupture of the supraspinatus tendon (see Chapter 4.1), long head of biceps and Achilles tendon (see Chapter 4.11) are the most common serious tendon injuries that present to an emergency department (ED). Injury may be secondary to an acute event or chronic overload that is often asymptomatic until a tear occurs, and the extent of the rupture may be partial or complete.

Management

Treatment is aimed at the earliest return to normal function, with the least likelihood of recurrence. Refer a complete tear, particularly in active people, for orthopaedic surgery for consideration of operative repair. Manage partial tears conservatively, but they too may have a better outcome if repaired surgically, depending on local hospital practice and surgical availability.

One exception is a long head of biceps tendon tear, which usually results in a mostly cosmetic defect—the 'Popeye' sign. However, in highly active people or those with associated rotator cuff pathology surgical repair is often indicated. [5]

An ultrasound can confirm the diagnosis. Magnetic resonance imaging (MRI) is equally or more sensitive and specific depending on which tendons are being imaged, although it is much less readily available.

PRETIBIAL LACERATION

These are most common in elderly patients, often from trivial trauma that tears a flap of skin, particularly if taking steroids. Ask about general mobility and safety issues at home.

Management

The majority of these wounds will heal with conservative management. Clean the wound, remove blood clots, trim obviously necrotic tissue and unfurl the rolled edges of the wound to determine actual skin loss. Refer the patient immediately for consideration of debridement +/– early skin grafting if there is large skin loss, gross contamination, major haematoma or marked skin retraction preventing alignment of the skin edges.[6]

Otherwise, lay the flap back over the wound and hold in place with adhesive skin-closure strips (Steristrips). Then cover the wound with a non-adhesive dressing, and apply a firm crêpe bandage and instruct the patient to keep the leg elevated when not walking. Determine the need for tetanus immunization or booster.

Arrange follow-up with either outpatient wound services, or if unavailable, to the ED in 5 days for review and a dressing change, or earlier if blood or serum has seeped through the wound dressing, known as 'strike-through', which increases the risk of secondary infection.

DEGLOVING INJURY

Evaluation

Degloving injuries are caused by either a shearing or traction force on the skin, causing it to be torn from its underlying capillary blood supply. When the skin actually peels off it leaves an obvious exposed open injury, or the skin may remain intact causing a closed injury.

A closed degloving injury is much harder to diagnose[7] with up to one-third thought to be missed at the time of initial trauma.[8] It occurs most

commonly in the hip, thigh or pelvic region and usually in the setting of high energy trauma. The clinical exam is often complicated by underlying bony injuries. The most consistent finding is soft fluctuance and/or hypermobility of the skin. Decreased cutaneous sensation is often but not always present.[7] The best diagnosis is on imaging; CT is reasonable but MRI is the preferred imaging modality.[9] Pain may or may not be prominent and/or may relate to an underlying bony injury.

Management

Arrange specialist assessment and admission for all degloving injuries by the appropriate surgical team, usually plastic and/or orthopaedic surgery. Keep any degloved skin, as it may be used as a skin graft.

Do *not* be tempted simply to replace the skin into its original position and hold it there with sutures or adhesive skin-closure strips (Steri-Strips), as this is inadequate. Degloving injuries are also a high-risk wound for tetanus.

CHRONIC OVERUSE (OVERLOAD) INJURIES

Chronic overuse injuries develop wherever tissue microtrauma occurs at a rate that exceeds the body's natural ability to heal. Few require emergency treatment, but general knowledge of these conditions is valuable to advise patients on cause and management.

Classification

Bony overuse injuries follow a continuum from pain on activity only, through local tenderness to pain at rest, with loss of function. Many will have led to a stress fracture by the time of presentation to an ED.

Other overuse injuries are classified by the tissue type and the extent of injury and are often best diagnosed by the timing of the pain in relation to physical activity. They are further classified by the presence or absence of inflammation. See Table 14.4.2 for a classification of chronic overuse syndromes.

Management

Most chronic overuse injuries are managed with a decrease in activity and NSAIDs, though their use in stress fractures is controversial.[10,11] Arrange referral to a physiotherapist or specialty physician, such as sports or performing arts physician, as appropriate. Tendon-related injuries may benefit from a steroid injection, which should only be performed by doctors trained in the technique (orthopaedic surgeons, rheumatologists, sports physicians or some ED doctors).

Specific chronic overuse injuries that require more extensive management are summarized in Table 14.4.3.

NON-ARTHRITIC JOINT AND SOFT-TISSUE DISORDERS

General management of non-arthritic joint and soft-tissue disorders

Joint pain, swelling and tenderness mimicking arthritis may be due to inflammation of

Table 14.4.2 Classification of chronic overuse syndromes

Grade	*Symptom*
I	Pain after activity
II	Pain early on and after activity; activity not limited
III	Pain throughout activity, which is limited
IV	Pain at rest

Table 14.4.3 Stress fractures which require active specialist management

Injury	*Associated with*	*Symptoms*	*X-ray*	*Other imaging*	*Management*
Pars interarticularis	Gymnasts, ballet dancers, fast bowlers	Unilateral low back pain, worse on extension	Pars # often seen	CT or MRI definitive, XR+Bone scan alternative option	Avoiding hyper extension for 6/52, consider brace for 6–12/52; core stability retraining once healed
Femoral neck (see Chapter 4.7)	Athletes/military increased activity	Vague thigh/groin pain with loading	Often normal	Bone scan or MRI, CT less sensitive	If <50% of bone fractured, decrease activity, if >50% ORIF
Femoral shaft	Dancers	Vague thigh/knee pain with loading	# Usually visible	CT or bone scan	Lateral cortex—ORIF, medial cortex (much rarer) non-weightbearing 6/52
Anterior cortex of mid-tibia (see Chapter 4.10)	Distance runners, ballet dancers	Progressive anterior leg pain with activity	Anterior # line, thickened cortex	Bone scan? Non-union versus recent injury	Decrease activity, intermedullary nail if progresses
Talus (see Chapter 4.12)	Repeated falls/ jumping from height	Foot/ankle pain worse with weightbearing	Usually normal	Bone scan, CT or MRI	6/52 non-weightbearing in POP
Navicular	Increased running/ marching	Vague midfoot pain with point tenderness over navicular	May show #	Bone scan, CT or MRI	6–8/52 non-weightbearing, ORIF if fails to heal
Base 2nd metatarsal	Ballet dancers	Forefoot pain on exercise	# Usually visible	Bone scan, CT or MRI but usually not needed	Non-weightbearing on crutches for 4–6/52
Base 5th metatarsal (see Chapter 4.12)	Ballet dancers	Midfoot pain with activity	# Usually visible	Bone scan, CT or MRI but usually not needed	Non-weightbearing with POP for 6/52 or direct ORIF as often fail to heal
Sesamoid bone of hallux	Increased running/ marching	Forefoot pain, tender/swelling over ball of foot	Often hard to interpret	Bone scan or MRI	6/52 Non-weightbearing with crutches then orthotics to correct biomechanics

CT, Computed tomography; *MRI*, magnetic resonance imaging; *ORIF*, open reduction internal fixation; *POP*, plaster of Paris; *XR*, x-ray; 6/52, 6 weeks.

periarticular structures. Most patients can be treated with NSAIDs, such as ibuprofen 200 to 400 mg orally tds or naproxen 250 mg orally bd and/or with paracetamol.

Underlying or secondary true arthritis also may be present and complicate the presentation. Joint aspiration is indicated to rule out a septic arthritis and, when this is suspected, follow local guidelines as to who performs it. Refer the patient in whom a septic joint has been excluded back to the general practitioner (GP) or outpatients unless mobility is so significantly affected that he or she requires admission.

Do not perform a steroid injection in the ED, as complications, such as septic arthritis and joint destruction, do occur. This is best left to the specialist who undertakes long-term care. Some of the more common presentations include the following.

Torticollis ('wry neck')

Diagnosis

Torticollis is abnormal unilateral neck muscle spasm, resulting in the head being held in a bent or twisted position. The aim of the history and examination is to exclude a serious underlying cause such as local sepsis/abscess, recent trauma, cervical disc prolapse, acute drug dystonia, raised intracranial pressure, or even a carotid artery dissection.[12]

Management

Benign 'wry neck' most commonly occurs on waking after sleeping in an awkward position or follows unaccustomed activity or minor trauma. Arrange for cervical imaging if there is a history of possible bony trauma or cervical pathology. Give benztropine 1 to 2 mg intravenously when drug-induced dystonia is suspected.

Once serious causes have been excluded, use NSAIDs +/– paracetamol. Recommend gentle manipulation or muscle energy techniques to slowly work loose the muscles in spasm. Discharge the patient back to the GP with analgesia and ongoing exercises/stretches to maintain neck alignment.

Adhesive Capsulitis (Frozen shoulder)

Diagnosis

Frozen shoulder (adhesive capsulitis) has a natural history lasting 1 to 5 years, with an average duration of 2.5 years. It begins with an acutely painful period of 3 to 9 months with a progressively decreasing range of motion at the glenohumeral joint, and a 'freezing phase' over 4 to 12 months starting soon after the pain. Pain tends to be worse at night or when lying flat. The decreased range of motion usually resolves in the 'thawing' phase, but this may take from 1 to 4 years.

A frozen shoulder may occur spontaneously, but more commonly follows local trauma (which can be trivial), non-shoulder surgery, immobilization, a cerebrovascular accident or shingles. There is an increased risk in diabetic patients where the condition may present bilaterally, in smokers, with hyperlipidaemia and in those on treatment with protease inhibitors. It is more common in females with a peak incidence age of 55 years and in the non-dominant arm.

On examination, the most sensitive sign is loss of passive external rotation at the glenohumeral joint. Test for this by first immobilizing the scapula by placing a hand over the top of the shoulder to exclude scapulothoracic movement.

TESTING PASSIVE EXTERNAL ROTATION OF THE GLENOHUMERAL JOINT – ADDITIONAL ONLINE MATERIAL

Management

Treatment options depend on the stage of the disease. The initial painful phase can be temporarily improved by intra-articular or oral steroids; NSAIDS may also have a role in symptom relief. Once the freezing stage has been reached then orthopaedics procedures to release the contracted capsule are potentially of benefit. Physiotherapy has conflicting evidence, with some studies showing prolongation of impaired function and others showing some improvement, usually when the patient is in the thawing stage.[13]

Supraspinatus tendonitis

Diagnosis and management

Supraspinatus tendonitis is one of the causes of the 'painful arc' occurring between 60 degrees and 120 degrees of shoulder abduction. Perform a shoulder x-ray, which may reveal calcification in the supraspinatus tendon and/or 'hooking' of the acromion, decreasing the subacromial space and predisposing to this condition.[14] Patients may present at the time of acute rupture of calcific material into the subacromial bursa, which causes significant pain.[15] Ultrasound is used for diagnosis and to facilitate aspiration and local steroid injection.

Give an anti-inflammatory analgesic and consider referral to the orthopaedic or rheumatology clinic, especially if calcific tendonitis is present.[14] A 1.25 mg/h glyceryl trinitrate patch over the subacromial space has been shown to be more effective than physical therapy alone in decreasing pain in non-calcific tendonitis. [16]

PAINFUL ARC

Subacromial bursitis

Diagnosis and management

Subacromial bursitis may follow rupture of calcific material into the subacromial bursa that again causes a 'painful arc' on attempted shoulder abduction or constant severe pain in the shoulder. Manage as for supraspinatus tendonitis, above.

Tennis and golfer's elbow

Diagnosis and management

Tennis elbow (incorrectly termed lateral epicondylitis) causes pain over the lateral epicondyle of the humerus from chronic angiofibroblastic tendinosis. There is disorganized tissue and neovascularization but minimal actual inflammation of the extensor origin of the forearm muscles involved in repetitive movements, such as using a screwdriver or playing tennis. Advise the patient to avoid the activity causing the pain and to rest the arm.

Give an anti-inflammatory analgesic and refer for physiotherapy. Eccentric and isometric exercises are most effective in treating and preventing recurrence.[17] A tension strap also can be used to control symptoms, particularly when a patient presents within the first 6 weeks. A local steroid injection often reduces short-term pain and improves movement in the first 6 weeks, but has a worse longer-term outcome.[18]

Golfer's elbow (medial epicondylitis) is a similar condition affecting the medial epicondyle and the flexor origin. Management is the same.

Olecranon bursitis

Diagnosis and management

Painful swelling of the olecranon bursa is due to local trauma, gout or infection, usually with *Staphylococcus aureus*. Aspiration under sterile conditions for microscopy (looking for crystals and/or bacteria) and culture is indicated where possible as physical exam is poorly sensitive for differentiating septic from traumatic bursitis. Imaging is indicated when a foreign body is suspected.[19]

Refer the patient for drainage of the bursa under anaesthesia and/or ultrasound guidance if significant bacterial infection or a foreign body is confirmed, or if a septic arthritis is suspected due to markedly reduced movement at the elbow (see Chapter 14.2). Otherwise, give an anti-staphylococcal antibiotic, such as di- or flucloxacillin 500 mg orally qid for 10 days in an immunocompetent patient +/– a non-steroidal anti-inflammatory analgesic and refer back to the

GP.[19] Immunosuppressed patients warrant initial intravenous therapy if a septic bursitis cannot be excluded.

Prepatellar bursitis (housemaid's knee)

Diagnosis and management

This is a prepatellar bursitis secondary to friction or, occasionally, infection. Treat by giving an anti-inflammatory analgesic, avoiding further trauma.[20] If initial treatment fails and infection has been excluded, consider a steroid injection[20] by an orthopaedic or rheumatology specialist, or by arrangement with the patient's GP. When local infection is suspected, aspirate, if possible, for culture, microscopy and crystals, and start an anti-staphylococcal antibiotic, such as di- or flucloxacillin 500 mg orally qid for 10 days and refer back to the GP.

Refer the patient to the orthopaedic specialist for intravenous antibiotics and/or local drainage if systemic infection is suspected.

De Quervain stenosing tenosynovitis

Diagnosis and management

This causes tenderness over the radial styloid, a palpable nodule from thickening of the fibrous sheaths of the abductor pollicis longus and extensor pollicis brevis tendons and pain on moving the thumb. Treat by resting the thumb in a splint and by using an anti-inflammatory analgesic.[21]

Refer to a rheumatology specialist for consideration of a local steroid injection, although it may require surgical release of the tendon sheaths if the local steroid injection fails.[21]

Plantar fasciitis

Diagnosis and management

Plantar fasciitis presents as a painful midfoot, especially in the sole or arch, which is worse on first weight bearing and improves after 10 to 15 minutes of walking, and recurs during load bearing for an extended period. It is one of the most common causes of recurrent foot pain and may be one manifestation of the spondyloarthropathy seen in Reiter syndrome, ankylosing spondylitis and psoriatic arthritis (see Chapter 14.3). It also can be triggered by an acute increase in exercise. On examination, there is tenderness of the plantar fascia, especially at the calcaneal attachment.[22]

An x-ray may reveal a bony spur extending along the plantar fascia, but this has no bearing on the initial management. There is poor evidence for any specific therapy; however, expert opinion recommends orthoses (over-the-counter has been found to be better than custom fitted in one study), reduction in activity and NSAIDs.[22]

Carpal tunnel syndrome

Diagnosis and management

This is a compressive neuropathy of the median nerve at the wrist, most commonly affecting middle-aged females. Secondary causes include rheumatoid arthritis, diabetes, post-trauma, such as a Colles fracture, pregnancy and—rarely—myxoedema, acromegaly and amyloidosis. However, most cases are idiopathic or related to minor repetitive trauma.[23]

Patients complain of pain and burning paraesthesia in the distribution of the median nerve in the hand, primarily the thumb, index, middle and lateral aspect of the ring finger. It is typically worse at night or following repetitive strain, especially with higher loads or vibrating tools.[23]

Perform Phalen's test by reproducing paraesthesia in the distribution of the median nerve following 60 degrees of wrist hyperflexion, or look for Tinel's sign eliciting median nerve paraesthesia by tapping on the volar aspect of the wrist over the median nerve. Test for reduced sensation over the palmar aspect of the affected digits and weakness of thumb abduction, associated with thenar muscle wasting in chronic cases.

Treat with an anti-inflammatory analgesic and immobilize the wrist in a volar splint in the neutral position, particularly at night. Refer resistant cases to an orthopaedic specialist for consideration of steroid injection or carpal tunnel decompression.[23]

BACK PAIN

This is a common problem that usually simply requires analgesia and patient education. Assessment is targeted at determining whether concerning features, 'red flags', are present which mandate further investigation. Back pain may be subdivided into four major categories:

- direct major spinal trauma
- indirect mechanical back trauma (non-specific low back pain)
- back pain with radiculopathy
- back pain with focal 'hard' neurology, or a specific serious cause suspected.

Direct major thoracic and lumbosacral spine trauma is covered in Chapter 3.3.

Back pain 'red flags'

Every patient presenting to the ED with acute low back pain must be assessed for the presence of 'red flag' symptoms or signs suggesting a potentially serious underlying cause[24]:

- Signs and symptoms of infection and/or high-risk factors for spinal infection
- Signs and symptoms of spondyloarthritis
- New or progressive neurological deficit:
- History of malignancy
- Significant trauma
- Unexpected weight loss
- Elderly, corticosteroid use and/or other osteoporotic risk factors.

Although the majority will end up having a diagnosis of musculoskeletal pain, laboratory testing and/or imaging is indicated when red flags are present. See Table 14.4.4 for the differential diagnosis and investigation.

Indirect mechanical back trauma (non-specific low back pain)

Clinical features

History

Bending, lifting, straining, coughing or sneezing may precipitate acute, severe low back pain, causing intense muscle spasm or even complete immobility. It is common for patients to have apparently minor back discomfort on one day, then wake with severe spasm the next.

Examination

This is focused on excluding any focal 'hard' neurology or radiculopathy. Giving adequate analgesia so that pain does not limit strength is an important part of the assessment. See Chapter 3.3 for a description of the myotomes, dermatomes and nerve roots in the leg.

Hard neurology is characterized by the loss of sensation, reflexes or true weakness. A radiculopathy is characterized by pain or subjective altered sensation following a dermatome. These should both be absent. Imaging is not usually indicated unless symptoms are continuous for greater than 6 weeks and are not previously investigated.

Management

The mainstay of management is patient education along with adequate analgesia to allow active physical therapy.[25] The ED management consists of excluding more serious causes, then educating and reassuring the patient while ensuring adequate analgesia to allow movement. Analgesic best evidence is for NSAIDs in isolation.[25] Paracetamol as a sole agent has been found not to be effective at the 3-week follow-up and is not recommended by some guidelines.[26] However, if stronger analgesia is required it should be used as the short-term effect on pain was not studied. Muscle relaxants have been found to be effective for short-term analgesia but often have significant side effects; if needed, try baclofen 10mg tds.[27] Opiates are not recommended[25] but are often required for the subset of patients who have presented to an ED; aim to minimize duration of therapy with these agents. Short-acting opiates may be required to allow adequate physical exam by ensuring

Table 14.4.4 Differential diagnosis and investigation of serious disorders causing back pain

Suspected diagnosis	*History/symptoms/findings*	*Investigations*
Infection Osteomyelitis Discitis Epidural abscess	Fever IVDU Immunosuppression Recent instrumentation or infection Hard or progressive neurology	FBC/CRP/ESR ESR most sensitive Blood culture MRI best imaging
Cancer Primary Secondary	Previous cancer Unexplained weight loss Age >50 (65 in some series) Failure to improve after 4–6 weeks	XR MRI if neurology
Spinal cord compression Cauda equina Infections as above	Urinary retention Incontinence (bladder or bowel) Saddle anaesthesia Sensory &/or motor level (NB often patchy in cauda equina or epidural abscess)	MRI
Fracture	Osteoporosis Long term steroid use Pain significant at rest	XR + CT if >50% height loss or retropulsed fragments
Ankylosing spondylitis	Age <30 Pain worse at night Morning stiffness Improves with exercise	ESR/CRP HLA-B27 Pelvis XR
Spinal stenosis	Leg pain >> back pain Pseudoclaudication No pain when patient is seated Thigh pain after 30s lumbar extension	CT MRI if neurology

CRP, C-reactive protein; *CT*, computer aided tomography; *ESR*, erythrocyte sedimentation rate; *FBC*, full blood count; *IVDU*, intravenous drug user; *MRI*, magnetic resonance imaging; *XR*, x-ray.

strength is not limited by pain. Benzodiazepines are often used[28] but have not been found to be effective by any well-performed studies [29]; only consider their use as an adjunct in the setting of high patient anxiety.

Patients who are able to mobilize without more complex analgesic regimes may be discharged to the care of their GP for ongoing follow-up and education concerning posture and lifting. Patients who require ongoing opiate analgesia will require admission, either to an ED short-stay ward for nursing care and regular analgesia prior to physiotherapy review, or to an inpatient ward according to hospital policy, most commonly under orthopaedics or general medicine.

Back pain with radiculopathy

Clinical features

These patients not only have a similar presentation to those with non-specific low back pain, but also have neuropathic pain following one or more lower leg dermatomes. Examination may reveal subjectively altered sensation but with intact sharp/dull (or hot/cold), 2-point discrimination and proprioception. Straight-leg raising may exacerbate radicular symptoms. Strength and reflexes are also intact, with no reported incontinence or urinary retention.

Imaging is again not indicated unless symptoms are progressing with increasing numbers of dermatomes or there are continuous symptoms for more than 6 weeks.

Management

Management is the same as for non-specific back pain, with the addition of more specific neuropathic pain analgesia, such as pregabalin 25 to 75 mg bd or amitriptyline 10 to 25 mg nocte (lower doses in older patients +/– tapentadol SR 50 mg bd or tramadol 100 to 200 mg SR bd).

Back pain with focal 'hard' neurology, or a specific serious cause suspected

This small group of patients with hard neurology consisting of true weakness, loss of sensation and/or reflexes requires further investigation and specialist referral (usually neurosurgery or orthopaedics). The timing of this investigation will depend on the acuity and extent of the symptoms or signs. Acute onset or ongoing progression mandate emergent investigation and referral for treatment. Subacute or chronic symptoms (especially if from a single nerve root) may be investigated and managed on a less urgent basis in discussion with the specialist team, particularly if they are unlikely to be reversible.

Other patients with 'red flag' symptoms or signs also must be investigated urgently (see Table 14.4.4). They may have any of the following conditions.

Spinal infection

Clinical features

Spinal infections include epidural abscess, discitis and vertebral osteomyelitis. Risk factors are recent instrumentation (prolonged epidural catheter > surgery > brief, such as obstetric epidural catheter), immunosuppression, alcoholism, diabetes, intravenous drug use, contiguous infection or distal infection with bacteraemia. The classic progression of symptoms is from back pain to radiculopathy, to weakness, to paralysis with progression from radiculopathy to paralysis sometimes occurring over hours. Fever is absent in over one-third of cases.

Investigations

A normal white cell count (WCC), erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) virtually exclude the diagnosis, with ESR being the most sensitive and WCC the least. Blood cultures should be taken, although CT-guided or surgical specimens are more likely to culture the causative microbe. MRI is the imaging modality of choice to confirm or exclude the diagnosis.

Management

Progressive neurology requires urgent operative intervention with the decision on which antibiotic(s) prior to surgery discussed with the treating team. In patients without neurology, the treating team may elect to manage conservatively. Empirical antibiotic therapy is targeted at skin flora, including methicillin-resistant *Staphylococcus aureus* (MRSA) and dental flora, unless it is suspected that is has spread from a focal infection, such as *Escherichia coli* or *Streptococcus pneumoniae*.

Spinal cancer

Clinical features

Acute symptoms are most likely in the setting of previous cancer, particularly those that metastasize to bone (lung, breast, prostate, renal, thyroid and melanoma). Unexplained weight loss, age >50 years and symptoms failing to improve after 1 month, are risk factors. Examination should thus include skin (melanoma), breasts, chest, abdomen and prostate to look for a primary tumour.

Investigations

Plain x-ray may be adequate to find a bony lesion, but more information with high sensitivity is obtained from CT scanning. An MRI is indicated if there is any focal neurology.

Management

If cancer is found or is highly suspicious, admit the patient to hospital. Spinal cord compression may respond to radiotherapy and a pathological fracture may require stabilization. Otherwise, management is with analgesia, and the investigation is aimed at determining the primary tumour, which will dictate the definitive treatment.

Fracture (vertebral compression)

Clinical features

Suspect this with significant pain at rest, long-term steroid use or known osteoporosis even with minor trauma. Examination is aimed at excluding focal neurological complications.

Investigations

Plain x-ray is the initial investigation. CT is indicated if there is greater than 50% vertebral height loss or retropulsion of fragments into the spinal canal is noted.

Management

Analgesia is as per non-specific back pain. It is extremely rare for these injuries to be unstable or to require immobilization or surgical stabilization, although admission for analgesia and bedrest may be necessary.

Spinal cord compression or cauda equina syndrome

Clinical features

Spinal cord compression or cauda equina syndrome (lesion at or below the first lumbar vertebra) may be due to tumour, infection or central disc prolapse. Urinary retention is the most sensitive sign of cauda equina syndrome, which is seen in ≈90% of cases. A history of incontinence and perineal or perianal 'saddle area' anaesthesia or bilateral leg weakness may also occur. The neurology findings will correspond to a specific level in the case of spinal cord compression, but may be inconsistent and patchy in cauda equina syndrome.

Investigation

Urgent MRI is the investigation of choice, with CT of some value, particularly if bony injury is suspected or if MRI is unavailable. Imaging should not delay urgent transfer to definitive treatment under the care of a spinal surgeon.

Management

Urgent surgery. Corticosteroids are not supported unless due to a steroid-responsive tumour.

Ankylosing spondylitis

Clinical features

Ankylosing spondylitis is a chronic inflammatory enthesopathy affecting the axial skeleton. It usually occurs in males (5:1) below the age of 30 years, causing pain that improves with exercise and worsens with rest, sometimes resulting in waking in the second half of the night due to discomfort. Examination may be unremarkable or show a general decreased range of spinal motion in more advanced cases.

Investigations

The ESR and CRP are usually raised. HLA-B27 is sensitive for the disease and is present in around 95% of Caucasian and Chinese patients. Pelvic x-ray often shows sacroiliitis.

Management

Commence NSAIDs at a maximum dose and refer to rheumatology outpatients follow-up. Regular physiotherapy including hydrotherapy is essential.

CONTROVERSIES

- Indications for surgical versus conservative management for soft tissue or chronic overuse injuries, particularly in elite athletes/young manual workers to reduce the time to return to elite or work activity.
- Who should perform joint aspiration and/or intra-articular/intralesional steroid injections and their safety.
- Sensitivity of inflammatory markers to exclude spinal infection.

Testing passive external rotation of the glenohumeral joint (eFigs. 14.4.1 and 14.4.2)

Have the patient sit or stand comfortably with their arm by their side. The exam is most easily performed with the examiner standing either behind the shoulder to be examined or slightly further to the side. It can be done from in front of the patient, in which case the actions of each hand will need to be reversed

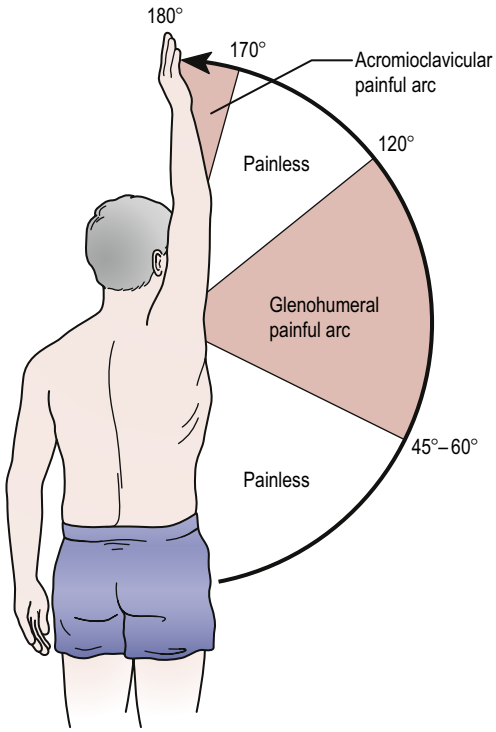
Place the opposite hand (i.e. if examining a right shoulder, use your left hand) over the top of the shoulder to prevent movement of the scapula.

Use the other hand to gently grasp the patient's forearm just distal to the elbow and flex the patient's elbow to 90 degrees.

Then assess the passive range of motion of external rotation at the glenohumeral joint.

Painful arc of the shoulder

The patient actively abducts their shoulder from by their side to overhead. Pain through the arc of 60 to 120 degrees abduction is indicative of subacromial pathology (e.g. supraspinatus tendonitis, subacromial bursitis). Pain in the last 10 to 15 degrees is indicative of acromio-clavicular joint pathology.



EFIG. 14.4.1 Painful arc of the glenohumeral joint on abduction ~60 to 120 degrees is due to subacromial pathology, ~170 to 180 degrees is due to acromio-clavicular joint pathology. (From Magee DJ. *Orthopedic Physical Assessment*. 4th ed. Philadelphia, PA: Saunders; 2002, with permission.)

EFIG. 14.4.2 Testing passive external rotation of the glenohumeral joint while standing behind (A) or in front of the patient (B). The patient's elbow is kept by their side during the test and scapulothoracic movement is prevented/detected by the hand placed over the shoulder.

SECTION 15

DERMATOLOGY EMERGENCIES

Edited by *Biswadev Mitra*

15.1 Emergency dermatology

Ryan De Cruz • Vanessa Morgan • George Varigos

ESSENTIALS

1 **Emergency dermatology presentations may be divided into potentially life-threatening dermatoses, vesiculo-bullous conditions, petechial and purpuric rashes, and inflammatory dermatoses such as eczema, urticaria and psoriasis.**

2 **Potentially life-threatening presentations include Stevens-Johnson syndrome, toxic epidermal necrolysis (TEN), Sweet syndrome, drug rash with eosinophilia and systemic symptoms (DRESS) and erythroderma.**

3 **Petechial or purpuric rashes may represent cutaneous or systemic vasculitis, or coagulopathy; investigations are targeted at internal organ involvement, and management is multidisciplinary.**

4 **Cutaneous infections may be a primary presentation or a secondary complication of a primary dermatosis.**

Introduction

The pattern and form of acute dermatological conditions that present to the emergency department (ED) are confusing in that the clinical features, such as vasodilatation, exfoliation, blistering or necrosis, are the common endpoint of many different inflammatory processes in the skin.

The pathological process involves cytokines or chemokines and their effects create the visible response(s). The important clinical differences seen in these acute reactions should be recognized by the trained observer (Tables 15.1.1 and 15.1.2). This chapter aims to provide a clinical pathway from taking an appropriate history to having knowledge of the distinguishing clinical features of the likely differential diagnoses. The emergency presentations discussed are limited to specific dermatological conditions that may be seen in an ED as a true urgency.

It is important to use other resources with this chapter, such as a dermatology atlas or specialized texts, to provide greater detail on the conditions mentioned. The presentation of skin and soft-tissue infections (Chapter 9.5) and anaphylaxis (Chapter 2.8) are covered elsewhere.

POTENTIALLY LIFE-THREATENING DERMATOSES

Stevens-Johnson syndrome and toxic epidermal necrolysis

Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are acute severe cutaneous presentations characterized by extensive necrosis and detachment of the epidermis. Confusion exists between these two diagnoses and erythema multiforme (EM). EM was previously considered a variant of SJS/TEN, but it is now commonly accepted that they are clinically distinct disorders with different aetiologies and prognosis. Most consider EM minor and major to be related to infections (e.g. herpes simplex virus [HSV]); whereas SJS/TEN are variants of the same disorder defined by severity and are usually caused by drugs. SJS is also known to be triggered by mycoplasma infections. The distinction between EM major, SJS and early TEN is not important in the emergency setting; rather it is the recognition of a potentially serious dermatosis that is important, and the need for comprehensive assessment and monitoring.

The difference between SJS and TEN is defined by the extent of skin involvement. SJS affects 10% or less of the total body surface area (TBSA), whereas TEN affects more than 30% TBSA (Fig. 15.1.1). 'TEN/SJS overlap' refers to patients where there is between 10% and 30% TBSA involvement. The extent of necrolysis must be carefully evaluated since it is a major prognostic factor. Patients with HIV, over age 65 and those with malignancy are at increased risk of TEN.

Clinical features

Clinical features of SJS/TEN include a prodrome with upper respiratory tract (URTI)-like symptoms, fever, malaise, vomiting and diarrhoea. Skin pain may herald the development of SJS/TEN and is a sensitive sign of impending epidermal detachment. Symmetrical erythematous macules, mainly localized on the trunk and proximal limbs, evolve progressively to dusky erythema and confluent flaccid blisters leading to epidermal detachment.

Table 15.1.1 Definition of macroscopic skin pathological lesions

Papule	*Circumscribed firm raised elevation, less than 0.5 cm in diameter*
Nodule	A solid or firm mass more than 0.5 cm in the skin, which can be observed as an elevation or can be palpated
Purpura	Red-purple discoloration of skin or mucous membranes due to extravasation of red blood cells
Pustule	An accumulation of yellow-white fluid within a vesicle or papule; may be centred around a pore, such as a hair follicle or sweat glands, and sometimes appears in normal skin, including the palms and soles
Vesicle (s)	A visible accumulation of fluid in a papule of <5 mm The fluid is clear, serous-like and is located within or beneath the epidermis
Bulla (ae)	Large fluid-containing lesion of >5 mm
Plaque	An area or sheet of skin elevated and with a distinct edge, of any shape and usually wider than 1 cm

(Modified with permission from Rook AJ, Burton JL, Champion RH, Ebling FJG. Diagnosis of skin disease. In: Bolognia J, Jorizzo J, Rapini R, eds. *Textbook of Dermatology*. Oxford: Blackwell Scientific; 1992.)

Table 15.1.2 Definitions of patterns in skin disorders

Annular	Ring-like or part of a circle
Linear	Line-like
Arcuate	Arch-like
Grouped	Local collection of similar lesions
Unilateral	One side
Symmetrical	Both sides

FIG. 15.1.1 Toxic epidermal necrolysis.

The key to making the diagnosis is recognizing mucosal involvement, which may include conjunctival, oral mucosal, genital and sometimes perianal erosions, as well as an often severe haemorrhagic cheilitis. Gastrointestinal and respiratory mucosa can also be involved. 'Nikolsky sign' is the dislodgement of the epidermis by lateral finger pressure causing an erosion or lateral extension of the blister. It is a key finding in TEN.

TEN is almost always due to a drug which may, in rare instances, include illicit drug ingestion. Therefore ask about prescribed and over-the-counter drugs, such as non-steroidal anti-inflammatory drugs (NSAIDs), sulphonamides, allopurinol, nevirapine and anticonvulsants, such as sodium valproate and lamotrigine, as well as illicit drug use.

Investigations

Request a full blood examination (FBE), urea and electrolytes (U&E), liver function tests (LFT) and a blood glucose. These may also be used to calculate the prognostic SCORTEN (see below). Other tests to consider include antinuclear antibody (ANA), extractable nuclear antigens (ENA), C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), anti-skin antibodies, HIV and mycoplasma serology. Skin swabs for viral polymerase chain reaction (PCR) and bacterial culture should be taken, and chest x-ray (CXR), urine and blood cultures as indicated.

Biopsies are taken from the edge of a blister for histology and a perilesional site for direct immunofluorescence. Clearly state on the request slip that the differential diagnosis is of TEN. Epidermal (keratinocyte) necrosis is the histological hallmark of this condition.

Management

Cease the triggering drug or agent immediately and involve the intensive care unit and/or the burns unit early. Rapid institution of resuscitation measures is associated with a more favourable prognosis. Arrange assessment and treatment by the ophthalmology and ear, nose and throat teams for ocular and oral/pharyngeal involvement, respectively; urological and/or gynaecological review of patients with TEN is essential to prevent genito-urinary scarring.

TEN may continue to evolve and extend over days, unlike a burn, where the initial insult occurs at a defined time. The SCORTEN severity scoring system for TEN (Box 15.1.1) is similar in concept to the Ranson's score for pancreatitis. Calculate the SCORTEN severity score within 24 hours of admission and again on day 3 to aid the prediction of possible death (Table 15.1.3).

Box 15.1.1 SCORTEN severity score for toxic epidermal necrolysis

- Age >40 years
- Heart rate >120/min
- Presence of cancer or haematological malignancy
- Epidermal detachment involving body surface area >10% on day 1
- Blood urea nitrogen >10 mmol/L (28 mg/dL)
- Glucose >14 mmol/L (252 mg/dL)
- Bicarbonate <20 mEq/L

(One point is given for each variable)

Table 15.1.3 SCORTEN mortality prediction

Score	*Mortality (%)*
0–1	3.2
2	12.1
3	35.3
4	58.3
5 or greater	90.0

(Reproduced with permission from Guégan S, Bastuji-Garin S, Poszepczynska-Guigné E, et al. Performance of the SCORTEN during the first five days of hospitalization to predict the prognosis of epidermal necrolysis. *J Invest Dermatol*. 2006;126:272–276.)

Erythema multiforme

While not life threatening, EM is part of the differential of a potentially life-threatening reaction, such as SJS/TEN. EM is an acute usually mild, self-limited cutaneous and/or mucocutaneous syndrome that presents with the rapid onset of lesions within a few days, favouring acral sites. These are often mildly pruritic or painful papular or urticarial lesions, as well as the classical 'target' lesions, but with only one mucous membrane involved (EM major) or none (EM minor). Typically, the oral mucosa is involved showing a few, discrete, mildly symptomatic erosions. Rarely, the eye, nasal, urethral or anal mucosa may be involved. A mild prodrome may precede development of the rash.

FIG. 15.1.2 Erythema multiforme.

Most cases of EM are due to infection, most commonly HSV or mycoplasma. Drugs are now considered to be an uncommon cause (Fig. 15.1.2).

Investigations

Send a baseline FBE, U&E, LFT and CRP, as well as a skin biopsy if the diagnosis is uncertain, swabs for HSV PCR. Request a CXR and mycoplasma serology if there are respiratory symptoms.

Management

Usually, only symptomatic treatment is required with topical steroids, antihistamines, antiseptic mouthwashes and local anaesthetic preparations for oral involvement. For severe cases, treat EM with a systemic steroid, such as prednisolone (0.5 to 1 mg/kg/day). In recurrent EM due to HSV, oral antivirals are effective at preventing relapse.

Sweet syndrome

Sweet syndrome (acute febrile neutrophilic dermatosis) may resemble severe EM in the acute oedematous phase, presenting variably with fevers, arthralgias, sterile potentially painful pustules, plaques or nodules over the head, trunk and arms. The red-purple plaques/nodules are often referred to as 'juicy' indicating they are soft and pus-filled though not truly fluctuant.

Sweet syndrome is often a relapsing-remitting presentation that may be associated with an underlying haematological malignancy inflammatory bowel disease, rheumatoid arthritis or other connective tissue disease, pregnancy or infection, such as *Streptococcus* or *Yersinia* (Fig. 15.1.3).

FIG. 15.1.3 Sweet syndrome.

Sweet syndrome is highly responsive to systemic steroids; however, any underlying association must be sought and excluded by appropriate investigations.

Drug rash with eosinophilia

Drug rash with eosinophilia and systemic symptom (DRESS) is a severe skin reaction to a drug with systemic manifestations that carries significant morbidity and a mortality rate of 10%. It typically occurs within 2 to 6 weeks of drug initiation. It has been reported with the antiepileptics (phenytoin, carbamazepine, phenobarbital), lamotrigine, sulphonamides (including sulphamethoxazole and trimethoprim combinations and dapsone), minocycline, allopurinol, terbinafine, abacavir and nevirapine. Up to 70% cross-reactivity occurs between different aromatic anticonvulsants, which should therefore be avoided if someone has previously had a major reaction to an aromatic antiepileptic.

Fever and rash are the most common symptoms. Cutaneous involvement is often polymorphic usually starting as a morbiliform rash, which may later become oedematous, exfoliative or erythrodermic, and/or include non-follicular pustules. Often, rash involving the face indicates a more serious drug reaction and facial oedema and lymphadenopathy are frequent hallmarks of this syndrome.

Prominent eosinophilia is a characteristic feature that occurs in 60% to 70% of cases. Potentially serious internal organ involvement, such as hepatitis, nephritis, pneumonitis, myocarditis, thyroiditis and encephalitis can occur. Fever, skin rash and organ involvement may fluctuate and persist for weeks or months after drug withdrawal, with the delayed onset of sequelae reported.

Investigations

Diagnosis can be difficult because of the polymorphic rash and variable organ involvement. A skin biopsy should be taken for histopathology and, although not diagnostic, histological features of a drug reaction will assist in making the diagnosis. Also request a baseline FBE, U&E and LFT. Immunoglobulins and viral serology (Epstein–Barr virus, cytomegalovirus, human herpesvirus 6 or 7 [HHV6, HHV7]) should be sent, as transient hypogammaglobulinaemia and viral reactivation may be associated with fluctuations in symptoms. Other investigations should be as directed for systemic involvement, including baseline CXR, electrocardiogram (ECG) and Thyroid Stimulating Hormone (TSH).

Management

This usually includes admission to hospital and ceasing the suspected drug. Corticosteroids are the first line of therapy despite no consensus on dose or regimen; a starting dose of 0.5 mg to 1 mg/kg/day is reasonable. Fluctuation in symptoms and relapse can occur when the dosage is tapered. As a result, steroid therapy sometimes has to be maintained for several weeks, even months and a steroid-sparing agent may be required. Topical steroids should always be implemented to assist in systemic steroid tapering. Intravenous immunoglobulin (IVIG) may be required in cases of DRESS with severe systemic involvement such as severe hepatitis.

Erythroderma

The causes of erythroderma include eczema (40%), psoriasis (22%), drugs (15%), lymphoma (Sezary syndrome) (10%) and idiopathic (8%). Seek a history of previous skin disease, recent medications or recent changes to skin management, assess hydration and cardiac status, check for oedema, respiratory infection and a deep vein thrombosis (DVT).

Complications of erythroderma

Include:

- high output cardiac failure
- transepidermal water loss causing intravascular hypovolaemia (dehydration)
- hypoalbuminaemia contributing to intravascular dehydration.
- electrolyte imbalance
- hypothermia/temperature dysregulation
- thrombophlebitis/DVT
- infection, both cutaneous and respiratory, with pneumonia a major cause of death

Table 15.1.4 Causes of petechiae or purpura

Non-palpable purpura					
	Thrombocytopaenic disorders				
	With splenomegaly		*Without splenomegaly*		
Non-thrombocytopaenic	*Normal marrow*	*Abnormal marrow*	*Normal marrow*	*Abnormal marrow*	*Palpable purpura (vasculitis)*

Cutaneous disorders
• Trauma
• Steroids, old age
Systemic disorders
• Uraemia
• von Willebrand disease
• Scurvy, amyloid
	Liver disease with portal hypertension
	Myeloproliferative disorders
	Lymphoproliferative disorders
	Hypersplenism
		Leukaemia
		Lymphoma
		Myeloid metaplasia
			Immune: Idiopathic thrombocytopaenic purpura, drugs, infections including HIV
			Non-immune: Vasculitis, sepsis, disseminated intravascular coagulation, haemolytic-uraemic syndrome, thrombotic thrombocytopaenic purpura
				Cytotoxics
				Aplasia, fibrosis or infiltration
				Alcohol, thiazides
					Polyarteritis nodosa (PAN)
					Leucocytoclastic (allergic)
					Henoch–Schönlein purpura
					Infective:
					• Meningococcaemia
					• Gonococcaemia
					• Other infections
					  • Staphylococcus
					  • Rickettsia (Rocky Mountain spotted fever)
					  • Enteroviruses
					Embolic

Investigations

Request an FBE, U&E, LFTs and blood cultures if the patient's temperature is >38°C, or if the patient appears unwell with rigors, even if the temperature is normal, as the patient may have become poikilothermic but is still septic.

Send skin swabs for Microscopy/Culture/Sensitivities (MCS) and request a CXR. Arrange biopsy of the skin if the cause of the erythroderma is uncertain.

Management

Arrange to admit the patient. Treatment is general and supportive and includes:

- attention to temperature control, avoiding hypothermia
- Intravenous fluid replacement with careful charting of the fluid balance, monitoring urine output in particular
- referral to dietitian for high protein diet in the first 24 hours
- DVT prophylaxis.

Specific treatment includes:

- bath oil daily in bath or shower
- wet wraps three times a day (TDS):
  - **A.** topical corticosteroid (as appropriate) applied liberally
  - **B.** 50% white soft paraffin, 50% liquid paraffin applied liberally
  - **C.** wet tubular bandage or full-length pyjamas
  - **D.** dry tubular bandage or full-length pyjamas
- antibiotics for proven infection.

Supervision should be under the direction of the dermatology team. Intensive care may be necessary.

OTHER BULLOUS AND VESICULAR CONDITIONS

There are many causes of blistering skin rashes that range from common and harmless (but still distressing) to the uncommon and potentially life threatening. See Table 15.1.4 for the differential diagnosis of a vesicobullous rash.

Always ask about recent drug ingestion and about drug allergy in the event that a bacterial skin infection is diagnosed and antibiotics are required.

FIG. 15.1.4 Bullous pemphigoid.

Pemphigus vulgaris

Pemphigus vulgaris is characterized by flaccid bullae and **erosions**, together with oral ulceration. The Nikolsky sign is positive, though true vesicles and bullae are often rare as they often break easily to form erosions. The scalp, oral mucosa and genitals are commonly involved. Vegetating lesions, particularly in flexures, such as the axillae or on the scalp, may occur as 'pemphigus vegetans'.

Investigations

Send blood for U&E, LFTs and random blood glucose (RBG) as a baseline and for thiopurine methyl-transferase (TPMT) levels, reduction of which increases the risk of toxicity if adjuvant immunosuppression with azathioprine if required.

Send a serum autoantibody profile for antiskin antibodies ('anti-epithelial antibodies') directed against desmoglein 1 and 3. Arrange a biopsy of lesional skin for histology and perilesional skin, which should be sent **fresh** and not in formalin, for direct immunofluorescence. An alternative medium is Michel's if fresh transport is not possible.

Management

Start high-dose prednisolone initially at a dose of upto 1 mg/kg/day to achieve remission. Admit the patient under the care of a Dermatologist for consideration of other therapies, such as immunosuppression with mycophenolate mofetil, azathioprine, IVIG or rituximab.

Bullous pemphigoid

The usual presentation is an older patient with tense skin bullae that may occur on an erythematous base or from normal skin. Itch is a common symptom. Blisters may be small (vesicles) or large (bullae) and heal with scarring (Fig. 15.1.4).

Investigations

Send for FBC, electrolytes, urea and creatinine (EUCs), LFTs and RBG level as a baseline, plus serum for indirect immunofluorescence for autoantibodies to Bullous Pemphigoid Antigens 1 & 2 ('anti-basement membrane zone' antibodies). Also send a TPMT level, as adjuvant immunosuppression with azathioprine may be required. Arrange biopsy of an urticated or bullous lesion for histology and perilesional skin for direct immunofluorescence. If this is not possible, blister fluid may be sent for indirect immunofluorescence.

Management

Start prednisolone at a moderate dose, such as 0.5 to 0.75 mg/kg daily. A tetracycline antibiotic, such as doxycycline 100 mg daily and nicotinamide 500 mcg orally tds, may be used for their anti-inflammatory properties as adjuvant therapy. Admit patients for supportive care if blistering is widespread.

In more severe disease, steroid-sparing agents, such as azathioprine, methotrexate or mycophenolate mofetil, may be required. Super-potent topical steroids are also effective and may be used as monotherapy for localized disease.

PETECHIAL AND PURPURIC RASHES

Petechiae, bruising and ecchymoses

Consider and exclude potentially life-threatening causes, such as thrombocytopaenia and vasculitis, platelet abnormalities or over-anticoagulation (see Box 15.1.2 for causes of a petechial or purpuric rash). Take a full drug history, including anticoagulant medications, and ask about systemic symptoms including fever, bleeding tendency, travel history, alcohol abuse and known HIV disease.

'Senile purpura' are usually due to sun damage and ageing with subsequent loss of dermal support for blood vessels, which then bleed into the skin. Sometimes they can be dramatic but are always benign and resolve. When simple trauma is considered, remember non-accidental injury in all cases where the history is suspicious, 'hollow' or changes over time.

Cutaneous vasculitis

There are many potential causes of cutaneous vasculitis, such as drug-induced, viral and bacterial infections, autoimmune and connective tissue diseases including systemic lupus erythematosus (SLE), rheumatoid arthritis and inflammatory bowel disease, systemic vasculitis such as the antinuclear cytoplasmic antibodies (ANCA)-associated vasculitides, and polyarteritis nodosa. Rarely, malignancies and leukaemia may trigger a paraneoplastic vasculitis.

However, 50% of all cases of cutaneous small vessel vasculitis remain of undetermined aetiology or 'idiopathic' after extensive investigation, and are presumed to be of post-infectious origin. Cutaneous vasculitis is clinically best diagnosed when lesions are palpable and on the lower limbs, although they may spread to the buttocks and arms (Fig. 15.1.5). Sharp edges with stellate or irregular shapes (referred to as 'retiform purpura') indicate full thickness ischaemia and are a sinister sign of small-medium vessel thrombo-embolic occlusions; for example, meningococcal infection, and calciphylaxis in, for instance, chronic renal failure.

Pyoderma gangrenosum

An acute presentation of pyoderma gangrenosum is frequently a differential diagnosis of cutaneous vasculitis. It may begin as a discrete painful haemorrhagic pustule or grouped lesions that rapidly ulcerate, usually on the lower leg, causing larger lesions with neutrophilic inflammation with abscesses and necrosis, but no vasculitis on biopsy. It may be associated with inflammatory bowel disease, rheumatoid arthritis, blood dyscrasias, Behçet syndrome and malignancy, such as myeloma and leukaemia (Fig. 15.1.6).

Investigations for vasculitis

Send blood for a vasculitis screen including FBC, ESR, CRP, U&E, LFTs, hepatitis B and C serology, ANA, rheumatoid factor, ANCA, antistreptolysin O (ASO) titre, cryoglobulin screen, anticardiolipin and antiphospholipid screen, serum protein electrophoresis and complement (C_3/C_4) levels.

Send two sets of blood cultures prior to any antibiotic therapy, such as ceftriaxone 2 g intravenously, if meningococcal infection is possible. Send a fresh urine specimen for phase contrast

Box 15.1.2 Causes of a vesicular or bullous skin rash

Most common	Less common	Rare
Viral: • herpes zoster • herpes simplex Impetigo Scabies Insect bites and papular urticaria Bullous eczema and pompholyx Drugs: • sulphonamides • penicillin • barbiturates	Erythema multiforme major ('target lesions' rash, plus one mucous membrane involved) or erythema multiforme minor (1–2 cm 'target lesions' only): • mycoplasma pneumonia • herpes simplex • drugs such as sulphur, penicillins • idiopathic (50%) SJS and TEN with epidermal detachment and mucosal erosions: • drugs such as anticonvulsants, sulphonamides, NSAIDs and penicillins Staphylococcal scalded-skin syndrome (children) Dermatitis herpetiformis (gluten sensitivity) Pemphigus and pemphigoid	Porphyria cutanea tarda Epidermolysis bullosa

NSAIDs, Non-steroidal anti-inflammatory drugs; *SJS*, Stevens–Johnson syndrome; *TEN*, toxic epidermal necrolysis.

FIG. 15.1.5 Palpable purpura due to vasculitis.

microscopy, looking specifically for glomerular red cells and casts indicating renal involvement.

Arrange a biopsy, although this is usually performed after admission or dermatology referral to clinic. Send a fresh specimen for both immunofluorescence (Henoch–Schönlein purpura suspected) and culture (infection suspected), as well as a specimen in formalin for histology.

Management

Potential triggers (see above) should be sought and treated appropriately. General measures include rest and elevation of the legs, compression stockings and topical steroids. If systemic treatment is required, NSAIDs may be trialled before prednisolone. Antibiotics, steroids and cytotoxic immunosuppression are indicated based on the aetiology and severity of the disease, in consultation with a dermatologist.

FIG. 15.1.6 Pyoderma gangrenosum.

PRURITIC (ITCHY) DERMATOSES

Itch can be localized or generalized and may present with or without rash. While not an urgent problem, itch must be recognized as being distressing to the patient. The causes are many and varied and the prevalence of chronic itch (like chronic pain) increases with age. See Box 15.1.3 for causes of pruritus with or without skin disease.

Urticaria

Urticaria may be acute, relapsing or chronic (Fig. 15.1.7). It may also be a warning of impending anaphylaxis that necessitates immediate assessment for upper airway swelling, wheeze and/or hypotension (see Anaphylaxis, Chapter 2.8).

The causes of urticaria are heterogeneous and include immunological such as Immunoglobulin E (IgE-related), immune-complex or autoimmune; or non-immunological including physical, such as cold, heat, sweating, exercise, pressure, sunlight, water and vibration; drug-related, such as NSAIDs and radiocontrast media; or food and food additives. Alternatively, urticaria may be related to an underlying systemic condition such as infection, SLE or other vasculitis, malignancy including lymphoma, or urticaria pigmentosa (mastocytosis).

However, in many acute cases, no clear cause is found, and it is labelled 'idiopathic'. In chronic urticaria, defined as lasting more than 6 weeks, there is frequently no known aetiology, although autoimmune causes are eventually found in 30% to 40%. Classic urticaria appears as welts that are migratory and pruritic, and resolve without purpura/scars. High-dose antihistamines (2 to 4× the usual dose) are essential with or without concomitant oral prednisolone.

Box 15.1.3 Causes of pruritus with, and without, skin disease

With skin disease	Without skin disease
Drugs, scabies, pediculosis, insect bites, parasites (roundworm)	Hepatobiliary—jaundice, including primary biliary cirrhosis
Eczema	Chronic renal failure
Contact dermatitis	Haematological: • lymphoma • polycythaemia rubra vera
Urticaria	Endocrine: • myxoedema • thyrotoxicosis
Lichen planus	Carcinoma: • lung • stomach
Pityriasis rosea ('Herald' patch)	Drugs
Dermatitis herpetiformis (gluten sensitivity)	

FIG. 15.1.7 Urticaria.

Scabies

Scabies is a common parasitic infection that must be considered in any patient presenting with itch. It is more common in the elderly, particularly nursing home residents, and returned travellers (both domestic and international.) Scabies may present with an eczematous and/or urticarial picture, usually without a pre-existing history of eczema. Diagnosis requires careful examination of finger web spaces, flexures, wrists and the instep of the feet, for scabies burrows, and the penis and scrotum for scabetic nodules.

Crusted 'Norwegian' scabies is predisposed to by glucocorticoid therapy, organ transplant and HIV infection and in the elderly. Application of 5% permethrin cream from neck down for 42 hours, and repeated in 1 week, is first-line therapy. Oral ivermectin (200 mcg/kg) PO stat and repeated in 1 week should be considered as second-line therapy or in severe cases (Fig. 15.1.8).

Tinea

Tinea incognito refers to tinea corporis, which has been suppressed and modified in appearance due to the inappropriate use of topical steroids. The topical steroid suppresses the erythema and allows for excessive growth of the causative fungus. It is common in the feet (tinea pedis), hands (tinea manus) and genitals/buttocks (tinea cruris) especially in diabetics, the elderly and immunocompromised patients.

Investigations for pruritus

Send blood for the following:

- FBE for eosinophilia (a non-specific finding seen in atopy, scabies and parasitic infections) and to look for iron-deficiency anaemia
- iron studies for deficiency (a very common cause of pruritus)
- glucose level to screen for diabetes

FIG. 15.1.8 Crusted 'Norwegian' scabies.

- EUC to exclude renal failure
- LFTs to exclude hepatic impairment with jaundice, including primary biliary cirrhosis
- serum protein electrophoresis to look for a monoclonal gammopathy, particularly in patients over 70 years
- thyroid stimulating hormone to exclude hypothyroidism or hyperthyroidism
- coeliac serology, such as I Immunoglobulin A (gA) tissue transglutaminase antibodies.

Take skin scrapes from any suspicious areas for fungal culture and microscopy. In suspected scabies, send material to look for scabies mites, eggs or faeces on microscopy.

Management

General measures include avoiding triggers, in particular overheating and over-drying. Rehydrating the skin with good emollient is essential. Antihistamines for short-term use, particularly if sleep is impaired, such as promethazine 10 mg 8-hourly or chlorpheniramine 4 mg 6-hourly, with a clear warning to avoid alcohol and not to drive or operate machinery.

Attempt to identify a cause in every case. **Resist prescribing prednisolone for an itchy dermatosis when no cause has been identified.** Arrange appropriate investigations and refer the patient for dermatological follow-up.

ECZEMA AND PSORIASIS

Eczema

Atopic eczema is a common skin complaint often affecting the flexures (Fig. 15.1.9). It may present as an emergency in a number of ways. See Table 15.1.5 for an overview of aetiology, clinical features and management principles.

FIG. 15.1.9 Atopic flexural eczema.

Eczema is one of the most common causes of erythroderma. See earlier for management principles, which should always involve a dermatologist and may require intensive care unit admission.

Discoid eczema

Discoid eczema presents as discrete coin-like or 'nummular' erythematous plaques that may develop significant exudate and crusting. 'Satellite' lesions are common and skin involvement is often progressive, as one area of involvement 'drives' other areas of skin to become eczematous.

Investigation

Take swabs to exclude staphylococcal super-infection.

Management

Prescribe in bulk quantities a potent topical steroid, such as mometasone furoate 0.1% or betamethasone dipropionate 0.05% cream or ointment. Advise the patient that GENEROUS application once or twice daily may be required until all active eczema is resolved. Aggressive initial management for 2 or more weeks may be required, before gradually tapering topical steroids. Bleach baths are critical (12 mL/10 L water, bath oil and bath salts) as are emollients.

Allergic contact dermatitis

Allergy to plants typically presents in a 'streaky' or linear pattern. A severe facial flare of eczema may suggest an airborne allergen as a trigger. The use of hair dyes following a 'henna tattoo' (which may have been applied months or years before) can result in severe scalp and facial dermatitis, as henna used on hair is adulterated with paraphenylenediamine. The patient becomes sensitized to this compound, which is found in most hair dyes.

Some allergens are activated by the ultraviolet (UV) in sunlight to become symptomatic. This occurs in phytophotodermatitis (often a streaky or linear dermatitis on exposed areas that may be blistered or hyperpigmented), which is seen after contact with photosensitizing compounds found naturally in some plants, fruit and vegetables. Nickel sensitivity is a common cause of reactions to jewellery, particularly costume jewellery and, occasionally, to the clasp of a bra. These causes may or may not be obvious to the patient, so a careful focused history is essential.

Irritant contact dermatitis

The hands are commonly involved and may become secondarily infected. Patients may be severely incapacitated if both hands are affected and may need admission. Patients commonly have an atopic background, especially atopic eczema. Ask the patient how many times he or she washes the hands each day, as irritant contact dermatitis is common in health care workers, new parents and avid gardeners. Soap-free cleansers are critical, as are hand gloves and moisturizers.

Eczema herpeticum

Eczema herpeticum is a widespread herpes simplex infection complicating a pre-existing skin disease, most often atopic eczema. Consider this in any patient with an acute flare of eczema, particularly if the skin is painful. It presents as an acute eruption of monomorphic vesicles and/or erosions often with purulent exudate and crusting, but not necessarily with herpetiform grouping.

Table 15.1.5 Atopic eczema: acute attacks and complications

	Infective eczema	*Erythroderma*		*Acute eczema*	
	Eczema herpeticum	*Impetiginized eczema*	*Unstable eczema*	*Psychological*	*Contact*
Cause	Infection with herpes simplex, varicella, which can rapidly disseminate over the skin	Staphylococcal	Due to many factors systemic or external	Stressors	Allergen?
Examination	Grouped locally or generally Pinhead-sized papules or vesicles Clear or closed pustules Excoriated sharply defined circular erosions	Discharge and weeping Yellow and crusted blisters or erosions	Total body redness Scale or weeping. Pruritus Hypothermia Fever, sepsis	Severe red pruritus Disturbed sleep	Sharp edges Localized
Management	Antivirals if severe, early and eyes at risk	Oral antibiotics. Antiseptic (triclosan) soaks and wet dressings	Admission Oral steroids Ciclosporin	Admission topicals Oral steroids Paraffin, etc.	Oral steroids Admission

A preceding herpetic cold sore may or may not have been present. Some episodes present as a severe systemic illness with high fever, malaise and a widespread generalized eruption. However, there may be no systemic disturbance and the eruption may be quite localized, often to areas of pre-existing eczema.

Ocular HSV infection should be suspected if there is periorbital involvement or if ocular symptoms are present, such as eyelid oedema, tearing, photophobia, chemosis or preauricular lymphadenopathy, whether the eruption involves the face or not. An urgent ophthalmology opinion should be sought for complications, such as corneal ulceration, scarring and blindness.

Investigations

Viral swabs for PCR should be taken of vesicle fluid or the base of an erosion to confirm the diagnosis of HSV. Bacterial superinfection is common, so send a swab for bacterial MCS as well.

Management

Antiviral therapy is essential, such as valaciclovir 1 g TDS for 7 days. Antiviral prophylaxis may be required for recurrent attacks. If secondary bacterial infection is suspected, start an antistaphylococcal antibiotic, such as cephalexin 1 g BD for 5 days. Optimizing the topical management of eczema is also critical.

Psoriasis

Psoriasis may present acutely in the following patterns:

- Erythroderma: an unstable state that may be caused by systemic or external factors, including treatment. Clinically, it is indistinguishable from the other causes of erythroderma, as there is total body redness with no typical features of psoriasis. At presentation, hypothermia, sepsis and high-output cardiac failure must be recognized.
- Pustular psoriasis: triggered by systemic or external factors (including pregnancy), topical treatments, medication and oral steroids. Examination reveals yellow sterile pustules on plaques, diffuse generalized (Fig. 15.1.10) or localized red areas beginning around the paronychium of the digits or pulp. Arthritis may be present, and consider Reiter syndrome if there is a history of gastrointestinal or genitourinary symptoms. Hypocalcaemia may develop if the pustular psoriasis is generalized.
- Immune-activated psoriasis flares: caused by bacterial or viral infective foci in respiratory, bowel, gallbladder or urinary bladder sites. Typically, there are new guttate lesions or flares in old psoriatic plaques. Often there have been similarly triggered attacks in the past. Streptococcal pharyngitis is a common precipitant.
- Flare or rebound psoriasis: following cessation or poor compliance with therapy or after treatment with oral steroids.
- Palmoplantar psoriasis: may be pustular or may show a keratoderma (thickened skin), which can be difficult to distinguish from eczema, or even inflammatory tinea pedis. Patients are debilitated and unable to walk or care for themselves and therefore may require admission.

FIG. 15.1.10 Generalized psoriasis.

Investigations for acute psoriasis

Send blood for FBE, urea, electrolytes and creatinine (UEC) and LFTs, including a serum calcium (which may be low with pustular psoriasis). Send other investigations for systemic complications such as infection, including a skin swab and/or blood cultures, as well as monitoring for the side effects of therapy. A skin biopsy is usually performed in the ward or dermatology clinic if the diagnosis is in doubt.

Management

Treatments include UV therapy, methotrexate, cyclosporin, acitretin or biological therapy. These all require a dermatology consultation and careful review of past treatment. Admission is required if the patient has extensive areas involved, is systemically unwell or unable to manage at home.

Rotating therapies in psoriasis may be beneficial and a past treatment failure does not necessarily indicate that treatment will always be ineffective.

OTHER DERMATOSES

Skin cancer

Patients may present to an ED with lesions they, or a concerned family member or partner, are worried about. Important differential diagnoses not to miss include melanoma and non-melanoma skin cancer, including squamous cell and basal cell carcinoma. Refer the patient for prompt assessment by a dermatologist if the lesion looks suspicious, which will usually require a biopsy.

Herpes zoster

The first manifestation of herpes zoster is usually pain, which may be severe and accompanied by fever, headache, malaise and regional lymphadenopathy. Closely grouped red papules evolve to classical vesicles and then often pustules, in a dermatomal distribution. Rarely, the eruption may be multi-dermatomal or bilateral, particularly if the patient is immunosuppressed.

Diagnosis can be a challenge unless the dermatomal distribution of the eruption is appreciated. Vesicles on the side of the nose indicate involvement of the nasociliary branch of the ophthalmic division of the trigeminal nerve, which also innervates the cornea. Nasal herpetic infection (Hutchinson sign) may precede or accompany ophthalmic involvement, which necessitates urgent ophthalmological referral. Vesicles within the external auditory meatus associated with deep ear pain and lower motor neuron facial nerve palsy is the classic triad of Ramsay Hunt syndrome. Early diagnosis, and treatment with oral prednisolone and antivirals, is indicated.

Investigations

Take swabs for bacterial MCS and viral PCR for VZV to confirm the diagnosis.

Management

Prompt treatment with antiviral medication, such as famciclovir 250 mg tds, when seen within 72 hours of vesicle eruption, may prevent post-herpetic neuralgia.

CONTROVERSIES

- The treatment of TEN is controversial, with IVIG, prednisolone and cyclosporin at one time or another being advocated and then discredited. Currently, evidence suggests that IVIG improves survival. Qualifying criteria for IVIG therapy for TEN or SJS/TEN overlap and include: (1) diagnosis by a dermatologist, (2) body surface area of 10% or more, and (3) evidence of rapid evolution. IVIG should be initiated as quickly as possible, preferably within 24 hours of diagnosis. As it does not always limit the progression of TEN, further investigation is required. Several studies have concluded that corticosteroids did not stop the progression of the disease and were even associated with increased mortality and adverse effects, particularly sepsis.
- The use of immunomodifying agents and immunosuppressants, with their potential for toxicity, opportunistic infections, unusual side effects or severe rebound of cutaneous disease following cessation or poor compliance.
- The take-up of teledermatology makes it easier to obtain a second opinion in isolated areas or to triage patients better for dermatological review. Studies have now shown that teledermatology can provide rapid and accurate diagnosis and treatment advice for dermatological presentations to ED. Research is in progress to improve telemedicine services.

SECTION 16

OCULAR EMERGENCIES

Edited by *Peter Cameron*

16.1 Ocular emergencies

Mark J. Walland • R.C. Andrew Symons • James K. Galbraith • David V. Kaufman

ESSENTIALS

1 Always test and record visual acuity: use pinhole if usual spectacles are not available.

2 Chloramphenicol eyedrops are not a universal panacea.

3 Pain: sharp/scratchy = anterior (cornea or conjunctiva); aching = intraocular (intraocular pressure or inflammation)

Trauma

1 Computed tomography scan/x-ray where bony or globe penetration injury is suspected.

2 Remove prolapsed ocular tissue or protruding foreign bodies only in an operating theatre

3 Copious free irrigation for all corneal acid or alkali burns.

Unilateral red eye

1 Bacterial keratitis requires specific, intensive, antibiotic eyedrops.

2 Acute angle closure produces a hard, inflamed eye with a steamy cornea and a fixed, mid-dilated pupil.

Loss of vision

1 Triage cases of sudden vision change with care: painless can still be urgent.

2 Test the pupils for a relative afferent pupillary defect, which is an objective sign.

3 Local ocular pathology does not cause a visual field defect respecting a vertical midline.

4 Central retinal artery occlusion and endophthalmitis require immediate referral to an ophthalmologist.

5 Recent onset of distorted vision requires ophthalmic review within a few days to exclude exudative age-related macular degeneration.

6 New onset of floaters, particularly in association with flashes, requires dilated examination to exclude retinal detachment.

7 Elderly patients with acute visual failure have giant cell arteritis until proven otherwise and need oral steroid cover until the diagnosis is excluded.

Introduction

Acute ocular presentations are common. A seemingly trivial trauma may mask a more serious underlying injury. Similarly, a relatively transient episode of visual loss with no abnormality found on examination may herald blinding disease. Therefore all eye presentations in an emergency department (ED) should be carefully triaged and evaluated with the necessary equipment. Determine the patient's prior visual status, including the wearing of glasses or contact lenses and the use of any ocular medication, which can provide useful hints.

Basic ocular testing equipment should include:

- Snellen 6-m chart
- black occlusive paddle with multiple pinhole perforations
- slit-lamp biomicroscope: to examine the anterior segment and for removal of foreign bodies
- portable slit lamp: to examine reclining patients
- intraocular pressure (IOP)-measuring device (e.g. Tono-pen or iCare tonometers, which are portable, accurate and easily used)
- Fundus biomicroscopy lens or direct ophthalmoscope

Visual acuity testing

Vision is tested by a distance Snellen chart, using a pinhole device, if necessary, to provide 'corrected' vision: 'The patient sitting at 6 metres sees what a normal person sees at … (record value)' (e.g. 6/18). Vision less than 6/60 Snellen may be graded by the patient's ability to count fingers (CF) at a measured distance, discern hand movements (HM) or to project the direction of a light (PL) from various angles. The eye not being tested must be completely shielded by an opaque occluder.

Emergency eye trolley setup

Examining equipment

- Torch
- Magnifying loupe
- Desmarres lid retractors/lid speculum
- Sterile dressing packs
- Normal saline for irrigation
- Fluorescein strips (sterile)
- Topical anaesthetic (e.g. tetracaine 1%).

Treating

- Mydriatics (dilating): tropicamide 1%, cyclopentolate 1%
- Miotic (constricting): pilocarpine 2%
- Antibiotic ointment (e.g. chloramphenicol)
- Pressure control: acetazolamide 250 mg tablets; ampoules 500 mg (Diamox)
- Eye pads, plastic shields, skin adhesive tape
- Cotton-tipped applicators (sterile)
- 25 G, 23 G disposable hypodermic needles (foreign body removal).

OCULAR TRAUMA

History

The incidence of injuries varies with the environment and protective measures taken. The major injuries result from blunt trauma or penetrating injuries to the globe, with or without the retention of a foreign body. Mechanical interference with eye movement may result from orbital injury, either haematoma or interference with muscle function. Similarly, neuro-trauma may disturb the visual pathways or ocular motor nerves.

Examination

After an eye toilet to remove any debris, clot or glass from the eyelids, acuity is tested. Fresh local anaesthetic drops—preferably single use Minims—may be instilled to ease discomfort. Reassurance and extreme gentleness in subsequently examining the eye will allow a more definite assessment to be made. With penetrating trauma, any external pressure on the eye may result in ocular structures being squeezed out of the wound, drastically worsening the prognosis. Desmarres retractors (Fig. 16.1.1) can be useful to open the lids yet avoid globe pressure. To open lids that are adherent due to blood or discharge, gently bathe with sterile saline. Wipe the eyelid skin dry and apply gentle distractive pressure to skin below the brow and below the lower lid (i.e. over bony orbital rim) to open the lids.

Investigation

If a penetrating injury is suspected, perform a computed tomography (CT) scan or x-ray to exclude a radiopaque intraocular foreign body (IOFB). *If there is any possibility of metallic IOFB, magnetic resonance imaging (MRI) scans are contraindicated.* When an adequate examination cannot be made, or where occult perforation is suspected, examination under anaesthesia is necessary.

FIG. 16.1.1 Desmarres retractors for opening eyelids.

Management of specific injuries

Superficial injury

Corneal abrasion

The corneal epithelium is easily dislodged by a glancing blow from fingernails, twigs, stones or a paper edge. The trauma produces an acute sensation of a foreign body, with light sensitivity and excessive tearing. Lash ingrowth (**trichiasis**) may cause small abrasions.

Stain with fluorescein and measure the size of the epithelial defect. Antibiotic ointment (chloramphenicol) is instilled and an eye pad applied if a local anaesthetic is used. The condition heals spontaneously within 24 to 48 hours. Pain is due to the epithelial defect and also to reflex ciliary spasm, which may require short-acting cycloplegics, such as cyclopentolate 1%, in addition to oral analgesia.

Recent publications have suggested that topical **local anaesthetic** can safely be used for short periods as analgesia.[1] This is in contrast to a long-standing edict against such use—due to toxic effects that may delay corneal healing[2,3]—and represents a divergence in practice between emergency physicians and ophthalmologists.[4] The handful of small, controlled trials has yielded equivocal evidence on safety and efficacy.[1] As neither patient attendance for follow-up nor discarding of excess drops can be guaranteed, ongoing caution is urged as blinding side effects have been documented from overuse of topical anaesthetic.[5] Use is absolutely contra-indicated in pre-existing dry-eye conditions (e.g. Sjogren syndrome).[6] If deployed, use should be strictly for no more than 24 hours and the eye must remain protectively covered throughout.

Corneal foreign body

Small ferrous particles rapidly oxidize when adherent to the corneal epithelium, producing a surrounding rust ring within hours. Remove rusted particles with adequate topical anaesthesia and a bevel-up 25-gauge needle under a slit-lamp microscope. A difficult or adherent rust ring can be loosened by applying antibiotic ointment and padding for 24 hours, after which it is easily shelled out with the edge of a similar needle. Mechanical dental burrs can be difficult to sterilize and may cause large areas of epithelial removal and delay the patient's return to work. Wooden splinters are particularly dangerous as they may easily penetrate the eye and cause violent suppuration. In all suspected foreign body injuries, evert the upper and lower lids and examine with suitable lighting, magnification and fluorescein. The conjunctival fornices may be swept gently with a moist cotton bud under topical anaesthesia.

***Technique for upper eyelid eversion**: the patient must look down at all times; grasp the upper lid lashes and draw the lid down, then with a cotton bud in the other hand, depress the lid 11 mm above the central lid margin (i.e. above the tarsal plate) and counter-rotate the grasped lashes and lid around this cotton-bud fulcrum. The lashes may be held against the superior orbital margin with a finger and the cotton bud removed. When the examination is complete, release the lid and allow the patient finally to look up and the lid will revert to the normal position.*

Contact lens wear

Contact lens wearers may present with a foreign body sensation from multiple potential causes. Fluorescein staining and upper lid eversion will identify a 'lost' lens. Unless microbial keratitis is suspected, most cases should be told to desist with contact lens wear and be directed back to their primary eye-care provider.

Conjunctival laceration

Unless large, this rarely requires suturing. However, it is vital to ensure that this superficial laceration does not hide a deeper penetration of the globe. After instillation of local anaesthetic, the conjunctiva may be gently moved aside with a cotton bud to examine the bed of the laceration.

Penetrating injury

A careful history of possible penetrating trauma is crucial. Occupational trauma may be due to

high-speed penetrating metal fragments. Agricultural trauma often involves heavily contaminated implements. Seatbelt legislation has markedly reduced the incidence of penetrating eye injuries in road trauma, but eye problems can occur from airbag deployment and still occur from violent head and facial trauma.[7,8]

The eye is examined gently without pressure, as previously described. The penetration may be evidenced by an obvious laceration or the presence of prolapsed tissue with collapse of the globe. Conjunctival oedema (chemosis) and low IOP may indicate an occult perforation or bursting injury.

When a penetrating injury is either suspected or established, the patient must be transferred without delay to a centre where appropriate surgical facilities are available. During transport, cover the eye with a sterile pad and a plastic shield; prevent vomiting with anti-emetics; fast the patient and give intravenous fluids as necessary. Extruded tissue or projectiles should not be removed: intraocular contents will surely follow. Removal can only be undertaken in the controlled environment of an operating theatre. Prognosis depends on the extent of globe disruption.

Blunt injury

Concussion of the globe may cause tearing of the iris root, resulting in blood in the anterior chamber (**hyphaema**). A hyphaema greater than one-third of the anterior chamber usually indicates some damage to the drainage angle and may also be associated with concussive lens damage. Uninterrupted absorption of the hyphaema is essential. Traditional treatment has been admission to hospital and sedation, with the affected eye padded and the patient nursed semi-recumbent to encourage sedimentation of the blood in the anterior chamber to clear as much of the angle as possible. The application of Atropine 1% drops to 'splint' the ocular interior is logical but theoretically risks a re-bleed with the initial dilating effect.

A hyphaema may cause considerable pain due to raised IOP. To lower the pressure, oral or intravenous acetazolamide 500 mg is initially required, with topical IOP-lowering drops in the medium term. Pain is relieved by paracetamol or narcotics, with anti-emetics if necessary. Anti-platelet agents in any form should be avoided due to increased risk of secondary haemorrhage.

Bleeding recurs in up to 10% of patients, usually due to early mobilization in those with extensive iris damage, so that the patient should ideally remain rested until the blood has completely cleared from the anterior chamber. Subsequent ophthalmic follow-up will include assessment of the drainage angle for glaucoma risk and a fundus exam to exclude a traumatic retinal tear.

Smaller hyphaemas may be managed on an outpatient basis, perhaps with rest at home and the use of atropine drops, but can be sensibly considered only if daily IOP monitoring is not required.

Blunt trauma may be associated with assorted facial fractures including **orbital blow-out fracture.** Symptoms may include (particularly) vertical diplopia in the case of orbital floor fractures. Urgent repair is seldom required except where CT scanning demonstrates muscle entrapment in association with bradycardia, nausea and vomiting (**oculo-vagal reflex**), or in a young person with marked motility restriction and little external evidence of trauma (**'white-eyed blowout'**).[9] Indications for subacute surgical repair are residual, functionally significant diplopia (primary position or downgaze) or uncosmetic enophthalmos.

Chemical burns

The first principle of management—at the location where the injury was sustained—is copious irrigation of the eyes for at least 10 minutes with clean running water. *Do not delay* to await the availability of proprietary eye irrigants. Chemical trauma requires priority assessment on arrival at an emergency centre and immediate irrigation if this has not been done or has been inadequate, with the aim of achieving a neutral pH.

Alcohol and solvent burns occur from splashes while painting and cleaning. Although the epithelium is frequently burnt, it regenerates rapidly. The condition is very painful initially, but heals with a topical antibiotic and patching for 48 hours.

Alkali and **acid** burns are potentially more serious because of the ability of the burning agent to alter the pH in the anterior chamber of the eye and inflict chemical damage on the iris and lens. Caustic soda, lime and plaster—commonly used in industry—may inflict painful, deep and destructive ocular burns. Splashes of acids, such as sulphuric and hydrochloric, if concentrated, will cause equally destructive injury.

To assess the ocular burn, use topical anaesthetic drops and fluorescein staining to determine the area of surface injury; evert the eyelids, examine the fornices carefully and sweep gently with a cotton bud to ensure there is no particulate caustic agent remaining. Compress limbal blood vessels with a cotton bud: extensive stasis in perilimbal vessels is a poor prognostic sign.

Chemical burns where the epithelium is intact or minimally disturbed can usually wait 24 hours before review by an ophthalmologist. Burns involving more than one-third of the epithelium and the corneal edge, with any clouding of the cornea, are potentially more serious as subsequent melting of the cornea by collagenase action may ensue. These burns should all be further irrigated in the ED with a buffered sterile solution, such as Ringer lactated solution (Hartmann solution). The irrigation should continue until the tears are neutral to litmus testing.

More serious caustic injuries have shown a significant improvement in outcome with the introduction of 10% citrate and ascorbate drops, commencing 2-hourly for 48 hours and reducing over the week, in combination with 1 g oral ascorbic acid daily. This regimen has an inhibitory effect on corneal melting. Topical antibiotic (e.g. chloramphenicol) is used; topical steroid is used under ophthalmic supervision.[10]

Flash burns

Exposure of the eyes to prolonged or severe ultraviolet radiation results in widespread punctate epithelial loss from the corneal surface. This is most frequently seen in welders who have not used sufficient eye protection while working, or in adjacent, unprotected observers. Patients complain of delayed onset of moderate to severe ocular discomfort with excessive watering and foreign body sensation.

Ocular examination shows widespread punctate fluorescein staining, usually with no ulceration and no evidence of foreign body present. Apart from welding, other instances in which excessive ultraviolet radiation may be encountered are in alpine snowfields and tanning beds.

Treatment is supportive with oral analgesia, topical lubricants and explanation of the cause and likely time course. The symptoms generally settle within 24 to 48 hours as the epithelium recovers. Caution is urged in any decision to dispense local anaesthetic drops for analgesia, as noted previously.

UNILATERAL RED EYE

Any history of predisposing trauma should be obvious: these conditions have been outlined in the previous section. The type of pain can be useful in distinguishing the location of pathology: a sharp or scratchy discomfort implicates cornea or conjunctiva, whereas a deep-seated aching pain is likely intraocular inflammation or elevated IOP.

Acute infectious keratitis

The usually smooth surface of the corneal epithelium hinders the adherence of infectious agents and the rapid repair of any defect in the epithelium limits the likelihood of penetration by such pathogens. The flow of tears over the surface washes debris away and contains antibodies and lysozymes. If these defences are impaired in any way, there is the possibility of penetration into the corneal stroma, and active infection may occur.

Bacterial keratitis is characterized by a focus of infection with an associated inflammatory

response. Patients complain of sharp pain, redness, watering and a decrease in visual acuity. Fluorescein staining shows an area of ulceration over the infection, which appears as an opacity or area of whiteness within the cornea. Marked conjunctival and episcleral injection results in a unilateral red eye. Evidence of intraocular inflammation is usually present, with cells and flare being seen in the anterior chamber with oblique, narrow-beam slit-lamp examination. In severe cases, a collection of inflammatory cells can be seen in the inferior part of the anterior chamber as a sediment, called a **hypopyon**.

An attempt should be made to identify the infectious agent prior to commencing appropriate antibiotic treatment:

Corneal scraping technique

A specimen is taken via a scraping for microbiological assessment, including Gram staining and culture. Under topical anaesthetic, using a preservative-free single-use dispenser of benoxinate or tetracaine, a sterile, bevel-up 25 or 23 G needle held flat to the corneal surface is used to gather a small specimen from the local infiltrate. This is transferred directly to glass slides and also plated on to HB and chocolate agar plates for culture. Fungal cultures may be indicated.

Antibiotic therapy is not delayed until the results are available, but is commenced on a broad-spectrum basis, such as the intensive use of a fluoroquinolone eye drop (e.g. G. ciprofloxacin or ofloxacin) on an hourly basis. Chloramphenicol drops qid are not adequate treatment. Daily monitoring with slit-lamp examination is mandatory and severe infections require hospital admission. This regimen can be modified when culture and sensitivity results are available.

Herpes simplex keratitis usually presents initially as an infection of the epithelial cell layer, although with recurrent episodes, stromal involvement may be seen. It is most often a unilateral infection. As with other herpetic infections, it is not possible to eradicate the virus, but limitation of inflammatory-mediated damage is important. Patients complain of a scratchy, foreign body sensation, redness, watering and a variable decrease in visual acuity. On examination, the areas of infected epithelium can be seen as a branching irregularity or **dendrite** on the surface of the eye (Fig. 16.1.2). Multiple dendrites may be scattered over the surface, particularly in immunocompromised patients. These are best seen when the cornea is stained with fluorescein and viewed with the slit lamp

Treatment is directed to clearing the virus from the cornea to promote epithelial healing and to limit stromal involvement and damaging corneal inflammation. A single pass with a sterile cotton bud rolled across the ulcer will deplete the viral load; an antiviral ointment (aciclovir) is then instilled five times daily until there is resolution of the epithelial lesions and then ceased as long-term usage may be toxic to the unaffected corneal epithelium. *Steroid eye drops are contraindicated except under the strict supervision of an ophthalmologist.*

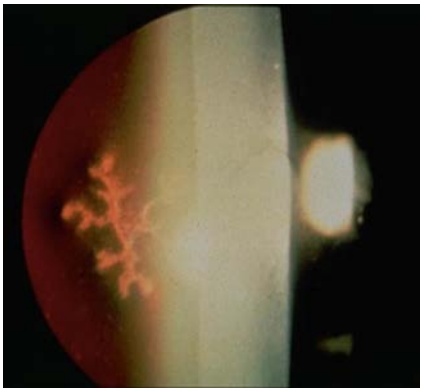

FIG. 16.1.2 Herpetic dendrite.

Adenoviral conjunctivitis

This highly contagious conjunctival infection is a common cause of viral conjunctivitis.

Initial presentation is usually a short history with a complaint of discomfort or swelling, watery discharge, redness, and ocular foreign body sensation. Commonly unilateral on initial presentation, it may ultimately extend contralaterally. There is often a history of either recent upper respiratory tract infection or contact with someone with a current episode of adenoviral infection.

Examination shows a follicular pattern of conjunctivitis, particularly in the sub-tarsal conjunctiva. In severe cases, subconjunctival haemorrhage and pseudomembrane formation can occur. There may be crusting of the lid margin and eyelashes. Uncommonly, the cornea can be involved with focal subepithelial infiltrates noted with minimal overlying epithelial disturbance. This is an immune response and can affect the visual acuity if in the visual axis. There is no evidence of intraocular inflammation. **Tender pre-auricular lymphadenopathy** on the affected side is characteristic.

It is an acute, self-limiting disease (2 to 3 weeks) for which no specific treatment is required (or available): there is no evidence that topical antibiotics or antiviral agents affect the course of the infection. Lid hygiene, lubricants and cold compresses may be helpful for symptomatic relief. *Topical steroid eyedrops are only given under strict ophthalmic supervision for corneal infiltrates if vision is affected.* Highlight the contagious nature of this condition and enforce standard restrictions on shared linen, towels, etc.

Acute iritis

Acute anterior uveitis (AAU) is an inflammatory response in the iris and ciliary body. As part of this response there is an increase in vascular dilatation and permeability with the release of inflammatory mediators and cells.

Acute iritis (AI) is usually an idiopathic condition with no systemic cause or association. Less commonly, associated conditions may include HLA-B27-related disease including ankylosing spondylitis, sarcoidosis, inflammatory bowel disease (including ulcerative colitis and Crohn disease), connective tissue disorders and ocular infection, including herpetic disease, toxoplasmosis, syphilis and tuberculosis. A complete history will often give clues to these associations, which are teased out in the post-acute phase.

AI is generally unilateral, although bilateral involvement is seen. It is characterized by pain, redness and visual disturbance. The pain is aching and constant, with photophobia due to pupillary movements in an inflamed iris. Dilatation of the conjunctival and episcleral vessels is apparent, particularly in the vessels adjacent to the corneal limbus, often referred to as **limbal flush**. Visual acuity can be reduced by varying degrees depending on the severity of inflammation. The pupil is constricted (**miosis**) due to irritation, but may be irregular due to 'sticky' iris adhering to the anterior lens surface (**posterior synechiae**).

Slit-lamp examination of the anterior segment with a narrow, oblique beam will reveal evidence of increased vascular permeability, seen as fibrin clumps, flare and inflammatory cells in the aqueous released from the vessels. In some cases, small collections of neutrophils can be seen aggregating on the posterior surface of the cornea as **keratic precipitates** (Fig. 16.1.3). The IOP may be raised.

In cases of severe inflammation, cells can accumulate in the inferior anterior chamber and a sediment level can be seen as a hypopyon. The presence of a hypopyon should lead to a search for an infectious cause, generally either keratitis or endophthalmitis.

In all cases of iritis is essential that a complete fundal examination be performed through a pharmacologically dilated pupil in order to determine the presence of inflammatory disease in the posterior segment. Thus a timely ophthalmic referral is indicated.

Treatment of AI is directed towards resolution of the inflammatory response and limiting any ocular damage from this inflammation. The mainstay of treatment is intensive, topical steroid eye drops (prednisolone acetate 1%, up to hourly in severe cases). In severe cases, orbital steroid injections or oral steroids may be necessary. Mydriatic eye drops (G. tropicamide 1% or cyclopentolate 1%) are used to break any lens–iris

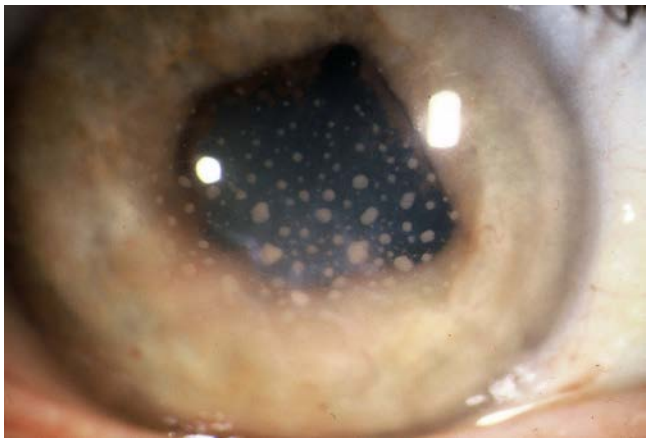

FIG. 16.1.3 Anterior uveitis with keratic precipitates and adhesions between the iris and anterior lens surface (posterior synechiae).

adhesions and to limit the extent of permanent adhesions. In 'splinting' the iris, these drops also provide pain relief by limiting pupil movement.

As the degree of inflammation decreases on slit-lamp examination, the topical treatment is decreased in frequency. The long-term use of topical steroid drops is not without risk and can be associated with the development of glaucoma, cataract and concurrent ocular surface infection, such as herpes simplex keratitis.

Endophthalmitis

Endophthalmitis is characterized by progressive inflammation of the vitreous and aqueous humours of the eye. Although it usually presents with reduced vision, ocular redness and ocular pain, characteristically in the presence of hypopyon and hazy ocular media, any of these features may be absent. The term 'endophthalmitis' is usually used to refer to cases of inflammation secondary to infection. 'Endogenous endophthalmitis' refers to cases of haematogenous spread of infection, while 'exogenous endophthalmitis' is used where infection is due to ocular trauma, intraocular surgery or intravitreal injection. Endogenous endophthalmitis may be bilateral.

Endophthalmitis must be urgently treated by an ophthalmologist to avoid loss of vision and of the eye itself. Especially in exogenous cases, this usually starts with the procedure of 'tap and inject'. This refers to obtaining a vitreous and often aqueous aspirate for microbiology and culture and often other testing for diagnostic purposes, followed by intravitreal injection of antibiotics. In endogenous cases a systemic work-up for the source of infection should be performed. Recently an increasing number of patients—particularly diabetics—with pyogenic liver abscesses due to *Klebsiella pneumonia* have been developing severe endogenous endophthalmitis[11,12]: beware the septic patient complaining of reduced vision.

Although the choice of intravitreal antibiotics is governed by the clinical situation, the standard initial treatment is with vancomycin and ceftazidime. Consideration should also be given to the possibility of fungal infection, which would require antifungal agents. Vitrectomy surgery is sometimes required in more severe cases to reduce the infectious and inflammatory burden in the avascular vitreous gel.

The retina may also be affected by viruses, especially in immunosuppressed states. The most common scenarios are cytomegalovirus **retinitis**, characterized by haemorrhages in areas of retinal opacity known as a 'cottage cheese with ketchup' appearance, and **acute retinal necrosis** (ARN), which features zonal retinal necrotic opacity and often severe ocular inflammation, and which most commonly arises from herpes zoster or herpes simplex infection.

Acute primary angle-closure (glaucoma)

Acute primary angle-closure (APAC) is characterized by an acute impairment of the outflow of aqueous from the anterior chamber in an anatomically predisposed (crowded) eye. This results in a rapid and severe elevation in IOP. Population mean IOP lies between 10 and 21 mm Hg but, in cases of APAC, can rise to >60 mm Hg. This is manifested as severe **pain**, blurring of vision and redness. The pain may be severe enough to cause nausea and vomiting and may be poorly localized to the eye. Visual disturbance can be preceded by **halos** around lights and, in established cases, is due to corneal oedema. Relative hypoxia of the pupillary sphincter due to elevated pressure results in a pupil unresponsive to light stimulation. The pupil is classically fixed and **mid-dilated** (in contrast to the miosis of iritis). The associated inflammation induces congestion of conjunctival and episcleral vessels. (The term 'acute angle-closure glaucoma' is no longer regarded as accurate, as there may be no optic nerve head cupping or visual field loss—the features that define glaucoma—at the acute presentation.)

Treatment of APAC is aimed at lowering the IOP and allowing the flow of aqueous from the posterior to the anterior chamber. Acetazolamide 500 mg intravenously and/or topical apraclonidine (Iopidine) or brimonidine (Alphagan) may be effective in acutely lowering the pressure and thereby reducing pain. If ineffective, subsequent constriction of the pupil with 2% pilocarpine, a parasympathomimetic, may alleviate the forward bowing of the iris, relieve the pupil block and re-establish aqueous flow and angle drainage. One drop is initially instilled every 5 minutes for 15 minutes and then half-hourly. However, if the pressure is very high the ischaemia induced will render the pupillary sphincter unresponsive to the pilocarpine. In these cases, it may be necessary to move to early laser treatment.

A laser peripheral iridotomy (PI) is performed using the yttrium:aluminium:garnet (YAG) laser to allow aqueous permanently to bypass the pupil and remove the risk of further episodes of APAC. This may be done acutely if corneal oedema does not preclude an adequate view. The anatomical predisposition to APAC is usually bilateral: miotics (G. pilocarpine 2% qid) are also instilled in the unaffected eye until YAG PI can be done (electively).

Laser iridoplasty—an alternative technique used when corneal oedema is severe—requires specific expertise.

SUDDEN LOSS OF VISION

Introduction

Acute visual failure is any acute loss of visual acuity, visual field or colour vision. Most of the sinister causes of acute visual failure are *painless* (Table 16.1.1) and the absence of apparent distress may result in the patient being triaged in error to a non-acute review. Effective emergency management depends upon rapid recognition of those conditions for which acute therapy is available (Table 16.1.2). Some conditions have no effective therapy or are more appropriately managed on an outpatient basis.

Clinical assessment

Fundus examination can be challenging for non-ophthalmologists. History can thus be crucial in distinguishing the varying causes of vision loss and thus directing care.

Table 16.1.1 Symptoms significant for cause in sudden vision loss

Symptom	*Condition*
Floaters (if recent onset)	Posterior vitreous detachment Vitreous haemorrhage Retinal detachment
Flashes (especially temporal)	Retinal detachment Migraine aura
Shadow (billowing curtain/cloud)	Retinal detachment Vitreous haemorrhage
Distortion	Exudative macula disease
Amaurosis fugax	Retinal artery occlusion Anterior ischaemic optic neuropathy
Pain on eye movement	Optic neuritis
Visual field loss	
Horizontal hemifield	Anterior ischaemic optic neuropathy Branch retinal vein occlusion Branch retinal artery occlusion
Vertical hemifield (bilateral)	Retrochiasmal CVA/compression
Whole-field (unilateral)	Vitreous haemorrhage Central retinal artery occlusion Anterior ischaemic optic neuropathy Central retinal vein occlusion Retinal detachment
Bilateral total loss of vision	Bilateral occipital infarction Toxic (methanol/quinine)

Table 16.1.2 Sudden vision loss for which acute therapy is available

Condition	*Therapy*
Central (or branch) retinal artery occlusion	Acetazolamide CO_2 rebreathing Pulsed ocular compression Anterior chamber paracentesis
Anterior ischaemic optic neuropathy	Steroids
Exudative age-related macular degeneration	Anti-VEGF injections Laser
Retinal detachment	Surgery
Endophthalmitis	Intravitreal antibiotics Surgery

Anti-VEGF, Anti-vascular endothelial growth factor.

History

Particular attention should be paid to the rapidity of onset, and the degree and location in space of visual loss, previous episodes and associated symptoms. (One should distinguish in the history between acute onset and acute *discovery* of visual loss, as a patient may discover decreased vision from, e.g. a cataract, by inadvertently covering one eye for the first time.)

Examination

Testing of the visual acuity and visual field will clarify uni- or binocular involvement.

Examination of the pupils is mandatory before pharmacological dilatation. *Test for a relative afferent pupillary defect (RAPD), one of the few objective signs.* When required, pupils will dilate in 10 to 15 minutes with tropicamide 1.0% drops, which last 1 to 2 hours. Pupils should not be dilated if the patient requires monitoring for a head injury.

Bilateral vision loss

Bilateral visual field loss usually implicates a retrochiasmal and, therefore, a non-ocular cause. However, this visual field defect will respect a vertical midline. In contrast, the retinal nerve fibre layer and retinal vascular elements within the eye are distributed around a horizontal midline and may thus involve a superior or inferior (i.e. horizontal) hemifield. *Localized ocular pathology does not cause a visual field defect respecting a vertical midline.*

Bilateral acute, complete, visual failure is uncommon. Bilateral occipital infarction may present with bilateral blindness, but pupil responses would be expected to be intact. Rapidly progressive bilateral sequential visual loss from temporal arteritis is occasionally encountered. Other pre-chiasmal causes of bilateral, simultaneous, ocular involvement include toxic causes, such as poisoning with either **quinine** or **methanol,** where the patient presents with bilateral blindness and fixed, widely dilated pupils. Visual recovery in these cases is variable and the efficacy of a range of therapeutic interventions is controversial.[13,14]

Central retinal artery occlusion

The history is typically of sudden, painless loss of vision in the affected eye over seconds. This may have been preceded by episodes of transient loss of vision (**amaurosis fugax**) in the previous days or weeks. The mean age of presentation is in the 70s. Men are more frequently affected and the patient may be a 'vasculopath'. Carotid disease is frequently implicated, with an embolus often being the cause of the obstruction, but its absence does not preclude the diagnosis, as the obstruction may lie behind the lamina cribrosa. Check the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) when an embolus is not seen, as temporal arteritis causes 5% of cases of central retinal artery occlusion (CRAO).

The visual acuity is drastically reduced, often to the level of light perception, with an RAPD present on the affected side. Fundus examination shows creamy-white retinal oedema (cloudy swelling) with a central red fovea—the 'cherry-red spot'—caused by the absence of oedema in the thinner retina at the fovea. The arterioles may be attenuated, with segmentation ('cattle-trucking') of the blood column. An embolus may be seen at any point along the retinal arterioles, from the disc to the periphery.

Acute treatment proceeds on the assumption that the cause is embolic. Therefore the principles of therapy are to vasodilate the retinal arterial circulation in order to promote dislodgement of the embolus from a proximal position and encourage its movement downstream to a less strategic site. All the measures currently used are directed to lowering the IOP, thereby relieving the compressive effect on the intraocular vasculature. Intravenous or oral acetazolamide 500 mg will lower IOP within 15 to 30 minutes; pulsed ocular compression ('ocular massage') involves cyclical

sustained compression of the globe for 10 to 15 seconds before sudden release of this compression, continuing for 5 to 10 minutes. The release of pressure may result in a momentary marked increase in the perfusion pressure gradient and dislodge an embolus. The use of carbogen gas (95% oxygen/5% carbon dioxide) is now largely historical, but carbon dioxide rebreathing may be tried for its central vasodilatory effect. Definitive reduction of IOP is achieved with anterior chamber paracentesis, a technique that requires the specific expertise of an ophthalmologist. Trials of timely intra-arterial fibrinolytic therapy have so far shown a discouraging level of co-morbidity from the treatment.[15,16] The place of hyperbaric therapy remains uncertain.[17] Visual outcomes are generally poor in CRAO, but occasional successes justify aggressive intervention if the patient presents within 12 hours. Non-acute management must include investigations to define the embolic source.

Central (branch) retinal vein occlusion

Central or branch retinal vein occlusion (CRVO) may present as a painless blurring of vision that is not sudden. Patients are usually in the older age group, often with systemic hypertension, diabetes mellitus and glaucoma. Visual acuity varies with severity, as does the presence of an RAPD. The characteristic fundus appearance is of extensive intraretinal haemorrhage with a variable number of cotton wool spots ('margherita pizza'). There may be disc oedema, with venous tortuosity and a generally congested appearance. If an insufficiently wide fundus view is obtained, the patient may be misdiagnosed with 'papilloedema' and subjected to unnecessary investigations.

There is no emergency management specific to the vein occlusion that will positively influence the visual outcome—systemic hypertension and raised IOP rarely require acute control—and the patient should therefore be referred to the next ophthalmic outpatient clinic.

Age-related macular degeneration

In 10% to 20% of cases of age-related macular degeneration (AMD), exudative (or 'wet' macular changes are seen due to the presence of choroidal neovascularization (CNV). These patients may present with painless blur of the central vision, and 'metamorphopsia', which is a complaint that objects that they know to be straight appear curved. Visual acuity is reduced, depending on the stage of the disease; an RAPD is rarely seen owing to the relatively small area of retina involved, which may manifest as a central scotoma on field testing. Macular drusen (yellow spots), retinal thickening and haemorrhage may be seen, with at least drusen usually also seen in the fellow eye.

Acute symptoms must not be dismissed. With appropriate treatment, central vision may be preserved in a proportion of these patients. Therefore ophthalmic review within 2 to 4 days is appropriate. Recent advances in treatment with anti-vascular endothelial growth factor agents, such as ranibizumab (Lucentis), bevacizumab (Avastin) and aflibercept (Eylea) have revolutionized the prognosis, and often sight can now be preserved[18].

Acute vitreo-retinal problems

Posterior vitreous detachment

Shrinkage and detachment of the vitreous is common in the older population and produces a new onset of floaters, which are wispy spots, threads or 'spider webs' in the vision. As part of this process, vitreous traction on the retina may produce flashes of light (photopsia) seen particularly in the temporal periphery of vision in that eye. These flashes can usually be distinguished from the visual aura of migraine. While posterior vitreous detachment (PVD) is usually not serious in its own right, early dilated examination of the retinal periphery is needed to exclude retinal tears, which predispose to detachment. Pigmented cells ('tobacco dust' or Shafer sign) in the anterior vitreous are associated with the presence of a retinal tear and therefore heighten the urgency of referral.

Retinal detachment

Acute retinal detachment (RD) is usually a result of a retinal tear or hole formation, with seepage of fluid into the subretinal space and lifting of the retina. Exudative and tractional RDs are less common and are associated with underlying pathology. A detached retina shows a visual field defect, which will be described as a shadow or curtain, corresponding to the area of detachment; that is, inferior field defect equals superior RD. Vision loss is painless. There may be an RAPD, depending on the amount of retina involved. Treatment will usually require surgery. If the visual acuity is normal, the macula is likely still attached, and referral to an ophthalmologist specializing in vitreo-retinal surgery is urgent in order to preserve central vision.

Vitreous haemorrhage

The common causes are proliferative diabetic retinopathy, chronic branch retinal vein occlusion, PVD or trauma. Patients with an acute vitreous haemorrhage (VH) may have symptoms varying from a few floaters causing blurred vision to a total loss of vision to a level of light perception, depending on the density of the haemorrhage. Any loss of vision is painless. The red reflex may be poor and the view of the retina may be similarly impaired. Media opacities do not affect pupil light reflexes, so *the presence of an RAPD suggests that the underlying retina is damaged or detached*.

The patient should be referred for early ophthalmic assessment—urgent if an RAPD is present—which may include B scan ultrasonography to exclude RD if the retinal view is inadequate. Anticoagulants should be avoided where possible.

Giant cell arteritis

Arteritic **anterior ischaemic optic neuropathy** (AION) is the feared visual loss of giant cell (temporal) arteritis (GCA). The patient is commonly in his or her mid-70s or older and is more often female. Presentation is with profound vision loss in one eye. This may have been preceded by brief premonitory visual obscurations or double vision, to which the patient may not have ascribed significance. Systematic questioning may reveal specific features, such as jaw claudication, headache, scalp tenderness, anorexia, malaise, weight loss or night sweats, and there may be a history of polymyalgia rheumatica in up to 50% of cases. GCA is a systemic illness with the potential for devastating visual loss, as well as long-term life-threatening non-ophthalmic complications.

Vision may be reduced at presentation to the level of perception of light only. An RAPD will be present and the optic disc is almost invariably oedematous, but the fundus may be otherwise normal. Total field loss in the affected eye is usual. Evidence of decreased acuity, colour vision deficits and disc oedema also should be sought in the other eye. Palpation of the temporal arteries will often be abnormal, with the pulses perhaps absent or the arteries thickened and tender.

Clinical suspicion requires blood to be drawn for ESR and CRP. Steroid treatment should then be started on an urgent basis and must not be delayed or deferred until after temporal artery biopsy. The biopsy will remain positive for at least several days despite steroids. Elevation of both ESR and CRP is highly specific for a diagnosis of GCA, but does not avoid the need for biopsy.[19] Urgent referral to an ophthalmologist is required.

Prednisolone 1 mg/kg daily is an accepted dose, although recent experience has suggested that 'pulse' methylprednisolone 500 mg intravenously daily or twice daily over 1 to 2 hours is safe and more efficacious in suppressing the inflammation, and this has become standard therapy in a number of centres. This is generally used for 3 days and oral prednisolone is then substituted.[20,21] Weaning oral treatment will be prolonged (at least 6 months) and should be undertaken in cooperation with a physician,

with attention also directed to the avoidance of steroid complications in this aged patient group.

Non-arteritic AION is classically seen in males in their late 50s and 60s who have a history of cardiac or vascular disease, hypertension, diabetes or smoking. The visual presentation may be similar to that seen with GCA—although the visual acuity and field loss may not be as profound (may be a hemifield loss) and the specific systemic symptoms are absent—so that management must be as for arteritic AION until GCA is excluded. The condition was well-known prior to the advent of sildenafil (Viagra), which has been inconclusively implicated in some cases.[22]

Optic neuritis

Optic neuritis classically presents in young females and may be the first presentation of a demyelinating illness. Visual symptoms are not usually sudden and presentation is thus seldom acute. The vision declines gradually over days, perhaps to the level of 6/36 to 6/60, with loss of colour vision being prominent. The common visual field defect is a central scotoma, but many variations are possible and an RAPD should always be present. If disc oedema is not seen, the diagnosis may be retrobulbar neuritis. There may be pain on medial or superior eye movement.

Good spontaneous recovery has made the value of treating optic neuritis controversial: the results of the Optic Neuritis Treatment Trial suggested that there is no place for oral prednisolone alone in management. The benefit of 'pulse' intravenous methylprednisolone seems restricted to shortening the acute episode, without influencing the possibility of progression to multiple sclerosis or the final visual outcome.[23] However, there is usually no role for acute intervention, and referral within a day or two to a neurologist or ophthalmologist is satisfactory.

CONTROVERSIES

- Local anaesthetic drops in treatment of corneal abrasions
- Emerging evidence of eye injuries from vehicle air bag deployment
- Role of hyperbaric oxygen or intra-arterial fibrinolysis in CRAO
- Role of sildenafil in causing non-arteritic AION

SECTION 17

DENTAL EMERGENCIES

Edited by *Peter Cameron*

17.1 Dental emergencies

Ian Hewson

ESSENTIALS

1. **An avulsed tooth reimplanted within 30 minutes has a 90% chance of survival.**
2. **Dental caries is the most common cause of dental emergency attendance.**
3. **Dental caries requires analgesia in the emergency department and referral to a dentist for definitive care. Antibiotics are not required unless the caries is complicated by abscess.**

Anatomy

The tooth consists of the crown, which is exposed, and the root, which lies within the socket covered by the gum; the latter serves to anchor the tooth. The gingival pulp carries the neurovascular structures via the root canal and is covered by dentine which, in turn, is covered by enamel, the hardest substance in the body (Fig. 17.1.1).

The deciduous teeth are 20 in number and erupt between the ages of 6 months and 2 years. The permanent dentition begins to erupt at around age 6 and, in the adult, consists of 32 teeth.

Dental caries

The most common cause of toothache or odontalgia is caries. Dental caries-related emergencies account for up to 52% of first contact with a dentist for children below the age of 3 years.[1] Dental caries is the cause of emergency visits to a dentist in 73% of paediatric patients.[2] Pain associated with dental caries is of a dull, throbbing nature, localized to a specific area and aggravated by changes in temperature in the oral cavity (hypersensitivity to hot and cold food or fluids).

Examination reveals tenderness of the offending tooth when tapped with a tongue depressor or mirror. Management includes symptomatic pain relief using analgesics, such as paracetamol with or without codeine, non-steroidal anti-inflammatory drugs (NSAIDs) and urgent referral to the dentist.

Periodontal emergencies

Pain is the most common cause of self-referral to the emergency department for dental problems. The common conditions causing dental pain are acute apical periodontitis and reversible and irreversible pulpitis resulting from dental caries.[3] Symptoms include painful, swollen gums with or without halitosis. On occasion, frank pus or bleeding from the gums may be the presenting symptom. At all stages, varying degrees of pain associated with inflammation are present.[4]

Infected gums can be an early clinical sign of undiagnosed diabetes, acute myeloid leukaemia (AML), HIV and graft-versus-host disease in bone marrow transplantation.

Management includes diagnosis of the periodontal disease and the offending tooth. Symptomatic pain relief can be achieved with

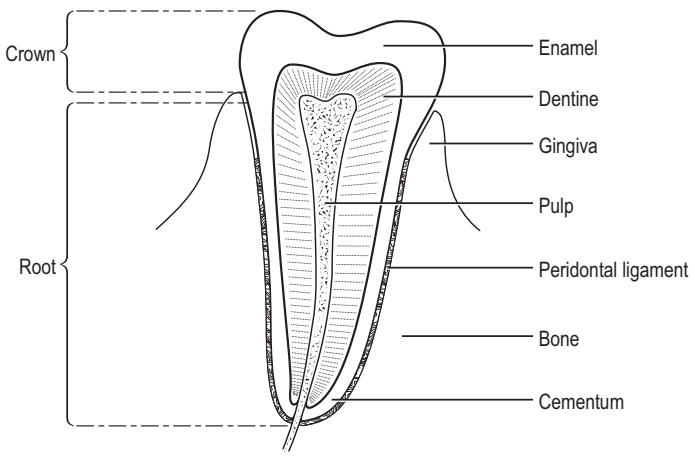

FIG. 17.1.1 The anatomy of a tooth. (From an original drawing by Ian Miller RN.)

analgesics, NSAIDs and warm saline rinses. Routine antibiotic therapy is not required unless there is evidence of gross infection locally, regional lymphadenopathy or fever. In all cases, urgent review by the dentist is mandatory.

Acute necrotizing ulcerative gingivitis (ANUG) is a severe form of gingivitis that could be related to stress and needs antibiotic cover and urgent referral to the dentist.

Alveolar osteitis (dry socket)

Dry socket occurs between 2 and 5 days following dental extraction. The dull throbbing pain is due to the collection of necrotic clot and debris in the socket. The condition is diagnosed on the history and examination, which confirms the acutely tender extraction site.

Treatment consists of irrigation (2% chlorhexidine) of the extraction site to remove the necrotic material and packing the socket with sterile gauze soaked in local anaesthetic, such as cophenylcaine, or placing alvogyl into the socket (butamben, iodoform and eugenol) followed by urgent dental review.[5]

Post–dental extraction bleeding

Bleeding from the socket within 48 hours after extraction results from reactionary haemorrhage due to opening up of the small divided blood vessels. Bleeding after 5 days is secondary haemorrhage due to infection that has destroyed the organizing blood clot.

General causes, such as hypertension and warfarin therapy, must be addressed to control the bleeding.

Management is essentially reassurance and careful suctioning to clear the debris and clot in the socket; this is followed by packing with gauze soaked in lignocaine with adrenaline or cophenylcaine and pressure. Or Surgicel may be placed into the socket.

Dilute aminocaproic acid (IV Amicar) 5 mL in 10 mL of normal saline may be used to rinse the mouth. Use Amicar or tranexamic acid–soaked gauze to bite on, applying direct pressure for about 30 minutes and repeat as required to control the bleeding. Occasionally the gingival flaps may have to be sutured under local anaesthetic.

Traumatic dental emergencies

Tooth avulsion is probably the most serious tooth injury. An avulsed tooth, if reimplanted in the socket within 30 minutes, has a 90% chance of survival.[6] The mechanism of injury in such cases is usually either an accidental sports-related facial injury or an assault.

Management

If the patient makes telephone contact with the emergency department, he or she is advised to locate the tooth because, even if the crown is broken, the root may be intact. The tooth should not be handled by the root to avoid damage to the periodontal ligament fibres; it is washed in running cold water and replaced in the socket. If this is not possible, the patient should place the tooth in the cheek or under the tongue and proceed immediately to the dentist. Do not scrub the tooth.[7,8]

The best transportation medium for an avulsed tooth is saliva. Cold milk or iced salt water are suitable alternatives. If the tooth can be replaced in the socket, this is the perfect environment even if it is not stable in the socket.

When the patient arrives in the emergency department with the tooth, clean it by holding it by the crown in sterile saline or Ringer solution; any foreign debris should be removed with forceps. The tooth should not be allowed to dry. Following irrigation, the tooth should be placed in the socket as close to its original position as possible and the patient referred to a dentist for stabilization with an arch bar or orthodontic bands.

The complications of reimplantation are ankylosis and loss of viability.

The 2010 Dental Trauma Guide by the Danish Dental Association supported by the International Association of Dental Traumatology provides an interactive drop-down menu on how to deal with every possible dental trauma.[9]

Dentoalveolar trauma in children

Concussion and subluxation

Concussion is an injury to the tooth without displacement or mobility. Subluxation is when the tooth is mobile but not displaced.

Management

This includes periapical x-rays as baseline, soft diet for a week and local dentist follow-up.

Intrusive luxation

This is the most common injury to upper primary incisors after a fall.

Management

If the crown is visible, allow the tooth to re-erupt. If the whole tooth is intruded, extraction is required, as it might otherwise affect the permanent dentition underneath.

Extrusive and lateral subluxation

If there is excessive mobility or displacement, extraction is recommended.

Avulsion

Avulsed primary teeth should not be reimplanted. Unless there is extensive soft-tissue damage, antibiotics are not required.

Dental fractures

The incidence of fractured teeth is reported to be 5 and 4.4 per 100 adults per year for all teeth and posterior teeth, respectively.[10] Based on these statistics, it can be deduced that the likelihood of experiencing a fractured frontal/anterior tooth is about 1 in 20 in a given year in adults and 1 in 23 for posterior teeth.

Traumatic injuries to the teeth have been classified as follows[11]:

Class I: Simple fracture of the enamel of the crown
Class II: Extensive fracture of the crown involving dentine
Class III: Extensive fracture of the crown involving dentine and dental pulp
Class IV: Extensive involvement and exposure of the entire pulp
Class V: Totally avulsed or luxated tooth
Class VI: Fracture of the root with or without loss of crown structure
Class VII: Displacement of tooth without fracture of crown or root
Class VIII: Fracture of the crown in its entirety (Fig. 17.1.2)

Management

Emergency management includes reassurance, adequate analgesia, replacement of an avulsed tooth in the socket and immediate referral to a dentist for further evaluation and appropriate management.

Specific treatment depends on the type of fracture[12]:

- Class I: Treated by smoothing the enamel margins and applying topical fluoride to the fracture site.

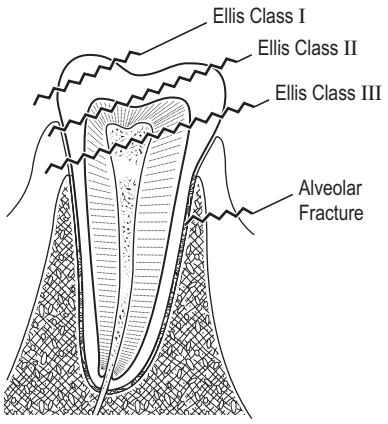

FIG. 17.1.2 Ellis classification. (From an original drawing by Ian Miller RN.)

- Class IIA: Calcium hydroxide dressing is applied as a bandage to provide a stable form of temporary restoration, which will be replaced by a more aesthetic restoration as soon as the vitality of the pulp is assured.
- Class III: If seen within 6 hours of the accident, it should be treated with calcium hydroxide direct pulp capping. If more than 6 hours but less than 24 hours have elapsed, pulpotomy is advised. If more than 24 hours have elapsed, since the accident, the treatment is total pulpectomy.
- Class IV: Treated with conventional filling for permanent teeth and total pulpectomy for a primary tooth.
- Class V: Managed as for an avulsed tooth.
- Class VI: If the pulp is necrotic, pulpectomy and root canal therapy are appropriate.
- Class VII: If the tooth is intruded, it should be extracted (deciduous teeth only). If driven through the labial plate of bone, it should be extracted; if not, it should be left alone to re-erupt. If the tooth is extruded, slowly move it back to its original position using finger pressure. Primary teeth, if mobile 2 weeks after the injury, should be extracted. Parents should be warned about possible damage to the developing permanent tooth.
- Class VIII: In a permanent tooth, pulpotomy or pulpectomy is appropriate. Primary teeth with this amount of destruction should be extracted.
- When a tooth is missing following facial trauma, a thorough intraoral examination is followed by appropriate radiographs to avoid missing an intruded tooth. When full intrusion of a tooth is suspected, a facial computed tomography (CT) scan may aid definite diagnosis.[13]

Temporomandibular dislocation

Temporomandibular dislocation can result from congenital weakness of ligaments, iatrogenic causes (traumatic extractions, prolonged dental procedures and direct laryngoscopy), trauma, drugs, epilepsy and even simple yawning. The dislocation may be unilateral but is more commonly bilateral. The condyle is most frequently dislocated anterior to the articular eminence.

The patient presents with an open bite and malocclusion. If unilateral, the mandible deviates to the unaffected side. The patient complains of severe pain in the ear and is unable to open or close the mouth fully. Management includes diagnosis and reduction. The patient is seated, with posterior head support, and the muscle spasm is overcome by using intravenous benzodiazepines, such as midazolam, and narcotic analgesia, such as fentanyl.

The mandible is held by the clinician with both hands, with the gloved thumbs placed intraorally just lateral to the lower molars. The mandibular condyle is then manipulated in a downward and backward direction below the articular eminence. In bilateral dislocation, it may be easier to reduce one side at a time using a lateral rocking motion.

Following the procedure, a post-reduction radiograph is taken to confirm enlocation. The patient is discharged with a supportive bandage to the mandible and a soft diet for the next few days is advised. Follow-up by the maxillofacial surgeon is essential, as temporomandibular dysfunction due to damage to the fibrous cartilage can lead to ongoing symptoms or recurrent dislocations.

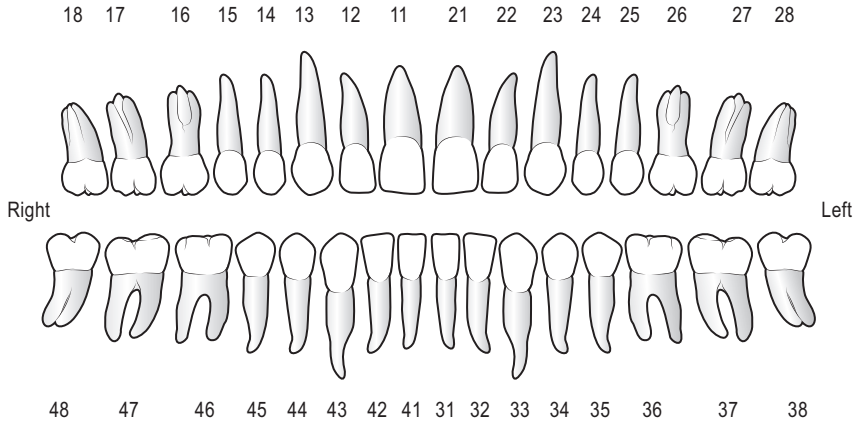

FIG. 17.1.3 Dental nomenclature. (From the FDI World Dental Federation Two-Digit Notation. ISO 3950:2009: Dentistry—Designation system for teeth and areas of the oral cavity.)

Dental infection and abscess (odontogenic infection)

Dento-facial infections usually arise from necrotic pulps, periodontal pockets or pericoronitis.

The symptoms are pain and swelling of the adjacent gingival tissue with facial swelling and fever.

Examination reveals erythema and tender swelling of the gingiva and, in severe cases, frank pus with halitosis. The offending tooth is tender on percussion.

Gingival probing, x-rays and orthopantomography (OPG) confirm the diagnosis.

Management

Periapical abscess requires root canal (endodontic) treatment and, in severe cases, extraction.

Periodontal abscess requires scaling and root planing (periodontal) treatment and, in severe cases, extraction.

Complications include the spread of infection into the submental, submandibular and parapharyngeal spaces of the neck as well as Ludwig angina (cellulitis of the floor of the mouth). If a collection is diagnosed on the CT scan, this requires intravenous antibiotic therapy and drainage.

Dental nomenclature

The international numbering system of teeth should be strictly adhered to in any form of communication. The mouth is divided into four quadrants: the right maxillary as 1, left maxillary as 2, left mandibular as 3 and the right mandibular as 4 (Fig. 17.1.3).

There are five primary teeth and eight permanent teeth in each quadrant.

CONTROVERSIES

- Dental services are generally not part of acute health service funding; therefore low-income patients may have to experience the medical complications of poor dental hygiene before being able to access appropriate care.
- Oil of cloves originated from India and was traditionally used topically for relief of dental pain, such as dry socket, prior to the availability of safe, approved topical anaesthetic agents. However, this oil is highly toxic to human cells even at relatively low concentrations.
- Even small amounts of clove oil (e.g. 0.03% [v/v]) can be life-threatening if ingested.

SECTION 18

EAR, NOSE AND THROAT EMERGENCIES

Edited by *Peter Cameron*

18.1 Ear, nose and throat emergencies

Carmel Crock • Nadine de Alwis

ESSENTIALS

1 Make sure that the ear-nose-throat (ENT) supplies in your emergency department are well stocked and maintained.

2 Develop agreed pathways/protocols with your local ENT department for common and serious presentations.

3 A foreign body in the ear requires atraumatic removal with appropriate equipment and a cooperative patient. Refer to ENT if you anticipate difficulty.

4 Exclude a perilymphatic fistula in blunt and penetrating ear trauma, which may be suggested by sensorineural hearing loss and dizziness.

5 Idiopathic sudden sensorineural hearing loss is an emergency treated with oral steroids.

6 Exclude septal haematoma in a fractured nose, as delayed diagnosis may lead to a saddle-nose deformity.

7 Fish bones commonly lodge in the tonsillar bed or at the base of the tongue. Refer to ENT for nasoendoscopy if you are unable to localize the bone and the patient is symptomatic.

8 Suspect supraglottitis in adults with sore throat, painful swallowing and minimal signs in the pharynx. Meningococcal strains are on the rise. Refer to ENT for nasoendoscopy.

Introduction

Ear-nose-throat (ENT) emergencies are common in emergency departments. The key to their successful management is the availability of appropriate ENT equipment (Box 18.1.1) and familiarity and practice in its use.

Box 18.1.1 Ear-nose-throat equipment

Ear
Otoscope
Portable headlight
Ear speculae and pneumatic attachment (Seigel)
512-Hz Tuning fork
House aural suckers: 11, 14, and 17 gauge, with adaptors
Merocel Otowick (Pope wick)
Alligator and cupped crocodile forceps
Jobson-Horne probe (wax curette)
Right-angled hook
Ear swabs

Nose/throat
Protective gown, gloves, eye protection (goggles)
Nasal speculae: Thudicum or Killian
Cophenylcaine (lignocaine/phenylephrine) spray and 1:10,000 adrenaline
Spray nozzles
Cotton wool balls
Nasal sucker (Frazier/Ferguson)
Cotton buds
Tilley forceps (nasal packing)
Silver nitrate sticks
Nasal packs: Rapid Rhino (single balloon anterior 5.5 cm, 7.5 cm and double balloon posterior 9 cm), Merocel (3.5 cm, 8 cm), Kaltostat rope
Absorbable packing e.g. Surgicel, Surgicel Fibrillar, Nasopore, Nasopore forte
Foley catheter and umbilical clamp
Tongue depressor
Large cotton swab sticks
Magill forceps and gauze
Laryngeal mirror and anti-fog solution
Curved artery forceps
#11 blade and scalpel handle

THE EAR

Perichondritis

This presents as painful swelling and redness of the pinna with sparing of the lobule. It may occur after minor trauma, high chondral piercing, a subperichondrial haematoma or severe otitis externa (OE). It can lead to liquefaction necrosis of the cartilage and severe cosmetic deformity of the ear. The primary organism is *Pseudomonas aeruginosa*. Urgent evaluation by ENT should occur. Depending on severity, treatment is with ciprofloxacin 750 mg PO bd (CC) in adult for 1 week with close follow-up or admission for ticarcillin/clavulanate 3.1 g IV q4–6h (CC). Remove involved piercings.

Swelling and redness of the pinna involving the lobule suggests pinna cellulitis, which is treated with anti-staphylococcal antibiotics.

Perichondritis should be distinguished from relapsing polychondritis, an autoimmune condition affecting cartilages of the ear, often

bilaterally, the nose and sometimes laryngeal and costal cartilages.

Acute otitis externa ('swimmer's ear')

This is an infection of the external auditory canal, often caused by swimming, ear syringing, or the use of cotton buds or a hearing aid. Bacterial OE is often caused by *Pseudomonas aeruginosa* or *Staphylococcus aureus*. In about 10% of cases the cause is fungal, such as *Aspergillus* or *Candida* spp.[1]

Features include severe otalgia, discharge, pain on traction of the pinna (this helps distinguish it from otitis media), canal debris and, in more severe cases, canal oedema with little or no view of the tympanic membrane. Suspect fungal infection in patients without water exposure who have used anti-bacterial ototopicals and in those with recurrent OE (especially in diabetics). Fungus may also be involved if there is prominent itch, much debris (often grey/black) and less canal oedema.

Treatment involves removing debris from the canal and assessing whether the tympanic membrane is intact (it may not be possible to see this) as well as prescribing antibiotic or antifungal drops, advising the patient on water precautions and avoiding the use of cotton buds. An ear swab is not normally taken on initial presentation.

Canal debris can be removed with tissue spears (to wick moisture, not to rotate within the canal) or by suction under direct vision using a headlight, aural speculum and metallic house suction catheter (if trained for this procedure). The tympanic membrane is examined and pneumatic otoscopy performed. Fungal OE can cause perforation of the tympanic membrane.

If the discharge is purulent and voluminous and the ear canal is not oedematous, suspect an acute or chronic suppurative otitis media or cholesteatoma.

If the tympanic membrane is intact, framycetin sulphate/gramicidin/dexamethasone (Sofradex) is prescribed for likely bacterial OE. For fungal OE, treatment may include Locacorten-Vioform or Otocomb drops (the latter are thick and tend to block the ear), Otocomb ointment or clotrimazole cream packing with ENT follow-up in 14 days. Ciprofloxacin 0.3% (Ciloxan) (CC) is used if there is perforation of the tympanic membrane.

If there is marked canal oedema, an otowick is inserted to deliver drops and ciprofloxacin/hydrocortisone (Ciproxin HC) used, with ENT review for wick removal in 2 days.

Instruct patients not to allow water in their ears for 2 weeks. A cotton wool ball covered in Vaseline and placed in the external meatus is one effective means. Avoid non-disposable ear plugs.

Differential diagnoses

Occasionally there will be acute otitis media (AOM) with perforation and secondary OE, and both oral antibiotics and ear drops may be required.

In diabetics, the elderly or immunocompromised patients with a discharging ear, consider malignant OE (skull base osteomyelitis), which can be fatal. Presentation includes dull earache, especially at night, pain on chewing, persistent ear discharge and treatment failure. The pathognomonic sign is granulation tissue in the floor of the ear canal. There may be associated cranial nerve palsies (VII, IX, XII). Refer suspected cases to ENT.

A squamous cell carcinoma or basal cell carcinoma of the external ear canal may present as OE, particularly in the elderly.

Furuncle

A furuncle (boil) in the external ear canal presents as an exquisitely tender, localized swelling and is commonly caused by *S. aureus*. Management includes insertion of an otowick, Sofradex ear drops, oral flucloxacillin 500 mg qid (CC) for 5 days and oral analgesia, with ENT follow-up. Incision and drainage under local anaesthetic may be required if there is fluctuance.

Acute otitis media

Presentation is with symptoms of an upper respiratory tract infection, severe otalgia and blocked sensation. It is clinically defined as a red, bulging tympanic membrane. There should be poor or no mobility of the tympanic membrane on pneumatic otoscopy. A tympanic membrane perforation may occur, with otorrhoea. Tuning fork tests demonstrate a conductive hearing loss, with Weber lateralizing to the affected ear. Facial nerve function should be documented. Some unsteadiness may occur; if this is severe, suspect complications.

Initially manage with regular simple analgesia. Commence antibiotics if bilateral or severe infection, unresolving infection after 48 hours of observation or if this is the only hearing ear. Give amoxicillin 500 mg tds (CC) 3 times a day for 5 days. If response is inadequate after 48 to 72 hours, upgrade to augmentin duo forte. If unresolving within 48 to 72 hours of commencing the upgrade, refer urgently to ENT for consideration of a grommet. Rare causes of atypical AOM include autoimmune or vasculitic conditions, syphilis and tuberculosis.

Complications of AOM should be sought and excluded. These include tympanic membrane perforation, suppurative labyrinthitis, mastoiditis with subperiosteal abscess, meningitis, facial nerve palsy, otic hydrocephalus, petrous apicitis, cerebral abscess and venous sinus thrombosis. Seek immediate ENT advice for suspected complications.

Acute mastoiditis

Particularly in children, mastoiditis can still occur secondary to partially treated AOM; it presents with swelling, redness and tenderness over the mastoid with the pinna pushed forward. Refer to ENT for computed tomography (CT) scan of the temporal bones, intravenous antibiotics and consideration for surgery.

Idiopathic sudden sensorineural hearing loss

This is an otologic emergency. The patient may wake and notice a sudden hearing loss or may present with a blocked ear, unaware of any hearing loss. There is often associated tinnitus and mild disequilibrium. A tuning fork test shows the Weber test lateralizing to the unaffected ear. Whisper voice testing confirms hearing loss.

The cause is unknown but may be vascular, viral or autoimmune in origin. Consider herpes zoster oticus if there is otalgia or vesicles are seen on the pinna or in the canal. If tuning fork testing is consistent with a sudden sensorineural hearing loss (SSNHL), the patient is commenced empirically on oral prednisolone 1 mg/kg up to 60 mg daily (CC) (for 7 days then reducing over a week) and urgent audiogram and ENT follow-up planned for the same or following day. Intratympanic steroids may be used by ENT if there are contraindications to oral steroids. Outpatient magnetic resonance imaging (MRI) is performed to rule out an acoustic neuroma. Sixty percent of patients with idiopathic SSNHL regain some hearing over time.

Acute facial (seventh) nerve palsy

Determine whether this is an upper or lower motor neuron (LMN) palsy. The cause of upper motor neuron (UMN) seventh nerve palsy is often a stroke. There is sparing of forehead muscles and there may be other neurological signs. In LMN seventh nerve palsy, the entire side of the face is affected, including the forehead muscles. The House-Brackmann scoring system should be used to record the degree of facial palsy.

Causes of acute LMN seventh nerve palsy include Bell palsy, Ramsay-Hunt syndrome (herpes zoster oticus), AOM, cholesteatoma, trauma (temporal bone fracture) and rarely autoimmune conditions, vasculitic conditions and infections such as HIV, Epstein-Barr virus (EBV) and syphilis. A parotid tumour, metastatic perineural invasion

and facial schwannoma can cause acute palsy if there is a sudden bleed into the mass but generally these cause slowly progressive, partial facial palsy.

Bell palsy is a diagnosis of exclusion. It is an acute, unilateral, usually complete paralysis and should always show some recovery with time. Symptoms include pain behind the ear, hyperacusis and abnormal taste. It may be viral in origin. Treatment is with oral prednisolone 1 mg/kg up to 70 mg (CC) for 5 days. There is low-quality evidence for benefit from antivirals, but it is an option if commenced within 72 hours of onset.[2] If there is incomplete eye closure, ocular lubricants and ophthalmology referral is required. Eighty percent of patients recover fully within 3 months. If there is no recovery, refer to ENT, and an MRI is warranted.

Ramsay-Hunt syndrome (herpes zoster oticus) usually presents with severe otalgia followed by vesicles on the pinna and/or in the canal. There is often sensorineural hearing loss and a dense facial palsy. Prognosis is poorer than with Bell palsy. Treatment is with an antiviral within 72 hours of the appearance of the rash (famciclovir 250 mg tds (CC) for 7 days or valaciclovir 1 g tds (CC) for 7 days) and oral prednisolone as above.

Ear trauma

In trauma to or around the ear, consider the possibility of cervical spine and head injury.

Base-of-skull fractures

Suspect this if the mechanism of injury is a high-speed motor vehicle accident, fall from a significant height, heavy crush injury or multitrauma. Clinical signs include raccoon eyes, the Battle sign and clear or bloody otorrhoea or rhinorrhoea with a halo sign on the bed sheet.

Anterior fractures mainly involve the cribriform plate; if there is also a dural tear, this will present with cerebrospinal fluid (CSF) rhinorrhoea. Do not insert a nasogastric tube if this is suspected.

Lateral fractures involve the temporal bone. Order a CT of the petrous temporal bone or reconstruction CT of the brain. Fractures that spare the otic capsule are more common and can include the ear canal, perforate the eardrum and disrupt the ossicles. Otic capsule involving fractures are more likely to cause facial palsy, CSF otorrhoea, perilymphatic fistula and sensorineural hearing loss but are less common. In all head trauma, document facial nerve function and inspect the ear. Complete facial palsy of immediate onset requires urgent surgical decompression by ENT. Any delayed or incomplete palsy can be managed with steroids and timely review by ENT, with an audiogram when possible.

Subperichondrial haematoma of the pinna

This results from blunt trauma to the pinna. It can lead to necrosis of the cartilage, causing a deformity known as 'cauliflower ear'. Refer to ENT for surgical incision and drainage. Small collections can be drained by needle aspiration or stab incision using sterile technique; however, these tend to recur if the dressing is inadequate. Larger collections involving multiple subunits of the pinna should be drained under general anaesthesia.

After needle aspiration or stab incision, apply a conforming pressure dressing, give oral flucloxacillin 500 mg qid (NDA), and arrange review in 24 hours. Do not suture the dressing through the cartilage, as this may cause perichondritis. Materials such as paraffin-soaked ribbon gauze, Bismuth subnitrate, Iodoform and Parrafin Paste (BIPP) gauze and Xeroform dressing can be moulded and lightly tacked to the overlying skin with a nylon suture. Over this a mastoid pressure dressing can be applied and removed by the patient in 24 to 48 hours and then replaced with a soft headband for 1 week. The conforming dressing can be removed after 1 week and the soft headband should be used over the ear whilst sleeping for further 1 to 2 weeks. Contact sport should be avoided for 3 weeks to prevent recurrence.

Lacerations to the auricle

Refer wounds involving the ear cartilage to ENT or plastic surgery for repair. Simple skin lacerations involving the auricle can be sutured (using 5-0 or 6-0 non-absorbable nylon). Give tetanus prophylaxis as indicated and oral flucloxacillin 500 mg qid for 5 days (NDA).

Foreign body in ear

In adults, common foreign bodies in the ear are cotton bud tips, rubber pieces of hearing aids, pieces of silicone ear plugs and live insects. Live insects should be drowned using olive oil, Waxsol or lignocaine 2%.

A foreign body (FB) in the ear should be removed atraumatically under direct vision with a head light, the largest appropriate ear speculum and a cooperative patient. Crocodile forceps, a right-angle hook or metal suction catheter can be used, depending on the type of FB. Hard beads should not be grabbed with crocodile forceps, as they can be pushed in further; use a hook instead. After removal, document the appearance of the tympanic membrane and whether it is intact.

If the practitioner is not experienced in use of the equipment or the foreign body is impacted, the patient can be referred to ENT for its removal. This is not an emergency.

Barotrauma

This can occur on descent of a plane or during scuba diving, causing a haemotympanum, which causes otalgia and a blocked sensation; however, it usually resolves spontaneously. More severe barotrauma may result in perforation of the tympanic membrane and rupture of the oval or round window, resulting in a perilymphatic fistula. This is suggested by sensorineural hearing loss, a positive fistula test, vomiting, dizziness, unsteadiness and a positive Hallpike test. If these features are present, refer urgently to ENT.

Acoustic trauma

Exposure to a sudden loud noise may cause temporary or permanent hearing loss, which may present as tinnitus with or without otalgia and sensitivity to noise. Refer patient for a formal audiogram and an ENT opinion. Steroids may be required. Counsel the patient on hearing protection to prevent further damage.

Traumatic tympanic membrane perforation

This may occur in the setting of a blast injury, diving, slap to the ear or a penetrating injury such as from a cotton bud or sharp plant. Exclude perilymphatic fistula, especially in postero-inferior perforations.[3]

For penetrating perforations arrange an urgent audiogram (same or next day). If a perilymphatic fistula is suspected, arrange urgent ENT referral for possible surgical exploration.

For non-penetrating injuries without clinical evidence of sensorineural hearing loss or lasting dizziness, an audiogram can be arranged in 6 weeks' time to objectively document that the perforation has healed.

Advise the patient to keep the ear dry and arrange ENT follow-up.

THE NOSE

Epistaxis

Epistaxis is a common presentation, particularly in elderly patients on antiplatelet and anticoagulant medication. Over 90% of epistaxis is anterior, arising from the Little area antero-inferiorly on the nasal septum, and it can be controlled with simple measures. In the elderly with significant bleeding, assessment and treatment of epistaxis will progress simultaneously. Assess airway, breathing and circulation and insert intravenous lines, taking blood (including full blood count, group and hold and coagulation studies with or without liver function tests, depending on history)

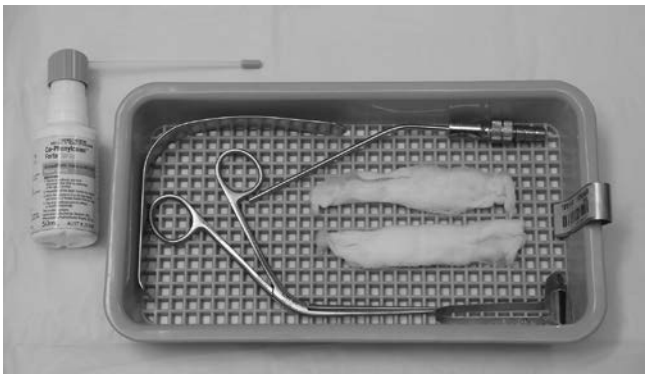

FIG. 18.1.1 Epistaxis tray.

and commence intravenous fluid. Ask the patient or nurse to commence first aid, applying continuous, firm pressure to the anterior nares for 10 to 15 minutes. After donning a gown, gloves and eye shield/goggles, mask and headlight, open an epistaxis tray (Fig. 18.1.1) containing a tongue depressor, nasal speculum and nasal suction catheter and nasal packing (Tillley) forceps. Unroll two cotton wool balls and spray with lignocaine/phenylephrine (Cophenylcaine) until soaked (maximum 10 sprays in patients with cardiovascular disease). These will be used as nasal packs, providing topical local anaesthesia, vasoconstriction and decongestion of the nasal mucosa. Use the nasal speculum and suction catheter to suction clots from the nose and gently pack both sides of the nose with Cophenylcaine-soaked cotton wool. Any nasal packing can cause a vagal response.

Using the tongue depressor, examine the back of the throat for posterior bleeding. Wait for 10 to 15 minutes, then remove the cophenylcaine-soaked cotton wool and seek the source of bleeding. If the bleeding recommences, repack the nose, as earlier. This process may need to be repeated several times until the bleeding slows or stops.

If the bleeding site can be clearly identified (as by touching it with a cotton bud tip and causing bleeding), it can be cauterized using a silver nitrate stick in a rosette fashion. Make sure that the site is not bleeding at the time of cautery and that the silver nitrate does not run onto the face, as it can then cause a superficial burn and stain the skin. Avoid cautery to both sides of the nasal septum, as this can result in septal necrosis and perforation. Surgicel can be applied over the cauterized site and barrier ointment, such as Nasalate or mupurocin 2%, prescribed. The patient can be discharged if there is no further bleeding after 1 to 2 hours including ambulation within the department.

For patients on an antiplatelet or anticoagulant, consider avoiding cautery and packing the nose with absorbable packing, such as Surgicel fibrillar or Nasopore, to avoid the need for removal. Check the International Normalized Ratio (INR) of patients on warfarin and manage over-coagulation.

If anterior epistaxis cannot be controlled by the outlined measures, a nasal pack such as a Rapid Rhino™ can be used, inserted parallel to the nasal floor and slowly inflated with air. A nasal tampon (Merocel) is an alternative, but it is more traumatic and requires lubrication. Commence oral cephalexin 500 mg bd (CC) to avoid toxic shock syndrome. Admit all patients with bilateral packs and the elderly or patients with obstructive sleep apnoea/respiratory disease/multiple comorbidities and unilateral packs. Uncomplicated patients with unilateral packs can be discharged and reviewed in 48 hours for removal of the pack.

In posterior epistaxis, bleeding is often from both nostrils and down the back of the throat. Most epistaxis, however is still anterior, with failed anterior packing most commonly due to inadequate suctioning of the posterior blood clot prior to nasal packing rather than true posterior bleeding. A 9-cm Rapid Rhino 900™, which has both anterior and posterior balloons, can be used, or a Foley catheter plus anterior nasal packing with ribbon gauze, secured with an umbilical clamp. If the bleeding cannot be controlled, the patient may have to undergo surgery for ligation of the sphenopalatine artery and rarely the anterior ethmoid artery.

Patients who have had functional endoscopic sinus surgery, septoplasy and turbinectomy can present with heavy bleeding. Management should involve resuscitation measures, initial packing of the nose with cophenylcaine-soaked cotton wool, followed by Nasopore. Rapid Rhino may be necessary to control bleeding while awaiting ENT arrival. Patients who have had septoplasty and require a nasal pack should have bilateral packing. On occasions, return to surgery to control the bleeding is required.

Topical application of the injectable preparation of tranexamic acid in epistaxis has been described, using cotton pledgets[4,5]; however, a recent Cochrane review did not recommend its routine use in non-surgical bleeding.[6]

Instruct patients on appropriate first aid (sitting with head forward, ice to suck and on back of neck, pinching the soft part of the nose together for 15 minutes), to refrain from hot drinks and hot showers for 24 hours, avoid blowing the nose, and to avoid straining as well as heavy exercise for 2 weeks.

Acute rhinosinusitis

With a presentation of nasal congestion, discharge, facial pain or pressure, it can be difficult to distinguish acute bacterial rhinosinusitis from more common viral rhinosinusitis, which resolves in 7 to 10 days without treatment. Symptomatic treatment involves regular oral analgesia, saline nasal spray, topical nasal steroid spray, and topical nasal decongestant for 3 days. If symptoms are severe, prolonged (>7 days) or worsening in an adult, consider oral amoxicillin 500 mg tds for 5 days as first line treatment. If nil improvment within 48hrs then upgrade to oral amoxycillin with clavulanic acid 875/125mg bd for 5 days. If there are any signs of complications such as unilateral periorbital oedema, then refer to ENT and commence IV broad spectrum antibiotics and IV dexamethasone as instructed.[7]

Complications include preseptal and orbital cellulitis, sub-perisoteal abscess, cerebral abscess and dural venous sinus thrombosis. Severe invasive fungal sinus infections (e.g. mucormycosis) can occur in the immunocompromised, including diabetics, requiring urgent ENT and infectious disease management. This can be a life-threatening emergency and usually presents with pain out of proportion to the clinical signs. A pale or dusky appearance of the nasal mucosa may be all that is seen, so clinical suspicion must remain high in immunocompromised hosts. If such a patient is presenting late, frank necrosis may be seen, along with orbital and cranial nerve involvement, although at this stage the mortality nears 80%.

Fractured nose

Nasal bone fracture, common after blunt trauma including contact sports and fights, is a clinical diagnosis and x-rays are unnecessary; however exclude other facial fractures, cervical spine and head injury. CSF rhinorrhoea suggests fracture of the cribriform plate. Refer immediately to ENT if there is gross deformity, open fracture or septal haematoma, which is managed with incision and drainage. A septal haematoma is a red boggy swelling over the septum, diagnosed by gentle pressure with the tip of a cotton bud. Delayed diagnosis of septal haematoma may result in necrosis of the nasal cartilage and a 'saddle nose' deformity.

If there are no indications for immediate referral, refer to ENT for review within 5-7days. This allows time for reduction of the swelling and enables proper assessment for consideration of manipulation under anaesthesia, ideally within 2 weeks of injury date.

Nasal vestibulitis

Nasal vestibulitis presents with crusting within the nose. Management is with local antibiotic ointment such as mupirocin 2%. It can lead to nasal cellulitis requiring systemic anti-staphylococcal antibiotics and prompt intravenous treatment if there is no improvement on oral therapy. This area is part of the 'danger space of the face,' as infections can spread via valveless venous channels from the superficial to the deep venous system, rarely leading to cavernous sinus thrombosis, which is nearly always fatal.

THE THROAT

Pharyngitis/Tonsillitis

A simple sore throat is often viral and antibiotics are not warranted; however, it can be difficult to distinguish viral from bacterial infection. If the patient looks unwell or has severe symptoms and signs—such as high fever, drooling, new-onset snoring, stridor, torticollis, trismus, voice change, severe adenopathy and dehydration—treat with an antibiotic, such as phenoxymethypenicillin 500 mg (child: 15 mg/kg up to 500 mg) q62h (NDA) for 10 days. A throat swab should be taken for emerging beta lactamase–producing group A streptococcal strains. If culture is negative and the patient is improving, antibiotics can be ceased. Treat with antibiotics all indigenous Australians, patients who have had previous rheumatic fever and the immunocompromised.

Epstein-Barr virus (infectious mononucleosis) can present in young adults with severe sore throat and confluent white exudative tonsillitis. Amoxicillin should be avoided in EBV as it can cause a morbilliform rash. Treat with intravenous fluids and paracetamol. Occasionally intravenous dexamethasone is warranted for symptomatic relief. A Monospot test can be used to confirm the diagnosis; although a negative test dose cannot exclude EBV, but serology can. Viral infections can predispose to secondary bacterial infection; thus, if there are upper airway obstructive symptoms or symptoms persist or are worsening, treat with antibiotics.

In all cases of tonsillitis, if there is difficulty tolerating oral fluids, dehydration or a complication is suspected, consider admission for intravenous paracetamol, fluids, dexamethasone 8 mg stat, benzylpenicillin 1.2 g q6h. Rarely, grossly enlarged tonsils can cause upper airway obstruction and admission to a high-dependency unit (HDU) is warranted.

Quinsy (peritonsillar abscess)

Presentation is with unilateral throat pain, fever for 3 days or more, muffled 'hot potato' voice and trismus. There is unilateral swelling of the soft palate, with the tonsils displaced inferomedially and the uvula displaced to the contralateral side.

Management is aspiration or incision and drainage under local anaesthesia, in most institutions performed by ENT. Admit and give intravenous benzylpenicillin 1.2 g qid (NDA) and intravenous metronidazole 500 mg tds (NDA).

In patients over 40 years of age, especially smokers, consider squamous cell carcinoma of the tonsils and ENT follow up is recommended.

Epiglottitis/Supraglottitis

Epiglottitis, previously mainly a childhood disease, has become rare since introduction of *Haemophilus influenzae* B vaccine.

Supraglottitis, infection and swelling of the tissues above the vocal cords including the epiglottis, occurs mainly in adults. Organisms are varied, including *Streptococcus pneumomiae* and viruses. Presentation is with sore throat, odynophagia, dysphonia and sometimes stridor.[8] Have a high index of suspicion in adults with painful swallowing, a hoarse voice and minimal signs in the pharynx to explain the symptoms; refer to ENT for flexible nasoendoscopy. Supraglottitis can on occasion cause airway compromise in adults. Management includes close monitoring of the airway, admission to an HDU or intensive care unit (ICU) under ENT, intravenous ceftriaxone 1 g daily for (NDA) 5 days (NDA) and intravenous dexamethasone 8 mg stat then regular dosing (NDA).[9] There is emerging meningococcal supraglottitis in the unvaccinated adult population.

Post-tonsillectomy bleeding

Classified as primary (within 24 hours post-operatively) or secondary (after 24 hours, normally day 5 to 10 and related to infection), post-tonsillectomy bleeding can rarely cause death from airway obstruction or haemorrhagic shock.

With an increase in day-case tonsillectomy, emergency departments are likely to see an increase in presentations due to primary post-tonsillectomy bleeds. These require a return to surgery.

Notify ENT, summon senior help, insert large-bore intravenous access and take blood for full blood count, coagulation studies, group and hold. Give bolus intravenous normal saline 20 mL/kg and intravenous paracetamol. Sit the patient upright to facilitate removal of blood.

If the patient is not actively bleeding, do not attempt to remove blood clot visible on the tonsillar bed; instead, await ENT arrival.

In brisk active bleeding, suction blood and, if a bleeding point on tonsillar fossa can be visualized, firmly apply a large cotton swab stick soaked in 1:10,000 adrenaline (or gauze soaked in 1:10,000 adrenaline held with Magill forceps) and apply pressure for 20 minutes.

If bleeding cannot be controlled with these measures, urgent return to surgery is warranted. Intravenous tranexamic acid 1 g (15mg/kg) may be given. Although there is no direct evidence for its use in post-tonsillectomy bleeding, it has been shown to reduce the need for transfusion in post-surgical bleeding.

Foreign body in throat

Oropharyngeal foreign body

Chicken or fish bones may lodge in the tonsils (commonest site), tongue base, vallecula or pyrifom fossae. Rare serious complications include perforation, retropharyngeal infection and mediastinitis.

History is crucial, with onset of discomfort at the time of eating and pinpoint pain suggestive of a FB. There may be local tenderness on moving the larynx. The patient may clearly indicate the site of lodgement by pointing to a site on the neck. Using a headlight and tongue depressor, inspect the tonsils and tongue base. Tilley forceps can be used to remove a bone visible in the tonsils or tongue base.

Use a laryngeal mirror to inspect the vallecula and pyriform fossae. If no FB is seen and the patient remains symptomatic, refer to ENT for nasoendoscopy. If no bone is seen on nasoendoscopy and the history is suggestive, ENT will consider non-contrast CT of the neck.

Oesophageal foreign body

An oesophageal food bolus or bone may cause partial or complete obstruction, with inability to swallow saliva.

A lateral neck x-ray will show fish bones, when present, 20% of the time; however, subtle signs such as loss of the cervical lordosis may indicate oesophageal FB. In symptomatic patients, refer to ENT for nasoendoscopy. ENT may consider a CT of the neck or may perform rigid oesophagoscopy, depending on the history and examination (laryngeal crepitus or pain on moving the larynx, drooling, inability to swallow saliva). Soft oesophageal FBs can be dealt with by gastroenterology, but sharp objects should be referred to ENT with the aim of removal within 24 hours. Referral pathway depends on local protocols.

SECTION 19

OBSTETRICS AND GYNAECOLOGY EMERGENCIES

Edited by *Biswadev Mitra*

19.1 Pelvic pain

Anusch Yazdani

ESSENTIALS

1 **History, abdominal and age-appropriate pelvic examination guide diagnosis.**

2 **History and examination can be supplemented, but not replaced, with appropriate investigations.**

3 **A normal pelvic examination should not preclude gynaecological referral, even in the absence of other findings.**

4 **The possibility of pregnancy must be considered in *all* patients of reproductive age with abdominal or pelvic pain under the following well-iterated tenets:**
- **All female patients are pregnant until proven otherwise.**
- **All pregnant patients have an ectopic pregnancy until proven otherwise.**

5 **Give effective analgesia with the regular administration of non-steroidal anti-inflammatory drugs (NSAIDs).**

Introduction

Pelvic and lower abdominal pain in female patients is a complex and challenging complaint. It is the second most common gynaecological symptom after vaginal bleeding, and the large differential diagnosis for female pelvic pain makes a definitive diagnosis in the emergency department (ED) difficult. A systematic approach is essential.

The emergency physician should aim to stabilize the haemodynamically unstable patient, provide adequate analgesia where appropriate, identify conditions that require early surgical intervention and expedite the investigation and further management of females with pelvic pain.

Classification

Pelvic pain is traditionally classified as either acute or chronic. Conditions causing pelvic pain can be life threatening or inconsequential, gynaecological or non-gynaecological and/or non-organic. These presentations are often complex and require ongoing care and management, often by multiple specialties.

Presentation

This chapter outlines the initial presentation and management of the most common gynaecological conditions associated with acute and chronic pelvic pain.

History

A detailed pain history is essential in the assessment of abdominopelvic pain. This should include the site, severity, onset and time course, character, radiation, associated symptoms, radiation or shift and exacerbating or relieving factors.

As such, parietal pelvic pain may be well localized and occur secondary to peritoneal irritation, such as in appendicitis and mittelschmerz. More generalized and diffuse abdominal pain may be associated with intraperitoneal blood or inflammation resulting from an ectopic pregnancy or a tubo-ovarian abscess. Severity of pain is best assessed by the impact of the pain on function, such as activities of daily living or acute incapacitation.

Pain of abrupt onset is associated with sudden events, such as ovarian cyst rupture or adnexal torsion. Gradually worsening pain is suggestive of a long-term process, such as endometriosis or chronic pelvic inflammatory disease (PID). Pain with sexual intercourse (dyspareunia) may be associated with any pelvic process, including adnexal pathology and endometriosis.

Table 19.1.1 Causes of acute pelvic pain

	Non-gynaecological		
Gynaecological	*Intestinal*	*Urological*	*Other*
Complication of pregnancy: ectopic, miscarriage	Appendicitis	Cystitis	Hernia
Complication of ovarian and adnexal cysts and masses	Diverticulitis	Acute urinary retention	Pelvic vein thrombophlebitis
Pelvic inflammatory disease	Inflammatory bowel disease	Urolithiasis	
Adnexal torsion	Gastroenteritis	Pyelonephritis	
Leiomyoma complication	Bowel obstruction Constipation		

Pain radiation may provide a clue to the underlying origin, such as pain referred via the hypogastric nerve plexus to the lower abdomen from the uterine fundus, adnexae and bladder dome. The S2–4 sacral nerve roots transmit pain from the lower uterine segment, cervix, bladder trigone and rectum to the lower back, buttocks, perineum and legs. A history of associated urological, gastrointestinal and musculoskeletal symptoms is essential.

Sexual and reproductive history

The reproductive history should focus on the current menstrual pattern and any relation to pain, the last normal menstrual period (LNMP), menarche, menopause, pregnancies (regardless of outcome) and previous gynaecological surgery. A sexual history, taken appropriately and with due consideration to privacy and confidentiality, should include time of last intercourse, contraception, number of partners, possibility of physical or sexual abuse and sexually transmitted diseases (STDs).

Psychosocial impact

Finally, the clinician should particularly consider psychosocial factors in the evaluation of chronic pain. The symptoms of fatigue, loss of energy and depressed mood are commonly associated with chronic pelvic pain; thus a screen for anxiety, depressive and somatoform disorders is essential.

Enquire about relationship distress, the partner's understanding and response to the pain and the family's response to how the patient is managing her pain.

Examination

Examination starts with an assessment of the body habitus and an establishment of baseline observations, including height, weight, temperature, pulse and blood pressure, which may indicate life-threatening haemorrhage, such as an ectopic pregnancy or overwhelming sepsis associated with a tubo-ovarian abscess. The examination then proceeds in a systematic manner from the hands to the feet. As in all intimate examinations, it is important to provide early analgesia and establish rapport with the patient, who may be reticent, frightened or embarrassed.

Abdominal examination

Commence the abdominal examination with inspection for distension associated with obstruction, ascites or abdominal masses. Palpation and percussion can delineate areas of generalized or localized tenderness and may replicate the patient's pain. Check for hernias, inguinal nodes and other non-gynaecological causes for the patient's symptoms at the same time (Table 19.1.1).

Pelvic examination

In the sexually active patient, a pelvic examination is an important differentiator of the aetiology of pain. However, it is not mandatory when the diagnosis is certain – for example, in early-pregnancy bleeding (see Chapter 19.4). Perform this only in the presence of a chaperone, after providing a careful explanation of the procedure and obtaining consent.

It is important to note that bimanual examination has been shown to have limited sensitivity and specificity in the evaluation of pelvic organs, independent of the experience the examiner. The overall accuracy of pelvic examination under anaesthesia compared with operative findings has been estimated at 70% for specialists and 60% for medical students. Not surprisingly, there is lower sensitivity for the detection of adnexal pathology compared with the assessment uterine size or contour. Similarly, even in specialized endometriosis units, the sensitivity and specificity of vaginal examination for retro-cervical and recto-vaginal disease is only around 70%.

However, as a low-cost, low-risk intervention, it is recommended that a vaginal examination be considered as part of the assessment of the infertile couple. The pelvic examination guides the suspicion of pelvic pathology, which will then increase the predictive value of any subsequent targeted investigations, such as ultrasound.

The pelvic examination includes the following:

- Visual examination of the vulva and urethral meatus to identify varicosities, infection or abnormal lesions.
- Speculum examination to visualize the cervix, cervical os and the vaginal vault. Note any vaginal discharge and take endocervical and vaginal swabs. However, performance of a routine cervical screening test is *not* encouraged.
- Bimanual (vagino-abdominal) examination to examine the cervix, uterus and adnexae.

The uterus is normally mobile, but conditions such as endometriosis or adhesions may cause fixation. An enlarged uterus is associated with pregnancy, fibroids or adenomyosis. The uterine axis is dependent on a number of other local pelvic factors such as the content of the bladder or bowel. A retroverted uterus can be normal, but a fixed retroverted uterus is classically associated with pouch-of-Douglas pathology, such as endometriosis.

Uterine tenderness occurs with any cause of pelvic peritonism but also conditions such as adenomyosis or fibroid degeneration. An open cervical os may be associated with the passage of intrauterine pathology, such as a failed pregnancy or clots. Cervical excitation (pain on moving the cervix) is non-specific and associated with any condition producing pelvic peritonism, such as blood or other irritants in the peritoneal cavity, including PID (see Chapter 19.2). Palpable adnexal masses are associated with more gross pathology, such as an ovarian cyst.

A normal pelvic examination does not exclude pelvic pathology but guides the selection of further definitive investigations, such as an ultrasound scan (USS) or laparoscopy.

Rectal examination

A rectal examination, where appropriate, completes the pelvic examination. This should be performed only once, preferably by the doctor providing continued clinical care. Practitioners should take note of stool consistency, faecal occult blood and the presence of a mass lesion. A rectovaginal examination allows palpation of the posterior cul-de-sac for ovarian masses, the posterior wall of the uterus and the uterosacral ligaments for nodularity and tenderness in association with endometriosis.

Laboratory investigations

Laboratory investigations depend on the history and physical examination and are tailored to the individual patient. They include the following.

Urinalysis

Urinary beta subunit of human chorionic gonadotrophin (β-hCG) is rapid, inexpensive and accurate. This should be performed in all female patients of childbearing age. The presence of leucocytes in the urine may indicate infection with a sensitivity of around 70% to 75%, but it may also be associated with inflammation of adjacent pelvic organs. The presence of red cells may indicate urolithiasis.

The urine should be sent for microscopy, culture and sensitivity if urinary tract pathology is suspected. The urine should also be sent for chlamydial and gonorrhoea polymerase chain reaction (PCR) in suspected PID (see Chapter 19.2).

Microbiological swabs

Take endocervical swabs for chlamydia, gonorrhoea and *Ureaplasma* during the speculum examination. Specific viral and bacterial swabs vulval swabs should be taken only in the presence of a vulval lesion, such as suspected herpes simplex infection.

Blood tests

Beta human chorionic gonadotrophin

The β-hCG is produced by the outer layer of cells of the gestational sac (the syncytiotrophoblast) and may be detected as early as 9 days after fertilization (see Chapter 19.4). False-positive and even false-negative serum and urine tests do occur but are extremely rare.

Full blood count, erythrocyte sedimentation rate and C-reactive protein

A full blood count may show anaemia. A leucocytosis may indicate underlying infection or inflammation. An elevated erythrocyte sedimentation rate (ESR) or C-reactive protein is a non-specific marker of acute inflammation and would be included in the clinical diagnosis of PID at some centres.

Tumour markers

Tumour markers have a limited role in the evaluation of pelvic pain in the ED. Markers such as CA 125 may be sent in the evaluation of an adnexal mass or when endometriosis is suspected. Serial levels improve the sensitivity and specificity of such markers, usually on an outpatient basis.

Imaging

Ultrasound scan

Ultrasound should be considered a non- or minimally invasive extension of the physical examination. Other than the pregnancy test, this is the single most useful investigation in the diagnosis of acute gynaecological presentations.

Ultrasound determines normal anatomical findings, such as uterine size; the thickness and morphology of the endometrium, myometrium and adnexae; as well as pathology, such as fibroids, ovarian cysts, endometriomata, hydro/pyosalpinges, tubo-ovarian masses and tumours.

USS is more accurate at predicting abnormal pelvic pathology, as confirmed by laparoscopy, than pelvic examination alone. Bedside operators familiar with the transabdominal and transvaginal (endocavitary) ultrasonographic examination can obtain more accurate information faster, thereby improving time to consultation or discharge. However, there are pitfalls associated with missing uncommon diagnoses. Such investigations should be followed up by a formal ultrasound.

Computed tomography scan

A computed tomography (CT) scan has poor soft tissue resolution and therefore a limited role in the assessment of pelvic pain. It may be helpful in the definition an abdominopelvic mass that cannot be assessed by USS, the identification of a urinary calculus, a Spigelian hernia or appendicitis. The radiation risk should be considered, particularly if a repeat scan is needed.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) most appropriately defines adenomyosis, congenital reproductive abnormalities and endometriotic lesions. Although this modality has a limited role in an emergent ED assessment, it has a specific role in the evaluation of acute pain in the adolescent and in advanced gestation.

DIFFERENTIAL DIAGNOSIS

Patients attending the ED present with

- acute pelvic pain
- chronic pelvic pain

Importantly, patients with chronic pelvic pain may present acutely with a de novo pathology or an acute exacerbation of chronic pain.

Acute pelvic pain

Table 19.1.1 lists conditions that present to the ED with acute pelvic pain. The causes may be considered under the following.

Pregnancy-related

A pregnancy test must be performed in all women of reproductive age; if diagnosed, an ectopic pregnancy must then be excluded (see Chapter 19.4).

Pelvic inflammatory disease

See Chapter 19.2 on the evaluation of PID.

Adnexal mass or cyst

Ovarian mass or cyst

- 'Functional' ovarian cysts are either follicular cysts that develop during the first 14 days of the menstrual cycle prior to ovulation or luteal cysts that develop following ovulation. Such cysts are usually asymptomatic unless a complication, such as haemorrhage, rupture or torsion occurs. As these cysts are related to normal ovarian activity, an ovarian cyst in the postmenopausal woman should never be considered 'functional'.
- Neoplastic masses may be benign or malignant. Features that increase the risk of malignancy include being post-menopausal, the presence of ascites and increasing size or complexity of the lesion.
- Infective masses usually arise as part of a tubo-ovarian mass in association with PID.
- Endometriomata are deposits of endometriosis in association with the ovary, forming a collection of altered blood and cellular debris, hence the term 'chocolate cyst'.

Non-ovarian adnexal mass or cyst

- Para-ovarian and paratubal cysts are related to either the ovary or, more commonly, the fallopian tube.
- A hydrosalpinx arises in the blocked fallopian tube.

Any of these structures may present acutely due to rupture, haemorrhage or torsion.

Rupture of an ovarian cyst

Follicular cyst expansion and/or rupture at ovulation is accompanied by ovarian bleeding and peritoneal irritation, known as mittelschmerz, during the mid-cycle. Rupture of a corpus luteum cyst usually occurs between days 20 and 26 of the menstrual cycle and is associated with intraperitoneal bleeding. Rarely, such bleeding may be catastrophic, particularly if the patient is anticoagulated or has a coagulopathy.

An USS differentiates a ruptured ectopic pregnancy from a bleeding corpus luteum cyst, although they may coexist.

Intra-ovarian haemorrhage

Haemorrhage may occur into a functional cyst or tumour. The sudden onset of sharp unilateral pain with increasing intensity results from ovarian capsule distension. There may be localized or generalized peritonism dependent on the degree of peritoneal irritation and haemorrhagic extravasation. Pelvic examination may reveal a focal expanding adnexal mass, which is confirmed by USS.

Haemorrhagic ovarian cysts may be managed conservatively. Indications for intervention include haemodynamic instability, failure to obtain adequate analgesia and failure of symptom resolution.

Torsion of adnexae

The adnexae include the ovary and fallopian tube. Torsion occurs when these structures twist on their supportive appendages, compromising their vascular supply. This most commonly occurs in the third decade of life and accounts for 3% to 5% of emergency gynaecological surgery.

Over 90% of cases of adnexal torsion are associated with cystic tumours or simple cysts of the ovary. Torsion of the fallopian tube is less common and is associated with a hydrosalpinx, tubal ligation and pelvic adhesions. Both adnexal torsion and torsion of the fallopian tube present with an enlarging adnexal mass secondary to venous obstruction and secondary oedema.

Pain associated with adnexal torsion is commonly sudden in onset, sharp, unilateral and increasingly severe on a background of a dull pelvic ache. Classically it radiates from the pelvis to the flank ('reverse renal colic') and is associated with nausea, vomiting, low-grade pyrexia and urinary symptoms secondary to bladder irritation. Late cases can present with ovarian necrosis, frank peritonitis and shock.

Ovarian infection

This may rarely occur as a primary event with mumps or tuberculosis; most commonly it occurs in the setting of PID with the formation of a tubo-ovarian abscess (see Chapter 19.2).

Chronic pelvic pain

Chronic pain has been defined as pain lasting for more than 6 months, but is now recognised as pain that extends beyond a period of healing and levels of pathology that are often low and insufficient to explain the presentation. It affects millions of women worldwide and accounts for 10% of gynaecology outpatient attendances.

The commonest diagnoses associated with chronic pelvic pain are endometriosis and pelvic adhesions. However, up to 60% of patients have no visible pathology at laparoscopy and 25% remain without a definitive diagnosis.

Patients may present to the ED with an unrelated acute cause of pelvic pain, an acute exacerbation of their chronic condition or the inability to manage their debilitating condition.

Cyclic pelvic pain

Cyclic pelvic pain occurs in 30% to 50% of women of reproductive age and interferes with normal daily activities in up to 12% of cases. Cyclic pain is typically related to ovulation or menstruation, but many nongynaecological conditions can have cyclical exacerbations. Many conditions that cause cyclic pain, such as endometriosis, may ultimately come to cause acyclic, chronic pain (Table 19.1.2).

Table 19.1.2 Causes of cyclic and acyclic pelvic pain

Cyclic	*Acyclic*
Mittelschmerz	Chronic PID
Endometriosis[a]	Pelvic adhesions
Adenomyosis	Uterine prolapse
Cervical stenosis[a]	Chronic urethritis
	Diverticulitis
Leiomyoma (fibroid)	Irritable bowel syndrome
Primary dysmenorrhoea	Levator syndrome
	Detrusor instability
	Interstitial cystitis
	Abdominal hernia
	Abdominal wall myofascial pain
	Abuse syndromes: physical and sexual
	Depression

PID, pelvic inflammatory disease
[a]May become 'acyclic'.

Mittelschmerz

Mittelschmerz is the transient mid-cycle pain occurring at or after ovulation; it is related to increasing ovarian capsular pressure due to ovulation. The pain is typically poorly defined but becomes localized following follicular rupture and the release of fluid and/or blood, causing peritoneal irritation.

There are usually minimal findings on physical examination. Mittelschmerz is a clinical diagnosis, but USS may reveal the presence of a recently ruptured follicle. Regular NSAIDs and reassurance should be provided. Although the pain on presentation may be severe, it usually resolves spontaneously.

Endometriosis

Endometriosis is defined as the presence of ectopic endometrial glands and stroma outside the uterine cavity. Initially, the pain may be cyclic and associated with menses; as the disease progresses, however, the pain often becomes continuous and acyclic.

Endometriosis affects women of reproductive age and is the second most common cause of cyclic pain in this age group. Up to 60% of patients investigated for infertility and pain are found to have endometriosis.

Typically the pain commences a few days prior to the menses and extends variably into or beyond this period. Persistent unilateral mid-cycle pain is suggestive of an endometrioma. Patients commonly present with dysmenorrhoea (75%), dyspareunia (20%), tenesmus or an adnexal mass (endometrioma).

Adenomyosis

Adenomyosis is a benign condition characterized by the extension of endometrial glands and stroma into the myometrium. The majority (>80%) of cases involve multiparous women in the fourth and fifth decades of life. Patients usually present with menorrhagia and dysmenorrhoea.

Pelvic examination reveals a symmetrically enlarged, slightly tender uterus with a diffusely boggy consistency. Rarely, a distinct mass (adenomyoma) may be palpated or imaged.

USS may reveal generalized uterine enlargement with an indistinct endomyometrial junction. MRI will more clearly demonstrate the pathology but is rarely indicated in the ED assessment.

The definitive diagnosis is usually made by histology, most typically at hysterectomy.

Leiomyomata (fibroids)

Leiomyomata or fibroids are benign tumours of myometrial origin. They are the most common pelvic tumour and occur in 25% of Caucasian women and 50% of black women. Their aetiology is unknown but they enlarge in pregnancy and regress after menopause.

Symptoms relate to the space-occupying effect of the lesion and may lead to chronic pelvic pain with or without bleeding. Acute pain occurs with torsion or degeneration; torsion usually involves pedunculated subserosal lesions. Degeneration results from the rapidly expanding lesion restricting its own blood supply and may occur during pregnancy as a differential of acute pelvic pain.

Primary dysmenorrhoea

This is painful menstruation in the absence of pelvic pathology and is a diagnosis of exclusion. Primary dysmenorrhoea is associated with the release of prostaglandins, principally PGF2α, from the endometrium during menstruation. This causes uterine contractions, arteriolar vasoconstriction and uterine ischaemia, with the most intense pain occurring as the menstrual flow is subsiding. Primary dysmenorrhoea usually coincides with the onset of ovulatory cycles 4 to 12 months after menarche and affects up to 10% of young nulliparous women.

Primary dysmenorrhoea is associated with spasmodic, crampy lower abdominal pain radiating to the lower back and upper thighs and lasts for 24 to 48 hours. Associated symptoms include headache, nausea and vomiting. Symptoms may be alleviated by the regular administration of NSAIDs or by suppressing ovulation with the oral contraceptive pill.

Acyclic pelvic pain

Chronic pelvic inflammatory disease

See Chapter 19.2.

Pelvic adhesions

Adhesions occur when anatomical structures are abnormally bound to one another by bands of fibrous tissue. They are believed to account for pain suffered by up to 33% of patients with chronic pelvic pain, although their exact role is uncertain. They are associated with PID, endometriosis, abdominal surgery, perforated appendix and inflammatory bowel disease.

Adhesions contain nerve fibres and some of the pain perceived by patients may relate to this nerve tissue. The pain is often consistent in location and aggravated by sudden movements, intercourse or physical activity. Laparoscopy is the gold standard for its diagnosis and treatment.

Psychological

There is an association between chronic pelvic pain and somatization disorders. In addition, many women with chronic pelvic pain have suffered physical, sexual and emotional abuse and psychiatric disease is often related.

Conclusion

Female pelvic pain is a complex and challenging problem in the ED. A systematic evaluation may find a diagnosis in acute pelvic pain, but chronic conditions require review and follow-up by a specialist unit.

The resuscitation of the acutely unwell patient, exclusion of pregnancy-related problems, provision of adequate analgesia, prompt initiation of appropriate investigations and specialist referral for ongoing evaluation are fundamental to the management of gynaecological pelvic pain.

CONTROVERSIES

- Accuracy of emergency physician–focused pelvic ultrasound scan to evaluate pelvic pain
- Diagnosis and management of acute-on-chronic and chronic pelvic pain syndromes

19.2 Pelvic inflammatory disease

Erica Kreismann • Gar Ming Chan

ESSENTIALS

1 **Pelvic inflammatory disease (PID) is infection and/or inflammation of the upper genital tract.**

2 **The clinical features cover a spectrum of presentations that depend on the extent of infection and/or inflammation, the anatomical structures involved and the specific microorganisms.**

3 ***Chlamydia trachomatis* is the most common pathogen identified in sexually transmitted PID. Other pathogens include *Neisseria gonorrhoeae* and mixed anaerobes.**

4 **The sequelae of PID include ectopic pregnancy, infertility and chronic pelvic pain.**

5 **Screening high-risk patients for sexually transmitted infections reduces the incidence of PID.**

Introduction

Pelvic inflammatory disease (PID) refers to a clinical syndrome resulting from infection or inflammation involving the usually sterile upper genital tract in women. Although infection can be secondary to pregnancy, instrumentation or other primary abdominal infection, the term PID is primarily reserved for an infection initiated by a sexually transmitted infection (STI). Despite differing aetiologies, these can have similar clinical presentations and are often distinguishable through thorough history taking and physical examination.

Most cases of PID are caused by the ascent of microorganisms from the vagina and endocervix into the upper genital tract.[1] The passage of organisms through the cervix is facilitated by disruption of the cervical barrier (e.g. by an STI, *Chlamydia trachomatis* and *Neisseria gonorrhoeae*, or by a surgical procedure). The majority of PID cases (85%) are caused by sexually transmitted (ST) pathogens, whereas less than 15% are associated with enteric organisms (*Escherichia coli*, *Bacteroides fragilis*, group B streptococcus, *Campylobacter*) or respiratory pathogens (*Haemophilus influenzae*, group A streptococcus, and *Staphylococcus aureus*).

Early identification and treatment are important to reduce the serious sequelae of PID, which can be debilitating; including endometriosis, salpingitis, oophoritis, peritonitis, peri-hepatitis (Fitz-Hugh–Curtis syndrome [FHCS]), tubo-ovarian abscess, ectopic pregnancy, chronic pelvic pain and infertility.

Epidemiology

The true incidence of PID is indeterminable as there are no standardized clinical criteria for diagnosis. Additionally, asymptomatic or subclinical PID as well as under-diagnoses are known to occur.

Up to 300,000 women are treated as outpatients and 10,000 are admitted to Australian hospitals each year with a diagnosis of PID. The highest reported incidence involves patients between ages 20 and 29 years. The rate of hospitalization is up to nine times higher in the indigenous population.

Risk factors

Risk factors for PID include any sexually active female with multiple partners, age below 25 years, history of PID or STIs and procedures or conditions that involve disruption of the normal cervical barrier. Chlamydial infection is the most common cause of sexually transmitted PID in Australia. The presence of an intrauterine contraceptive device (IUCD) increases the risk of PID

in the first 3 weeks following insertion.[2] There is also an increased risk of PID during or shortly after the menses.[3]

Presentation

No symptom or sign is pathognomic of PID and the diagnosis of PID includes a spectrum of clinical conditions determined partly by the anatomical location of the infection and by the pathogen involved. Clinical diagnosis remains the most important practical approach.

The assessment of a patient with suspected PID must involve the exclusion of other possible diagnoses, such as ectopic pregnancy, endometriosis, ruptured ovarian cyst, appendicitis and urinary tract infection. However, in view of the significant sequelae of untreated PID, the current recommendation is to consider treatment in an at-risk woman with adnexal tenderness if no other cause for the local signs can be found.[4]

History

The history should assess recognized risk factors for STIs, such as young age at first sexual intercourse, younger age, high frequency of sexual intercourse, multiple sexual partners and non-barrier methods of contraception. History should also enquire about non–sexually transmitted causes, such as recent uterine instrumentation, including operative termination of pregnancy.

Abdominal pain of less than 3 weeks' duration is the most sensitive symptom of PID; the pain is usually suprapubic and diffuse but may lateralize. However, significant lateralization suggests an alternate diagnosis or a tubo-ovarian abscess. Other symptoms may include a new or changed vaginal discharge, dyspareunia, post-coital and/or intermenstrual bleeding.

Examination

Adnexal tenderness on bimanual examination is the most sensitive examination finding and is present in 95% of cases but has a specificity of only 3.8%.[4] Other examination findings with high sensitivity include lower abdominal, cervical motion or uterine tenderness. However, as isolated findings, each of these lacks sensitivity.

Rebound tenderness, fever, and decreased bowel sounds may be present. While the presence of fever is associated with a more severe infection, the absence of fever does not exclude the diagnosis.

Fitz-Hugh–Curtis syndrome (perihepatitis)

FHCS is a perihepatitis with focal peritonitis resulting from the transcoelomic spread of inflammatory peritoneal fluid to the subphrenic and subdiaphragmatic spaces. It occurs in approximately 10% cases of acute PID, and whereas FHCS is usually an incidental finding in patients with PID, occasionally right-upper-quadrant (RUQ) pain is the presenting symptom and the diagnosis is often considered only when upper abdominal ultrasound rules out biliary tract disease.[5]

Investigations

Haematology

There are no specific laboratory tests to diagnose PID. The white cell count, erythrocyte sedimentation rate and C-reactive protein are all raised as non-specific markers of inflammation but lack sensitivity and specificity for the diagnosis.

Biochemistry

Check a beta subunit of human chorionic gonadotrophin (β-HCG) level on all women of childbearing age. Although PID is uncommon in pregnancy, especially after the first trimester, the diagnosis of PID in pregnancy has significant implications.

Pelvic pain secondary to a complication of pregnancy, such as an ectopic pregnancy, is an important differential diagnosis.

Microbiology

Collect and send endo-cervical swabs for microscopy and culture and polymerase chain reaction (PCR) or the nucleic acid amplification test (NAAT) for *N. gonorrhoeae* and *C. trachomatis*. A positive result retrospectively supports the diagnosis of PID, defines antibiotic sensitivities and identifies the need to treat partner(s) with sexual contact over at least 6 months.[6] However, a negative result does not exclude the diagnosis, as the sensitivity of microscopy is only 60%.[6]

The presence of either purulent discharge or white blood cells (WBCs) in the vaginal discharge is a sensitive marker for PID. The diagnosis of PID is thus unlikely if the cervical discharge appears normal and there are no WBCs in a wet slide preparation.[7] All patients who are diagnosed with acute PID should be considered for a full sexual health evaluation, including hepatitis B, syphilis and HIV serology, plus partner contact tracing.[8]

Ultrasound

Ultrasound, particularly transvaginal, is valuable in the assessment of suspected PID to identify complications such as tubo-ovarian abscess and to exclude other causes of pelvic pain. However, ultrasound features, such as free fluid in the pouch of Douglas, lack sensitivity in the diagnosis of mild to moderate PID.

Laparoscopy

Laparoscopy is no longer considered to be a gold standard for the diagnosis of PID as, although it has a specificity approaching 100%, the sensitivity is as low as 50% to 80%. The main indications for laparoscopy include acute pain of uncertain origin and the diagnosis of chronic pelvic pain.

Differential diagnosis

Important differential diagnoses include ectopic pregnancy, endometriosis, complications of ovarian cysts and tumours, appendicitis, diverticulitis and urinary tract infection.

Management

The presumptive diagnosis of PID is made in high-risk female patients (see earlier discussion of risk factors) who present with lower abdominal or pelvic pain unattributed to other aetiologies and who have cervical motion, adnexal, or uterine tenderness on examination. The sensitivity of this clinical diagnosis is only 65% to 90%[6]; however, because of the serious potential reproductive sequelae, the initiation of empiric antibiotic therapy is warranted. Patients with mild to moderate PID may be treated as outpatients. There is no evidence of improved outcomes between inpatient and outpatient treatment with respect to fertility, chronic pelvic pain or recurrence of PID.[9]

Indications for inpatient treatment include severe PID, inability to tolerate oral antibiotics, failed oral therapy and/or compliance issues, pregnancy and when a surgical emergency cannot be excluded.

Antibiotic therapy

Sexually acquired pelvic inflammatory disease

- *Mild to moderate infection:* ceftriaxone 500 mg IM or IV as a single dose and azithromycin 1 g PO as a single dose plus metronidazole 400 mg PO q 12 h for 14 days plus azithromycin 1 g PO as a single dose plus either doxycycline 100 mg PO q 12 h for 14 days or (for women who are pregnant or patients suspected of being non-compliant with doxycycline) azithromycin 1 g PO as a single dose 1 week later.
- *Severe infection:* ceftriaxone 2 g IV qd plus azithromycin 500 mg IV qd plus metronidazole 500 mg IV q 12 h.[10]

If there is strong clinical suspicion of sexually transmitted infection, contact tracing and presumptive treatment of sexual contacts with azithromycin (1 g PO as a single dose) should be initiated. Sexual contacts should also be investigated for *C. trachomatis, N. gonorrhoeae* and *M. genitalium*.

Non–sexually acquired pelvic inflammatory disease

- *Mild-to-moderate infection:* amoxicillin plus clavulanate 875/125 mg PO bd for 14 days, plus doxycycline 100 mg PO q 12 h for 14 days.
- *Severe infection:* amoxicillin or ampicillin 2 g IV 6-hourly, plus gentamicin IV plus metronidazole 500 mg IV bd.

Disposition

Patients discharged on oral medication should be reviewed within 24 to 48 hours to assess the response to therapy. All patients with sexually acquired PID should be counselled regarding safe sex practices and other sexual health issues, such as hepatitis B and human papillomavirus vaccination.

Prognosis

Women with PID are at increased risk of ectopic pregnancy, chronic pelvic pain and infertility.

CONTROVERSIES

- Clinical criteria for the initiation of treatment in PID
- The role of ultrasound in the primary diagnosis of PID
- Indications for laparoscopy in PID

19.3 Abnormal vaginal bleeding in the non-pregnant patient

Erica Kreismann • Gar Ming Chan

ESSENTIALS

1 **Start the assessment of any patient with vaginal bleeding by excluding pregnancy.**

2 **Locate the anatomical site of bleeding and assess the severity looking for signs of hypovolemia and shock.**

3 **Familiarize yourself with the PALM-COEIN classification system.**

4 **Consider coagulopathy as a cause of heavy uterine bleeding in all patients, especially adolescents.**

Introduction

Vaginal bleeding is often divided into two major categories: bleeding which occurs in a pregnant patient and bleeding in the non-pregnant patient. Therefore, in conjunction with determining hemodynamic stability, the first step for a patient presenting with vaginal bleeding is to exclude pregnancy. See Chapters 19.4 and 19.5 if the woman is pregnant.

In this chapter, we will deal exclusively with bleeding in non-pregnant women. Abnormal vaginal bleeding is the most common reason women seek gynaecologic care.[1] Bleeding may be from the uterus, lower genital tract (vulva, vagina, cervix) or from systemic causes. The PALM-COEIN acronym was introduced in 2011 by the International Federation of Gynecology and Obstetrics (FIGO) with a goal of avoiding confusing or poorly defined terminology in the classification of acute abnormal uterine bleeding. With this system, aetiologies are classified as structural or nonstructural: PALM for structural (polyp, adenomyosis, leiomyoma, malignancy and hyperplasia) and COEIN for nonstructural (coagulopathy, ovulatory dysfunction, endometrial, iatrogenic, not otherwise classified).

Physiological uterine bleeding

Physiological uterine bleeding is associated with ovulatory menstrual cycles, which occur at regular intervals every 21 to 35 days, and last for 3 to 7 days. The average volume of blood loss is 30 to 40 mL (each normal sized tampon or pad holds 5cc when soaked through) with>80 mL being defined as menorrhagia.

The menstrual cycle is controlled by the hypothalamic–pituitary–ovarian (HPO) axis. During the first 14 days, oestrogen is produced by the developing follicle, leading to proliferation of the endometrium, which reaches a thickness of 3 to 5 mm. Oestrogen acts on the pituitary gland to cause the release of follicle stimulating hormone (FSH) and luteinizing hormone (LH), which result in ovulation. The corpus luteum then releases progesterone in excess of oestrogen.

Progesterone causes stabilization of the endometrium during the secretory phase of the menstrual cycle. In the absence of fertilization, there is involution of the corpus luteum and a

fall in oestrogen and progesterone levels. This results in vasoconstriction within the endometrium, which consequently becomes ischaemic and is shed as normal menstrual bleeding.

Pathological uterine bleeding

Pathological causes include infection, structural abnormalities, such as polyps, fibroids, arteriovenous malformations (AVM) or malignancy, drugs, hyperprolactinaemia, coagulopathy and thyroid endocrinopathy. Terms associated with abnormal uterine bleeding are inconsistently defined, but may be broadly considered as abnormal uterine bleeding with ovulatory menstrual cycles and abnormal uterine bleeding with anovulatory menstrual cycles.

Abnormal uterine bleeding with ovulatory menstrual cycles

The most common cause of abnormal uterine bleeding is menorrhagia occurring in ovulatory menstrual cycles. This presents as regular heavy bleeding and may result in anaemia. In these women, the menstrual blood has been shown to have increased fibrinolytic activity and/or increased prostaglandins.

Abnormal uterine bleeding with anovulatory menstrual cycles

Abnormal uterine bleeding or metrorrhagia due to anovulatory menstrual cycles, sometimes referred to as dysfunctional uterine bleeding (DUB), presents as irregular bleeding of variable volume. In anovulatory menstrual cycles and other high oestrogen states, there is a relative lack of progesterone to oppose the oestrogenic stimulation of the endometrium. This results in excessive proliferation and occasionally hyperplasia/metaplasia of the endometrium. The endometrium also becomes 'unstable' and prone to erratic sloughing.

Clinically, this presents as irregular, often heavy, menstrual bleeding. Anovulatory cycles are due to immaturity or disturbance of the normal HPO axis. This is seen at the extremes of reproductive ages, in the first decade after menarche and in premenopausal women, as well as in polycystic ovary syndrome (PCOS) and during times of either physical or emotional stress.

CAUSES OF ABNORMAL VAGINAL BLEEDING

It is essential initially to review all the possible causes of vaginal bleeding which may be considered by pathophysiology and/or pathological location (Box 19.3.1).

Box 19.3.1 Differential diagnosis of abnormal vaginal bleeding

- Ovulatory bleeding 'menorrhagia'
  Anovulatory bleeding: sometimes known as dysfunctional uterine bleeding (DUB)
- Uterine and ovarian pathology:
  uterine fibroids (pelvic pain, dysmenorrhoea)
  endometriosis; adenomyosis (dysmenorrhoea, dyspareunia, pelvic pain, infertility)
  pelvic inflammatory disease and pelvic infection (fever, vaginal discharge, pelvic pain, intermenstrual and postcoital bleeding)
  endometrial polyps (intermenstrual bleeding)
  endometrial hyperplasia; endometrial carcinoma (pelvic pain, abnormal bleeding, postcoital bleeding)
  polycystic ovary syndrome (irregular bleeding, infertility and hirsutism)
- Systemic disease:
  coagulation disorder; bleeding diathesis such as von Willebrand disease
  liver or renal disease
  hypothyroidism (fatigue, constipation, coarse features, alopecia)
- Iatrogenic cause:
  anticoagulation
  intrauterine device
  chemotherapy
  sex steroids

History

A careful menstrual history helps determine the cause of the vaginal bleeding. A history of vaginal trauma may indicate vulval or vaginal wall bleeding. The vaginal trauma may be associated with either consensual or non-consensual intercourse or a vaginal foreign body. Exposure in utero to diethyl stilboestrol (DES) should raise suspicion of vaginal malignancy.

The patient's estimate of the amount of vaginal bleeding is often inaccurate and has limited use in diagnosis, other than the presence of clots, which is abnormal and suggests heavy bleeding.[2] Ask about additional information, including known gynaecological cancer, a known bleeding disorder or a family history of a bleeding diathesis and exogenous sex steroid use. Up to 13% of women with heavy menstrual bleeding have some variant of von Willebrand disease, and up to 20% of women may have an underlying coagulation disorder.[3]

Postcoital or intermenstrual bleeding

Postcoital or intermenstrual bleeding may be symptomatic of cervical or uterine pathology. Common causes include ectropion or polyps on the cervix, infection or malignancy causing bleeding from the vagina, cervix or uterus.

Postmenopausal bleeding

Postmenopausal bleeding is related to vaginal or uterine conditions, which include infection, atrophy, trauma or malignancy. All postmenopausal bleeding is abnormal and requires follow-up evaluation for endometrial cancer. Risk factors for uterine malignancy include obesity, age >40 years, nulliparity, tamoxifen use, infertility and chronic anovulatory cycles.

Anovulatory bleeding

A diagnosis of anovulatory bleeding is classically made from the history of irregular menses with periods of amenorrhoea followed by heavy bleeding, in the absence of features suggesting a structural or a histological uterine abnormality.[2] A menstrual cycle of less than 21 days or more than 35 days, even if regular, is usually anovulatory.

Physical examination

First determine the haemodynamic stability of the patient. Physiological menorrhagia alone is rarely a cause of shock and other diagnoses, such as cervical malignancy or endometrial AVM, should be considered. Also look for evidence of anaemia, petechiae suggesting a bleeding tendency and thyroid endocrinopathy.

Abdominal and pelvic examination

Palpate the abdomen to assess for uterine enlargement. Inspect the vulva for local causes of bleeding, including trauma and infection. Vaginal speculum examination should include assessment of the vaginal walls and the cervix, ideally, with a clear plastic speculum for ease of view. Speculum examination will also allow an assessment of the site and amount of bleeding. Bimanual examination is indicated to assess for local tenderness, uterine size and/or masses and adnexal masses or cervical motion tenderness.

Investigations

These are based around laboratory tests and ultrasound scanning.

Laboratory investigations

- *Serum or urinary* β-hCG pregnancy test. Perform this immediately on all women of childbearing age, even in the face of assurances from the patient that pregnancy could not be possible. Urine pregnancy tests are highly sensitive, detecting β-hCG levels as low as 25 IU/L.
- *Full blood count.* Perform this in all patients to identify anaemia. Add iron studies if the blood count shows a hypochromic, microcytic picture.
- *Thyroid function tests.* These are only indicated in women with menorrhagia and anovulatory bleeding or with clear evidence of thyroid endocrinopathy (see Chapter 11.3). Do *not* send routinely.

- *Coagulation profile*. Perform on all adolescents and any women with unusually heavy uterine bleeding.

Radiology

- Ultrasound is requested to assess the pelvic organs. Particular attention is paid to the myometrium looking for fibroids or adenomyosis, the endometrial thickness and the endometrial cavity for polyps or retained products of conception (positive β-hCG).
- Ultrasound may also identify an AVM, which may be congenital or acquired either postpartum or, more commonly, post-instrumentation of the uterus.

Management

Management may be considered as general supportive measures and then specific treatment.

General supportive measures

Resuscitation should proceed in the usual manner with initial therapy determined by the degree of haemodynamic instability or severity of anaemia.

Specific treatment for structural lesions

Vaginal wall bleeding

Vaginal wall bleeding secondary to trauma generally settles spontaneously. Examination under anaesthesia (EUA) is indicated for vaginal trauma if the laceration extends beyond the mucosa or if examination is too uncomfortable for the woman.

Cervical bleeding

Cervical bleeding rarely requires immediate therapy. However, cervical bleeding from malignancy may occasionally be difficult to control as lesions tend to be friable. Attempt cautery with silver nitrate and, if this fails to control the bleeding, consider placing a vaginal pack. Refer the patient immediately to the gynaecology team.

Specific treatment for vaginal and endometrial infection

Vaginal and endometrial infections are dealt with as outlined in Chapter 19.2. Arrange for the partner(s) to have contact tracing and simultaneous antibiotic treatment as necessary.

Specific treatment for menorrhagia associated with ovulatory cycles

Choice of treatment depends on clinical stability, acuity of presentation, suspected aetiology of bleeding, comorbidities and desire for future fertility. Medical therapy is considered the first line for initial treatment.

Medical Management

Hormonal management is often the preferred initial treatment in patients without suspected bleeding disorders. Options include combined oral contraceptives, oral progestins or IV conjugated equine estrogen.[3]

Oral progestins, such as norethisterone 5 mg bd or tds or medroxyprogesterone acetate 10 mg one to three times a day, on days 1 to 21 of a 28-day cycle reduce blood loss by up to 83%, although adherence can be poor due to nausea, lethargy, headache, bloating with fluid retention and acne.[4] In addition, treatment should be limited to less than 6 months because of the risk of hypo-oestrogenism.

Levonorgestrel-releasing intrauterine system

While not commonly placed in the emergency department (ED), we must be aware, as acute care providers, of the option of a levonorgestrel-releasing intrauterine system (LNG-IUS). It can be used to treat heavy menstrual bleeding associated with ovulatory or anovulatory cycles and has high patient satisfaction rates. It reduces bleeding more effectively than a 21-day course of norethisterone and avoids the systemic effects of oral progestins.[4]

Tranexamic acid

Tranexamic acid is a plasminogen activator inhibitor that promotes local haemostasis, Recommendation is for eitheroral or IV transexamic acid, and it is considered first line in the acute setting.1 to 1.5 g orally, 6- to 8-hourly for the first 3 to 5 days of menstruation.[4] Side effects include nausea and leg cramps, but it is generally well tolerated. Although long-term studies have not shown an increase in thromboembolic events, active thromboembolic disease is a contraindication to use.[5] It reduces blood loss by around 47%.[4]

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) block prostaglandin PGE_2, a vasodilator found in excess in patients with menorrhagia.[6] The efficacy of NSAIDs is less than other therapies with only a 29% reduction in blood loss. However, they are well tolerated and are particularly helpful if there is associated dysmenorrhoea.

Usual doses are mefenamic acid 500 mg tds, naproxen 250 mg tds or ibuprofen 400 mg tds.

Combined oral contraceptive

As a longer-term therapy, the combined oral contraceptive pill reduces the mean menstrual blood loss by about 43% using a pill containing 35 µg of ethinyloestradiol. Contraindications include the desire for fertility and all contraindications to oestrogens.

Specific treatment for heavy anovulatory uterine bleeding

Acute irregular heavy bleeding is most commonly secondary to anovulatory bleeding. There are many different treatment regimens and ED physicians should select a range of agents with which to become familiar.[2,3,7,8] The underlying pathology is a relative lack of progesterone and so treatment should include progestin therapy to stabilize the endometrium. This may be combined with tranexamic acid and/or an NSAID, which decreases the amount of blood loss. If anovulatory cycles are expected to continue, then progestin therapy may need to be long term.

Progestin therapy

Medroxyprogesterone 10 mg orally, once daily for the same 12 days of each calendar month or norethisterone 5 mg orally, once daily for the same 12 days of each calendar month.[4] Side effects include bloating, headache, acne and breast tenderness.

Tranexamic acid and non-steroidal anti-inflammatory drugs

These can be added to progestin therapy for heavy anovulatory bleeding.

Combined oral contraceptive pill

The combined oral contraceptive pill (COCP) may be used to decrease blood loss in ovulatory cycles and to regulate and decrease blood loss in anovulatory cycles. It also provides contraception. Start a monophasic COCP that includes at least 30 µg of ethinyloestradiol and a progestin.

Consider histological assessment of the endometrium in patients over 35 years of age, prior to commencing hormone therapy. An antiemetic is recommended with hormonal therapy.

Other treatments not usually commenced in the emergency department

Surgical procedures

Dilatation and curettage (D&C) is a method of endometrial sampling and *not* a long-term treatment for menorrhagia or irregular menstrual cycles. The procedure is often combined with hysteroscopy, which allows visual assessment of the uterine cavity and biopsy if indicated. If structural abnormalities are revealed, polypectomy or myomectomy may be required. Other surgical interventions to be considered are uterine artery embolization, endometrial ablation and hysterectomy, and these should be discussed directly with the consulting gynaecologist and patient.

Other drug treatments

Other treatments that are not usually commenced in the ED include the levonorgestrel-releasing intrauterine system, such as Mirena,

or long-acting progestogens, such as medroxyprogesterone acetate (Depo-Provera), which may prove successful if oral agents fail.

Gonadotrophin-releasing hormone (GnRH) analogues should only be commenced by a gynaecologist when other medical and surgical treatments are contraindicated or prior to proposed surgery.

Disposition

Admit patients with haemodynamic instability or profound anaemia. Consult the gynaecology team if a significant underlying cause for the abnormal bleeding is likely. However, most patients may be discharged and followed up in an outpatient clinic.

CONTROVERSIES

- Precise regimen for progestins in the management of anovulatory bleeding.
- Indications for endometrial sampling, especially in postmenopausal women.
- Role of surgical versus medical therapy in the long-term management of menorrhagia.

19.4 Ectopic pregnancy and bleeding in early pregnancy

Gim Tan

ESSENTIALS

1 **Approximately 25% of all clinically diagnosed pregnancies are associated with bleeding in the first 12 weeks, of which approximately 50% of cases will be due to a failed pregnancy.**

2 **Ectopic pregnancy occurs at a rate of around 11:1000 diagnosed pregnancies.**

3 **The management of ectopic pregnancy and failed pregnancy may be surgical, medical or conservative.**

Introduction

Bleeding in early pregnancy is a common problem affecting approximately 25% of all clinically diagnosed pregnancies, and, of these, approximately 50% will have bleeding due to a failed pregnancy.[1] Other causes of bleeding include ectopic pregnancy and molar pregnancy; however, *most* bleeding is incidental or physiological and has no bearing on the outcome of the pregnancy.

Terminology

The terminology used to describe early pregnancy bleeding conditions is defined as follows.

Miscarriage

A miscarriage is defined as pregnancy loss occurring before 20 completed weeks' gestation or a foetus less than 400 g weight, if the gestation is unknown.

Threatened miscarriage

A threatened miscarriage is any vaginal bleeding other than spotting before 20 weeks' gestation.

Inevitable miscarriage

Inevitable miscarriage is a miscarriage that is imminent or in the process of happening.

Complete miscarriage

A complete miscarriage is when all products of conception have been expelled.

Failed pregnancy

A failed pregnancy is defined on ultrasound criteria. These include the finding of a crown rump length (CRL) greater than 6 to 10 mm with no cardiac activity or a gestational sac equal to or greater than 20 to 25 mm with no foetal pole (previously referred to as an anembryonic pregnancy or a blighted ovum).

A failed pregnancy may then remain in the uterus (previously termed a missed abortion) or may progress to either an incomplete or complete miscarriage, as defined by the presence or absence of pregnancy-related tissue in the uterus.

Pregnancy of unknown location

A pregnancy of unknown location refers to the situation where the beta subunit of human chorionic gonadotrophin (β-hCG) is elevated, but no pregnancy can be identified on ultrasound.

Ectopic pregnancy

An ectopic pregnancy is a pregnancy that is implanted outside of the normal uterine cavity. The most common location for an ectopic pregnancy is in the fallopian tube. Other sites include cervix (≈1%), ovary (1% to 3%), interstitial (1% to 3%), abdomen (1%) and, rarely, in a uterine scar.

The natural history of an ectopic pregnancy may be one of resorption, spontaneous miscarriage (vaginal or tubal) or it may continue to grow and disrupt the surrounding structures (rupture).

History

History should include the date of the last normal menstrual period (LNMP) and a complete obstetric and gynaecological history, including the use of assisted reproductive technology (ART). Risk factors for ectopic pregnancy include a past history of tubal damage, a previous ectopic pregnancy, pelvic infection, tubal surgery, assisted reproductive technology, increased

age, smoking and progesterone-only contraception. Intrauterine contraceptive devices (IUDs) decreases the chance of intrauterine pregnancies, but whether they increase the likelihood of an ectopic pregnancy is currently debated.[2]

When estimating the amount of vaginal bleeding, it is useful to quantify the blood loss compared with the woman's normal menstrual loss. Heavy bleeding and the passage of clots are more common with failed intrauterine pregnancy, as ectopic pregnancy is rarely associated with heavy bleeding.

However, the history of passage of foetal products should not be used as the basis for diagnosis of a miscarriage. Blood clots or a decidual cast may be misinterpreted as the products of conception. In addition, the correct identification of the products of conception does not exclude the possibility of a live twin or of a coexistent ectopic pregnancy (known as a heterotopic pregnancy).

Examination

Determination of the patient's haemodynamic status and the rate of ongoing bleeding are a priority. Hypotension, tachycardia and signs of peritoneal irritation suggest a ruptured ectopic pregnancy or bleeding from a corpus luteal cyst. A complete physical examination should be performed, including assessment of the woman's mental state, as pregnancy loss may have a profound psychological impact on some women. The role of pelvic examination in the assessment of early pregnancy bleeding is limited, providing that there is prompt access to transvaginal ultrasound examination. Pelvic examination does not provide further diagnostic information over ultrasonography used in conjunction with beta human chorionic gonadotropin assays. When performed, bimanual examination can localize tenderness and identify adnexal masses and can also give an estimate of the size of the uterus. However, bimanual examination lacks sensitivity and specificity in identification of a small, unruptured ectopic pregnancy and gives no information about the viability of the pregnancy. Speculum examination is indicated only in those presenting with severe bleeding or hypotension, as removal of obstructing endocervical products can be a crucial resuscitative measure.[3]

Investigations

Biochemistry

Beta subunit of human chorionic gonadotrophin

The β-hCG is produced by the outer layer of cells of the gestational sac (the syncytiotrophoblast) and may be detected as early as 9 days after fertilization. The β-hCG level increases by approximately 1.66 times every 48 hours, then plateaus, before falling at around 12 weeks to a lower level.

At any stage of the pregnancy there is always a large range of normal values and a single value cannot be used to determine the location or viability of the pregnancy. There is also potentially significant laboratory-to-laboratory variation, and as such, serial hormone levels may only be compared if they are from the same laboratory.

The half-life of β-hCG is approximately 48 hours, which results in the β-hCG level remaining elevated for a number of weeks post-miscarriage or termination. Therefore a positive pregnancy test or a single β-hCG level is unreliable to confirm ongoing pregnancy and cannot be used to identify retained products of conception. High levels of β-hCG may be associated with multiple or molar pregnancies.

Urine pregnancy test

Urine pregnancy tests are sensitive to a β-hCG level of 25 to 60 IU/L. Thus false negatives may rarely occur in the setting of early pregnancy or dilute urine.

Haematology

A full blood count and cross-match should be arranged for haemodynamically unstable patients. Blood group and Rhesus factor should be determined on all patients.

Ultrasound

Ultrasound should be performed in every patient to identify the anatomical location of the pregnancy and to assess foetal viability. The introduction of emergency department (ED) ultrasound provides a cost-effective method for the assessment of a patient presenting with bleeding in early pregnancy, but it does not preclude a formal ultrasound

Transvaginal ultrasound

A gestational sac can be identified as early as 31 days' gestation using transvaginal ultrasound. A yolk sac can be identified within the gestational sac at 5 to 6 weeks when the β-hCG is around 1500 IU/L (except in the case of anembryonic pregnancy). Embryonic cardiac activity should be identified by approximately 39 days' (5.5 weeks') gestation, at which stage the crown rump length of the embryo is approximately 5 mm.

Transabdominal ultrasound

The findings on transabdominal ultrasound are similar approximately 1 week later. Previously a β-hCG of approximately 1500 IU was called the discriminatory zone, meaning that if no pregnancy was identified in the uterus at this level, then an ectopic pregnancy could be diagnosed. However, trans-abdominal ultrasound is still valuable even when the β-hCG level is less than 1000 IU/L, as direct or indirect signs of an ectopic pregnancy can often be found at levels lower than 1500 IU.[4]

The two most common errors in the interpretation of early pregnancy ultrasound include the misidentification of a pseudo-sac or an endometrial cyst as an early gestational sac. A pseudo-sac is a small collection of fluid seen in the uterine cavity, often in association with an ectopic pregnancy. Secondly, assuming that an ultrasound finding of a uterus with no signs of pregnancy is a complete miscarriage, rather than correctly identifying the situation as that of a pregnancy of unknown location. One study of 152 women with a history and examination supporting a complete miscarriage had a 6% rate of ectopic pregnancy.

Heterotopic pregnancy

Identification of an intrauterine pregnancy does *not* exclude a coexistent ectopic (heterotopic) pregnancy. The incidence of heterotopic pregnancy in the general population is around 1:3889 but, in patients who have undergone ART, the incidence is as high as 1:100 to 1:500.[5] Thus, in the patient with risk factors and clinical features of an ectopic pregnancy, finding an intrauterine gestation cannot rule out a coexistent ectopic pregnancy.

Management

Rh(D) immunoglobulin

All patients should have their blood group and Rhesus (Rh) factor determined. As little as 0.1 mL of Rh(D) positive foetal blood will cause maternal Rh iso-immunization. In the first trimester, a dose of 250 IU Rh(D) immunoglobulin is given when there has been a miscarriage, termination of pregnancy (medical or surgical), ectopic pregnancy and chorionic villous sampling within 72 hours of onset of the bleeding. There is insufficient evidence that threatened miscarriage in the first 12 weeks necessitates anti-D. Further doses may be required in repeat or prolonged bleeding.

A dose of 625 IU Rh(D) is recommended for obstetric haemorrhage in the second and third trimester. Blood should be taken for Rh antibody titre prior to administration of anti-D, in order to detect those who have already become immunized.

ECTOPIC PREGNANCY

Haemodynamically unstable patient

A haemodynamically unstable patient with suspected ectopic pregnancy should be resuscitated and referred for surgical intervention. A ruptured

corpus luteal cyst may rarely cause similar haemodynamic compromise and is also diagnosed at laparoscopy.

Haemodynamically stable patient

The management options for a haemodynamically stable patient with an ectopic pregnancy found on ultrasound include observation, medical treatment or surgical intervention.

Factors to be considered in reaching a management decision include the location of the ectopic pregnancy, the β-hCG level, the size of the ectopic pregnancy, the presence of foetal cardiac activity and patient factors.

Selection criteria for conservative or medical management depend upon the gynaecological team, but may include stable patients with a low β-hCG (<1000 IU/L) which is falling, non-tubal ectopic pregnancy or a small tubal ectopic pregnancy (<3 cm) with no cardiac activity and a β-hCG level less than 5000 IU/L.

MISCARRIAGE

Haemodynamically unstable patient

Any patient with heavy vaginal bleeding, hypotension and bradycardia should have an immediate speculum examination as, occasionally, the products of conception cause dilatation of the cervix, which leads to cervical shock, a form of neurocardiogenic shock. Removal of the clot and products of conception from the cervical os usually results in cessation of bleeding and reversal of the shock.

Haemodynamic compromise may also be secondary to significant blood loss related to the miscarriage. Fluid resuscitation should be instituted simultaneously with attempts to control the bleeding by removal of blood clot and the products of conception from the cervix and vagina. Uterine contraction may be induced by administering ergometrine 200 μg IM if removal of clot and tissue fail to control the bleeding. Emergency surgical evacuation of the uterus is then required.

Haemodynamically stable patient

A haemodynamically stable patient with threatened miscarriage is treated expectantly. For other types of miscarriages, expectant, surgical or medical management (such as prostaglandin E1) may be considered in consultation with the gynaecology service. Expectant management is contraindicated if the woman has an increased risk of haemorrhage, if she has had an adverse or traumatic pregnancy related experience such as a stillbirth or miscarriage, if she is on anticoagulants or there is infection present. Currently, there is insufficient evidence to support the superiority of any one of these three treatment options. Although studies have assessed the time to achieve complete miscarriage and the frequency of complications, they suffer from different inclusion criteria and duration of conservative management.

Conservative management is usually associated with slightly longer duration of bleeding and pain and possibly the need for transfusion. The incidence of infection was similar or higher in the surgical group. Complications of surgery, such as cervical trauma, uterine perforation and intrauterine adhesions, were uncommon.

The woman's preference should be a consideration in recommending a treatment option and the haemodynamically stable patient may be discharged for ongoing care by the gynaecology team. Discharge advice should include explicit indications of when to return, such as heavy bleeding or signs of infection, and advice regarding pelvic rest and a clear follow-up plan.

Prognosis

Approximately 50% of patients with bleeding in early pregnancy will proceed to term. Only 60% of women with an ectopic pregnancy will conceive again naturally, and will have a recurrent ectopic rate of 25% to 30% in subsequent pregnancies.

Disposition

Patients with a threatened miscarriage and an ultrasound confirming a live intrauterine gestation have an 85% to 90% chance of the pregnancy progressing to term. Poor prognostic indicators include advanced maternal age, ultrasound findings of an enlarged yolk sac and foetal bradycardia after 7 weeks' gestation. Patients should be advised to avoid sexual intercourse and not to use tampons until after the bleeding has settled. There is no evidence to support improved pregnancy outcomes from recommending bed rest. Referral for counselling or psychological support may be indicated in some women.

Investigation for an underlying cause is generally not indicated until after a third consecutive miscarriage. These include anatomical uterine abnormalities, thrombophilic disorders such as antiphospholipid syndrome and Factor V Leiden, chromosomal abnormalities, immune disorders, hormonal disorders, infection and environmental and lifestyle factors.

Patients with a non-viable intrauterine pregnancy or an ectopic pregnancy are referred to a gynaecology service for ongoing management.

CONTROVERSIES

- Role of point of care ultrasound within the ED
- Indications for anti-D immunoglobulin
- Management of patients with pregnancy of unknown location
- Best practice for emptying the uterus following a failed pregnancy
- Best practice for managing an ectopic pregnancy

19.5 Bleeding after the first trimester of pregnancy

Fatima Rahman

ESSENTIALS

1 **Up to 5% of pregnant women will have significant bleeding after 20 weeks' gestation.**

2 **Resuscitation of the mother followed by ultrasound localization of the placenta are the priorities of management for patients with heavy vaginal bleeding after 20 weeks' gestation.**

3 **Secondary postpartum haemorrhage is commonly caused by endometritis or retained products of conception.**

Introduction

Pregnancy is measured in trimesters from the first day of the last menstrual period, totalling 40 weeks. The first trimester of pregnancy is week 1 through week 12, or about 3 months. Vaginal bleeding after the first trimester may be due to a number of causes. The most common is classified as 'incidental', where the bleeding is not directly related to pregnancy.

Antepartum haemorrhage

Bleeding from the genital tract that occurs after 20 weeks' gestation and before the onset of labour is classified as an antepartum haemorrhage (APH). APH complicates 2% to 5% of all pregnancies. It is associated with increased perinatal morbidity and mortality and contributes significantly to health care utilization.[1]

Postpartum haemorrhage

Primary post-partum haemorrhage (PPH) is defined as heavy (>500 mL) vaginal bleeding within 24 hours of delivery and is discussed in Chapter 19.7.

Secondary postpartum haemorrhage

Secondary PPH is defined as bleeding >24 hours, or up to 6 weeks after delivery, most commonly as a result of infection or retained products of conception.

ANTEPARTUM HAEMORRHAGE

Differential diagnosis

Incidental causes

These include bleeding from the lower genital tract, most commonly from physiological cervical erosion or ectropion, where the bleeding may be either spontaneous or post-traumatic, such as post-coital. Other causes that need to be excluded include bleeding from cervical polyps, cervical malignancy and cervical or vaginal infection.

Bleeding from haemorrhoids or vulval varices may also be mistakenly reported as vaginal bleeding.

Placenta praevia

Placenta praevia occurs when the placenta is situated in the lower uterine segment in the third trimester of pregnancy. It occurs in 0.5% of term pregnancies.[2] Bleeding in this situation is usually bright red and painless, unless associated with labour contractions and often presents with several small 'warning' bleeds.

Placental abruption complicates around 1% of pregnancies. Bleeding occurs from a normally situated placenta. This may be a marginal bleed (from the placental edge) or in association with significant placental separation.

Bleeding may be revealed when blood escapes through the vagina, or it may be concealed behind the placenta, with no evidence of bleeding from the vagina. A placental abruption may follow relatively minor blunt trauma, such as a fall onto the abdomen, or a shearing force, such as that applied in a motor vehicle deceleration crash. Placental abruption may also occur spontaneously associated with hypertension, pre-eclampsia, thrombophilia or with cocaine use.[3]

Vasa praevia

This is the presence of foetal vessels running in the amniotic membranes distant from the placental mass and across the cervical os, such as with a succinturate lobe of placenta or a villamentous insertion of the cord, so that an earlier ultrasound may have described a fundal placenta. These vessels occasionally rupture, often in association with rupture of the amniotic membranes.

When this happens, the bleeding is from the foetus, which may quickly lead to foetal compromise. The first indication of this may be foetal bradycardia or other abnormalities of the foetal heart rate seen on cardiotocographic (CTG) tracing.

Physiological

Vaginal blood mixed with mucus is called a 'show' and is due to the mucus plug or operculum within the endocervical canal dislodging as the cervix begins to dilate. This usually occurs at the time of, or within a few days of, the onset of labour and is not significant unless the pregnancy is preterm or associated with rupture of the membranes. As a general guide, when a woman needs to wear a pad to soak up blood, she should be assessed as having an APH.

History

The history should specifically include the following details:

- Timing and amount of blood loss—for example, number of pads with an estimate of the blood staining on each pad
- Associated pain or contractions —for example, constant abdominal or lower back pain (suggestive of abruption). Painless bleeding suggests placenta praevia
- Provoking factors —for example, trauma or sexual intercourse
- Foetal movements since bleeding commenced
- Previous episodes of bleeding in pregnancy
- Prior cervical damage (risk factor for cervical incompetence)

Examination

Assess the mother as a priority. A relatively low blood pressure with a systolic of 90 mm Hg and a resting tachycardia of up to 100 bpm is normal in pregnancy.

Examination after 30 weeks' gestation should be performed in a supine position with the right hip elevated by a pillow to give a 15-degree tilt of the pelvis to the left. This avoids the problem of vena caval compression (supine hypotension syndrome) from pressure of the gravid uterus reducing inferior vena caval venous return.

Speculum or digital vaginal examination

Speculum or digital vaginal examination should *never* be performed until the site of the placenta is determined by ultrasound, to avoid disrupting a low-lying placenta and precipitating torrential haemorrhage.

Once an ultrasound scan has excluded a low-lying placenta, an experienced operator may proceed to a speculum examination to look for liquor within the vagina in suspected rupture of the membranes, or to assess the cervix to localize the site of bleeding and to look for cervical dilatation.

A sterile speculum examination is indicated, again by an experienced operator, if preterm prelabour rupture of the membranes is possible, to decrease the risk of introducing infection.

Digital vaginal examination should be performed to assess the cervix for dilatation if labour is suspected.

Ideally, a CTG should be applied to assess the status of the foetus beyond 24 weeks' gestation. Auscultation of the foetal heart for several minutes should be attempted if this is not available. The baseline rate and variations related to contractions are important. The normal range of the foetal heart rate is 120 to 160 bpm, but a healthy term or post-term foetus may have a heart rate of between 100 and 120 bpm. Decelerations of the foetal heart rate may indicate foetal distress.

Investigations

Laboratory blood tests

Blood should be taken for baseline haemoglobin and platelet count, coagulation screen, Kleihauer test, blood group, Rhesus factor, Rhesus antibodies and a cross-match.

A pre-eclampsia screen should be ordered if the patient is hypertensive, including liver function tests and uric acid, as well as the platelet count.

Ultrasound

Ultrasound is used to assess foetal gestation, presentation, liquor volume and placental position. Many 'low-lying' placentas at 18 weeks are no longer classified as placenta praevia by 30 to 32 weeks, owing to the differential growth of the lower uterine segment as pregnancy progresses. A placental edge at least 2 cm away from the cervical os at term is considered safe to allow a planned vaginal delivery.

As only 50% of placental abruptions will be seen on ultrasound, it is unreliable for excluding this problem with the diagnosis usually made on clinical grounds alone. Transvaginal ultrasound with an empty bladder is best to visualize the cervix to look for shortening or 'beaking' of the amniotic sac into the internal os, which are signs of early cervical incompetence.

Management

Analgesia and anti-emetics should be offered. The need for analgesia should raise concerns for a moderate or severe placental abruption, or that the woman is in labour.

Incidental causes of bleeding usually require no specific therapy apart from explanation and reassurance.

Minor amounts of bleeding due to placenta praevia distant from term are managed by close observation, usually initially as an inpatient or later as an outpatient.

Small placental abruptions may also be managed conservatively with serial ultrasound scans to monitor foetal growth and regular CTG assessments. Delivery is usually advised round 37 weeks to pre-empt a massive placental abruption developing. Sometimes, a small retroplacental clot will cause weakening of the amniotic membranes and subsequent rupture of the amniotic sac 1 to 2 weeks after the initial bleed.

Massive antepartum haemorrhage, often with foetal demise when associated with placental separation, requires urgent delivery, possibly by caesarean section. Hypovolaemia and coagulopathies are treated as per usual guidelines.

Prognosis

A decision needs to be made in a hospital where there are no obstetric or neonatal facilities about when to transfer a patient to an obstetric unit. Corticosteroids should be administered to the mother if the foetus is between 23 and 34 weeks and delivery can be delayed for 24 hours. Two intramuscular doses of betamethasone or dexamethasone given over 24 hours decreases the baby's risk of developing respiratory distress syndrome, necrotizing enterocolitis and intraventricular haemorrhages.[4]

Administer 625IU anti-D as an intramuscular injection if the woman is Rhesus D negative.

If birth is imminent at a gestation less than 30 weeks gestation, consider a magnesium sulphate infusion for foetal neuroprotection.[5] Discussion about dose and timing should be with the obstetric staff receiving the woman if transfer is being planned.

The current survival rate of a baby admitted to a neonatal intensive care unit (NICU) is 40%, 50%, 60% and 70% at 24, 25, 26 and 27 weeks, respectively.[4]

Disposition

Depending on the underlying cause, women who have experienced a non-life-threatening APH, who are clinically stable, may be discharged home with outpatient review.

SECONDARY POSTPARTUM HAEMORRHAGE

Introduction

Secondary PPH is defined as excessive or prolonged bleeding from 24 hours to 6 weeks' postpartum. Normal lochia is moderately heavy, red vaginal loss for some days that settles to light bleeding or spotting by 2 to 4 weeks. Some women have a persistent brownish vaginal discharge for up to 8 weeks.[6]

Differential diagnosis

Common causes of secondary PPH include retained products of conception and endometritis. The bleeding is usually prolonged, moderate blood loss or a recurrence of blood loss after an initial decline.

Less common causes of secondary PPH include trophoblastic disease, uterine arteriovenous malformation (AVM) and any of the incidental causes outlined in the previous section. Reactivation of bleeding from an episiotomy or vaginal laceration may also be responsible. Annoying spotting may occur for several weeks in women using progestogen-only contraception, especially when concurrently breastfeeding, in the setting of an oestrogen-deficient endometrium.

History

Distinguishing endometritis from retained products may be difficult clinically and the two conditions often coexist. Endometritis may follow any type of delivery, but is more common in women with a history of prolonged rupture of the membranes and multiple vaginal examinations during labour.

Examination

Abdominal examination may show subinvolution of the uterus with retained tissue, while offensive lochia, uterine tenderness and systemic signs of infection support the diagnosis of endometritis.

An AVM presents with heavy vaginal bleeding and, occasionally, haemodynamic compromise.

Investigations

Full blood examination and two paired sets of blood cultures are indicated if the woman is

clinically septic. Send cervical swabs for microscopy and culture and *Chlamydia trachomatis* detection to help guide the management of endometritis.

Ultrasound is necessary to quantify the amount of retained products of conception and to confirm a diagnosis of an AVM.

Treatment

Empirical treatment with amoxicillin/clavulanic acid 875 mg/125 mg bd PO for 5 to 7 days as an outpatient is appropriate if endometritis is suspected but the woman is systemically well.[7] Erythromycin may be substituted in penicillin-sensitive patients. Admit systemically unwell patients for intravenous antibiotics.

Perform an ultrasound examination if bleeding persists to look for retained products. Patients with small amounts of retained products may be treated conservatively. Uterine curettage in the postpartum period is associated with the risks of uterine perforation or Asherman syndrome (formation of scar tissue in the uterine cavity) due to intrauterine adhesions and/or fibrosis.

CONTROVERSIES

- Suppression of labour in patients with APH
- Timing of delivery in patients with mild APH due to placental abruption
- The timing and interpretation of ultrasound investigation in patients with secondary PPH

19.6 Pre-eclampsia and eclampsia

Marian Lee

ESSENTIALS

1 **Pre-eclampsia is hypertension with organ-system dysfunction unique to the second half of pregnancy.**

2 **Maternal and foetal demise are inevitable and can only be stopped by pregnancy termination.**

3 **Early diagnosis is crucial as the rate of deterioration is unpredictable.**

4 **Eclampsia is a seizure complicating pre-eclampsia and leads to high maternal and foetal morbidity and mortality.**

Introduction

Pre-eclampsia is a hypertensive disorder unique to pregnancy. Maternal and foetal morbidity and mortality are high with pregnancy termination the only definitive treatment. In Australia, severe pre-eclampsia occurs in 1% to 2% of all pregnancies and accounts for 15% of maternal mortality. The perinatal mortality is 10% and accounts for 5% to 10% of pre-term deliveries.[1]

Definitions[2]

The blood pressure (BP) in a normal pregnancy falls in the first trimester, reaching a nadir in the second, and returns to the normal range by the third trimester. Hypertension is a BP of >140/90 mm Hg. A change of >30/15 mm Hg from the preconception level should prompt close monitoring. The four hypertensive disorders in pregnancy are:

- Chronic hypertension: predates the pregnancy.
- Gestational hypertension: during pregnancy and resolves within 6 weeks post-partum.
- Pre-eclampsia: hypertension with organ-system dysfunction occurring at >20 weeks gestation and up to 6 weeks post-partum.
- Pre-eclampsia superimposed on chronic hypertension.

Pathophysiology[3,4]

The pathogenesis of pre-eclampsia remains unclear, and some of the current thinking is discussed.

Abnormal placentation

In normal pregnancy, foetal trophoblasts migrate into the endometrial and myometrial spiral arteries, causing their remodelling into low resistance–high capacitance vessels. Trophoblasts in pre-eclamptic pregnancies do not migrate beyond the endometrial spiral arteries. They remain as high resistance vessels that jeopardize the blood supply to the placenta.

Endothelial dysfunction

The systemic effects are thought to result from endothelial dysfunction leading to high systemic vascular resistance. The end result is hypoperfusion of organ-systems. The cause is thought to be an imbalance between angiogenic and antiangiogenic factors.

Immunological cause

An immunological cause without definite evidence has been proposed for the following risk factors: first pregnancy, multiple pregnancy, pregnancy with a different partner or when the inter-pregnancy period is beyond 10 years with the same partner. See Box 19.6.1 for other risk factors.

Clinical features

Pre-eclampsia causes multiple organ-system dysfunctions that may not be evident on presentation. Checking the BP in patients of >20/40 weeks gestation is an essential component of the assessment. Hypertension detected must trigger the inclusion of preeclampsia in the differential diagnoses. The following are clinical features

Box 19.6.1

Age >40 years
BMI >30kg/m²
Gestational hypertension
Past history of pre-eclampsia
Family history
Antiphospholipid syndrome
Diabetes

that may be encountered. More than one organ system may be affected in pre-eclampsia.

Neurological

Neurological features are related to cerebral oedema. Headaches, visual symptoms, confusion and papilloedema should be sought. Stroke may also occur. Seizure, known as eclampsia, is the most time critical complication, with a high maternal and foetal mortality and morbidity.

Eclampsia is a self-limiting seizure that occurs as a complication of preeclampsia. It can occur any time after 20 weeks gestation and up to 6 weeks post-partum. However, it is less common after 24 hours post-partum. It is not always associated with hypertension but more likely to occur with severe preeclampsia with BP of >170/110 mm Hg, which accounts for two-thirds of cases. The rest have a lower BP, including a normal BP.[5] The magnitude of the BP is not a reliable way of predicting eclampsia, and unfortunately, there is no reliable way to detect its imminent onset. Persistent headache, visual disturbances, neurological deficit or hyper-reflexia should trigger preventive measures,[2] as there is a high risk of intracerebral haemorrhage in eclampsia. Eclampsia is the most important differential diagnosis to consider in pre-eclampsia. However, other causes of seizures need to be sought, especially when seizure occurs beyond the first 24 hours post-partum.

Cardiovascular[6,7]

In normal pregnancy, the fall in the diastolic BP and systemic vascular resistance (SVR) is coupled with a raised cardiac output. In pre-eclamptic pregnancies, the SVR is increased and coupled with a reduced cardiac output. There is left ventricular diastolic dysfunction. In practice, this means that patients are at risk of acute pulmonary oedema with injudicious intravenous fluid therapy.

Gastrointestinal

Pre-eclampsia may present with severe or persistent epigastric or right upper quadrant pain. A transaminitis twice the normal range may be found in isolation or associated with other features of the HELLP syndrome (HELLP stands for haemolysis, elevated liver enzymes and low platelets) discussed below. Biliary tract disease and fatty liver of pregnancy are alternative diagnoses.

The following features of pre-eclampsia need to be sought through investigations.

Renal[2]

Evidence of renal involvement needs to be sought in patients with oedema.

Proteinuria

The current practice is to use a spot urine protein/urine creatinine ratio to quantify the amount of proteinuria. Significant proteinuria is a ratio >30 mg/mol. Replacing the previous criteria of a 24-hour urine sample means early diagnosis can be made in the emergency department (ED).

Urine output

Oliguria is defined as <500 mL/day. It is acceptable to use 80 mL/4 hours in the ED.

Serum creatinine

Renal involvement is present when the serum creatinine is greater than 90 mmol/L. In normal pregnancy, serum creatinine lies in the lower normal range.

The differential diagnosis for renal insufficiency and hypertension are the vasculitic disorders, in particular Systemic Lupus Erythematosis (SLE) and antiphospholipid syndrome.

Haematological[2]

This has two components: haemolysis and thrombocytopaenia.

Haemolysis

Consistent with haemolysis are schistocytes on the blood film, raised serum bilirubin, LDH >600IU/L and a low serum haptoglobin.

Thrombocytopaenia

In normal pregnancy (1%), the platelet count can be as low as 100,000 × 10^9/L. Hence thrombocytopaenia is defined as <100,000 × 10^9/L and should prompt a search for disseminated intravascular coagulation (DIC). Differential diagnoses to consider are thrombotic thrombocytopaenic purpura and haemolytic uraemic syndrome.

HELLP syndrome[2]

HELLP is a marker of severe preeclampsia. The full syndrome is uncommon, and two of the three components are adequate for the diagnosis. The elevated liver enzymes refer to transaminitis that is at least twice normal. The differential diagnoses are fatty liver of pregnancy and biliary tract disease.

The foetus[2]

Evaluation of the foetus must be part of the evaluation for preeclampsia. Evidence of placental dysfunction is indicated by oligohydramnios and abnormal umbilical artery Doppler for reduced blood flow. Foetal well-being is gauged by cardiotocography.

Recognition of severe pre-eclampsia[2,6]

Early diagnosis of severe pre-eclampsia is crucial to management. The rate of deterioration is unpredictable. The following are features of severe pre-eclampsia.

1. Hypertension: SBP >160 mm Hg, DBP >110 mm Hg
2. Persistent cerebral or visual symptoms
3. Eclampsia
4. Acute left heart failure—acute pulmonary oedema
5. Persistent RUQ and/or epigastric pain with no alternative diagnosis
6. HELLP syndrome
7. Foetal growth restriction

Management

Once the diagnosis is made, the aim is to optimize maternal and foetal well-being prior to the inevitable termination of the pregnancy. The following is a prioritized management plan.

Eclampsia[2]

The specific priority beyond initial assessment and stabilization of the airway, ventilation and circulation is terminating the seizure, if present.

Stop the seizure

Benzodiazepines are the first-line drugs. Diazepam up to a dose of 10 mg is used intravenously. Clonazepam 2 mg, 5 minutely is an alternative.

Prevent further seizure

Mg_2So4 is used for the acute treatment of eclampsia after benzodiazepines, given as a loading dose and followed by an infusion. It is also used to prevent eclampsia in patients with clinical features consistent with severe preeclampsia.[6]

The mechanism of action is not well understood. It is given as a loading dose of 4 gram IV diluted in 100 mL of Normal Saline given over 15 minutes followed by an infusion at of 2g/h. For further seizures, another bolus of 2 to 4 grams is given over 10 minutes, together with a benzodiazepine.

The therapeutic range based on clinical experience, is 2.0 to 3.5 mmol/L. An IV bolus of 4 to 6 grams achieves this serum level within 30 minutes. An infusion of 2g/h leads to a serum level between 2.0 and 3.0 mmol/L.[8] It can be given intramuscularly with less predictable serum levels.

Table 19.6.1 Adverse effects of magnesium by serum levels

Serum Level	*Toxic effect*
3.2–5.0 mmol/L	Loss of deep tendon reflexes
4.0–6.0 mmol/L	Slurred speech and respiratory depression
20 mmol/L	Cardiac arrest

Monitoring for Mg toxicity symptoms is necessary. The adverse effects are related to serum concentration (Table 19.6.1).[6]

Aside from the potential toxicity, $MgSO_4$ causes uterine atony and contributes to postpartum haemorrhage.

Treat the hypertension[2,6]

The target BP is <160/100 mm Hg. No single antihypertensive is recommended. They are categorized into first and second-line drugs. Labetolol and hydralazine are both available in intravenous form, and their doses are given in the following discussion. Using the most familiar and appropriate drug in either category is recommended.

First-line antihypertensives: labetolol, methyldopa, oxprenolol Labetolol is an alpha and beta antagonist. It is contraindicated in asthmatics and cardiac failure. It may cause bradycardia and hypotension. It is given 20 mg IV, 10 minutely, up to a maximum dose of 300 mg.[9] The onset of action is within 5 minutes.

Second-line antihypertensives: hydralazine, nifedipine and prazosin Hydralazine is a directly acting vasodilator. When compared to labetolol, it has a poorer adverse effect profile. Hydralazine may cause maternal hypotension with a reflex tachycardia. It is given 5 mg IV or IM. Repeat at doses of 5 to 10 mg 30 minutely, up to a maximum dose of 20 mg.[9] The onset is 20 minutes.

Antihypertensives not recommended are ACEI and angiotensin receptor blockers due to risk of foetal renal injury; spironolactone due to antiandrogenic foetal effects and β-blockers may cause congenital anomalies.[6]

Pregnancy termination

The best time to deliver the foetus requires a balance of maternal and foetal risks.

Useful definitions[2] Immediate delivery is within a period of 48 hours.

Expectant delivery is beyond this period.

Maternal risks Pre-eclampsia leads to inevitable maternal deterioration manifesting as severe organ-system dysfunction such as eclampsia, acute pulmonary oedema, HELLP syndrome and placental abruption.

Foetal risks[2] Gestational age is central to the evaluation of the foetal risks and benefits of delaying delivery.

Less than 24 weeks: Delaying delivery is outweighed by the high maternal risks.

24 to 32 weeks: The foetal risks are respiratory distress syndrome, longer ICU admission and higher risk of caesarean section. The maternal risks are continuing deterioration of organ-systems.

>32 weeks: the optimal gestation for delivery for both maternal and foetal outcome is 36 weeks.

Delivery The role of the emergency physician is to diagnose and manage the acute complications of pre-eclampsia. Optimization of maternal and foetal well-being prior to delivery are done in collaboration with the obstetric and neonatal team.

Treatment of the hypertension

A BP of >160/110 mm Hg is significant hypertension and signifies severe pre-eclampsia. Urgent treatment is indicated to prevent eclampsia, intracerebral haemorrhage, posterior reversible encephalopathy syndrome and hypertensive encephalopathy (see the previous discussion for antihypertensives used).

General maternal management

Fluid management[2,3]

There is a risk of acute pulmonary oedema. Fluid challenges are given in volumes of 250 mL for hypoperfusion with careful monitoring. Otherwise, it is given at maintenance rate. Hypotension may not respond to intravenous fluids. Metaraminol and adrenaline are considered safe in pre-eclampsia.[2]

Thrombocytopaenia

There is a risk of peripartum bleeding for platelet count of <50,000 × 10^9/μL. Platelet transfusion is given at the time of delivery or for invasive procedures.

Foetal well-being[2]

Foetal monitoring and two specific agents are used to improve foetal outcome in pre-term delivery.

A single dose of betamethasone or dexamethasone is used pre-natally for pregnancy <34/40 weeks gestation, given ideally at 48 hours prior to delivery. This reduces the risk of neonatal death, respiratory distress syndrome and cerebral haemorrhage. The optimal steroid with its dosage regime is not known.[2,10]

Mg_2So4 is recommended for foetal neuroprotection for pre-term delivery at <30/40 weeks gestation. It reduces the risk of cerebral palsy.[2]

Summary

Pre-eclampsia leads to inevitable maternal and foetal morbidity and mortality. In the ED, the emphasis is on early diagnosis, treatment of acute complications, prevention of further deterioration and facilitating timely termination of the pregnancy. Early collaboration with the obstetric and neonatal team is essential.

19.7 Emergency delivery and complications

Stephen Priestley

ESSENTIALS

1 **Perform a rapid assessment of any pregnant patient arriving in labour at the emergency department to decide the most appropriate site for management.**

2 **Emergency department staff must be prepared to provide newborn resuscitation following an emergency delivery. Preparedness for newborn resuscitation requires preparation of a suitable area with ability to provide radiant heat, special equipment and trained dedicated personnel as well as a structured approach to assessment and intervention.**

3 **Necessary equipment, drugs and protocols must be immediately available within emergency departments so that unexpected deliveries can be managed safely.**

4 **Be prepared to manage sudden complications of delivery, such as shoulder dystocia, breech delivery or postpartum haemorrhage.**

5 **Establish and maintain lines of communication with regional obstetric services so that decisions regarding the management of labour and transfer of mothers and babies are optimum.**

Introduction

Occasionally a doctor working in an emergency department (ED) is faced with a patient in labour and required to manage a spontaneous vaginal delivery. This situation is generally accompanied by much anxiety on the part of the ED medical and nursing staff, but it is important that a calm, systematic approach be taken to minimize the risk of an adverse foetal or maternal outcome.

This chapter describes the management of a normal delivery in the ED and provides a brief outline of the recognition and management of abnormal deliveries and selected peri-partum complications.

Setting

There are a number of settings when childbirth may have to occur in an ED. Pregnant patients at different gestational ages may present to the ED at varying stages of labour.

Whenever a woman in the third trimester of pregnancy seeks treatment in the ED, the possibility that she is in labour must be considered. A wide array of non-specific symptoms may herald the onset of labour. Abdominal pain, back pain, cramping, nausea, vomiting, urinary urgency, stress incontinence and anxiety can be symptoms of labour.

The immediate management of a woman in labour will depend on the availability of obstetric services, the gestational age, known antenatal history and past obstetric history and on both the stage of labour and its anticipated speed of progression.

All ED deliveries should be considered high risk. Antepartum haemorrhage, premature rupture of membranes (PROM), eclampsia, premature labour, abruptio placentae, malpresentation, and umbilical cord emergencies are over-represented in the ED population.

Safe transfer to a delivery suite when there is adequate time is always preferable to delivery in the ED.

Women with the urge to push or with the head of the infant crowning are at imminent risk of delivery, which should then take place in the ED. If there is no delivery suite available, or a patient arrives with full cervical dilatation, the foetal presenting part is on the perineal verge and there is no time for transfer to an appropriate facility, arrangements must be made to perform the delivery rapidly in the ED. In these situations, the emergency physician should prepare for two patients, both potentially needing emergency care.

Precipitate labour

Patients who have precipitate labour—an extremely rapid labour lasting less than 3 hours from onset of contractions to delivery, which is more common in the multiparous—may have to stop in the ED even when en route to the delivery suite or another hospital because of the rapidity of the labour.

Concealed or unrecognized pregnancy

The diagnosis of a concealed or unrecognized pregnancy may also be made in the ED. Concealed pregnancies occur most commonly in teenage girls who do not tell anyone that they are pregnant and receive no antenatal care. Unrecognized pregnancy occurs most commonly in obese females who may present to the ED complaining of abdominal pain or a vaginal discharge and are found to be pregnant and/or in labour. Women with intellectual impairment or mental illness are another group who may present with an unrecognized pregnancy.

'Born before arrival'

The term 'precipitous birth' or 'born before arrival' (BBA) is commonly associated with precipitate labour and refers to women who deliver their baby prior to arrival at a hospital, usually without the assistance of a trained person. On arrival in the ED, both the mother and baby require assessment and may need resuscitation and completion of the third stage of labour. The term *precipitous birth* is also commonly used to describe deliveries that occur in the emergency department or areas outside of a labour and delivery suite.

The incidence of BBA is low but depends on the population studied. In Australia, the incidence of precipitate labour is approximately 1% to 2% in spontaneous non-augmented labours.

History

Assessment of the patient in labour in the ED includes obtaining information regarding gestational age, antenatal care, progression of the pregnancy and past obstetric and a medical history. Always enquire if the patient has a copy of her antenatal care record with her. Take a careful history regarding the onset and timing of contractions and the presence and nature of fetal movements in addition to a history of vaginal bleeding or discharge, which may represent the rupture of membranes.

Delivery in a hospital where there is no delivery suite should include immediate contact by

telephone with the nearest or most appropriate obstetric unit to obtain advice and organize postpartum transfer of the mother and newborn.

Gestational age

The gestational age may be determined from the last normal menstrual period (LNMP) if this is known. The Naegle rule is the most common method of pregnancy dating. The estimated date of delivery (EDD) is calculated by counting back 3 months from the last menstrual period and adding 7 days. As an example, if the last menstrual period was December 20, then the EDD will be September 27. This method assumes that the patient has a 28-day menstrual cycle with fertilization occurring on day 14. Inaccuracy occurs because many women do not have regular 28-day cycles or do not conceive on day 14 and many others are not certain of the date of their last period.

Antenatal ultrasound

Antenatal ultrasound is useful in gauging the estimated date of delivery where dates are uncertain, noting that scans performed later in the pregnancy are less accurate in dating the gestational age of the baby than those performed early. Additionally, a rough estimate of the gestational age of the baby can be made by abdominal examination. At 20 weeks' gestation, the uterine fundus reaches the umbilicus. Approximately 1 cm of fundal height is added per week of gestation until 36 weeks. At that time, the fundal height decreases as the foetus drops into the pelvis. These estimates can help to establish gestational age rapidly

Past obstetric history

The past obstetric history should include the duration and description of previous labours, the types of deliveries and the size of previous babies, in addition to a history of a previous caesarean section, the use of forceps or vacuum extraction, previous stillbirth, and history of abnormal presentation (e.g. breech presentation), shoulder dystocia, prolonged delivery of the placenta or a postpartum haemorrhage.

Maternal medical conditions

Maternal conditions—such as cardiac and respiratory disease, diabetes, bleeding conditions, hepatitis B and herpes simplex infection—should be documented. Record all drugs, whether prescribed, over-the-counter or illicit, that the patient is taking as well as any allergies. The presence of any bleeding or other complications during the pregnancy should also be noted. Obtain the results of antenatal investigations, including a full blood count, blood group, hepatitis B status, HIV, syphilis serology and any record of group B streptococcal bacteriuria or colonization.

Examination

General examination

A general physical and obstetric examination to confirm the progression of labour, the number of babies and the presence or absence of any complications related to the pregnancy and labour is made. In hospitals where there is a delivery suite, a member of that unit (usually a midwife) is called to attend the ED either to assist with immediate transfer to the delivery suite if possible or with the assessment and conduct of the labour within the ED. Occasionally a member of the ED staff will hold a midwife certificate, and this staff member should be tasked to assist with labour and delivery.

The general examination includes particular emphasis on vital signs and the abdominal and pelvic examination. Examine the patient's heart and chest and perform a urinalysis looking for evidence of infection, glucose or proteinuria, which may be associated with pre-eclampsia (see Chapter 19.6 Pre-eclampsia and Eclampsia).

Abdominal examination

Perform an abdominal examination to ascertain the height of the fundus, the lie and presentation of the foetus and to make an assessment of the engagement of the presenting part. The term *presenting part* refers to the foetal anatomic part proceeding first into and through the pelvic inlet. Most commonly, the foetal head is presenting, which is referred to as a cephalic (or vertex) presentation. The presence of scars and extra-uterine masses should be noted. Also assess the frequency, regularity, duration and intensity of uterine contractions.

Braxton Hicks contractions, or false labour, must be differentiated from true labour. Braxton Hicks contractions do not escalate in frequency or duration, in contrast to the contractions of true labour. By definition, these contractions are associated with minimal or no cervical dilation or effacement. Any discomfort associated with false labour is usually relieved with mild analgesia, ambulation or change in activity.

Unlike false labour, true labour is characterized by cyclic uterine contractions of increasing frequency, duration, and strength culminating in delivery of the foetus and placenta. In contrast to Braxton Hicks contractions, true labour causes cervical dilation to begin, marking the first stage of labour.

In the third trimester or during labour, ultrasonography can provide crucial information pertaining to impending delivery. When an ultrasonographer is available and if time permits, foetal viability, gestational age, and a survey of fetal and placental anatomy, lie and presentation may be obtained. The use of bedside trans-abdominal ultrasonography by emergency clinicians to evaluate such parameters expeditiously continues to rise as this modality becomes increasingly available and operator skill improves.[1]

Fetal heart rate

Count the foetal heart rate between contractions for 1 minute using an ordinary stethoscope, Pinard or a Doppler stethoscope. The heart rate should be between 110 and 160 beats per minute. Count the fetal heart rate for at least 30 seconds following a contraction. Slowing of the foetal heart rate during and immediately following a contraction is not uncommon and normally represents physiological reflexes associated with head compression. Persisting bradycardia greater than 30 seconds after a contraction may indicate umbilical cord compression or utero-placental insufficiency. Recommended management is to give the mother oxygen and position her in the left lateral position to ensure that uterine blood flow and fetal oxygenation is optimized.

If post-contraction bradycardias persist despite these measures, give an intravenous fluid bolus and seek specialist obstetric advice. Note any vaginal bleeding or discharge and record the amount, remembering that haemorrhage may also be concealed. Assess the colour and character of any amniotic fluid looking for evidence of meconium staining.

Vaginal examination

Perform an aseptic vaginal examination with the patient in the dorsal lithotomy position to assess the effacement, consistency and dilatation of the cervix, the nature and position of the presenting part (i.e. vertex or breech) and to exclude a cord prolapse. If unsure of the nature of the presenting part, a portable ultrasound can aid in diagnosis.

The exception to performing a vaginal examination is the gravid patient with active vaginal bleeding. Such a patient should be evaluated with an ultrasound to exclude placenta praevia *before* performing any pelvic examination.

If the membranes are intact and the labour is progressing satisfactorily, there is no indication to rupture them as there is an increased risk of cord prolapse when the presenting part is not well engaged in the pelvis. After the vaginal examination, apply a sterile perineal pad and allow the mother to assume whichever position gives her the most comfort while avoiding a totally supine position, as this has the potential for inferior vena cava (IVC) compression by the gravid uterus.

Transferring the patient

After this assessment, the decision whether to transfer the patient to a delivery suite either within the hospital or at a distant hospital must be made. Cervical dilatation greater than 6 cm in a multiparous patient and 7 to 8 cm in a primipara

Table 19.7.1 Equipment and drugs required for emergency delivery

Equipment	*Drugs*
Three clamps – straight or curved (e.g. Pean)	Adrenaline 1:10,000
Episiotomy scissors	Oxytocin 10 units
Scissors	Ergometrine 250 µg
Suture repair set	Vitamin K 1 mg
Absorbable suture material	Lignocaine 1%
Sterile drapes	Naloxone 400 µg/1 mL
Huck towels	Glucose 10%
Sterile gloves	
Soap solution	
Sterile bowls	
Neonatal resuscitation equipment, including appropriately sized suction catheters, oropharyngeal airways, masks, self-inflating bag (approximately 240 mL), endotracheal tubes, stylets, laryngoscopes, end-tidal CO_2 detector device, neonatal oxygen saturation probe	
Umbilical vein catheters, overhead warmer, clock with timer in seconds, warmed towels, and feeding tubes for gastric decompression	

makes transfer to a distant hospital a hazardous process because of the risk of rapid progression to full cervical dilatation and imminent delivery of the baby.

The availability and type of transport and personnel and the distance to be travelled must be carefully considered. Consult with the obstetric unit regarding the safety of transfer and make arrangements for reception of the patient. Consider contacting specialty neonatal transport services if problems are anticipated or the baby is premature.

Management

Preparation for delivery

Ongoing assessment of the maternal temperature, blood pressure, heart rate and contractions should be performed and recorded. Fetal heart rate should be counted every 15 to 30 minutes up to full cervical dilatation and every 5 minutes thereafter. The fetal heart rate is best measured with a Doppler device, commencing toward the end of a contraction and continuing for at least 30 seconds after the contraction has finished.

Unless there is a clear indication for an intravenous line, such as a history of postpartum haemorrhage or antepartum haemorrhage, bleeding tendency, evidence of pre-eclampsia or history of a previous caesarean section, placement of such a line for the normal delivery is unnecessary. Perform simple venipuncture for a haemoglobin, blood glucose and blood group and put some blood aside for cross-matching.

Equipment and drugs

Obtain a delivery pack, sterile surgical instruments and oxytocic drugs and place nearby (Table 19.7.1). Resuscitation equipment and drugs should be available. Assemble personnel with clear task delegation, remembering that reassurance and emotional support for the mother and the mother's partner is crucial during the entire labour. A specific member of staff may be delegated to provide this.

If a midwife or doctor experienced in delivery is available, he or she should assume control of the procedure and continue assessing the progression of labour and conduct the delivery of both the baby and the placenta. A doctor or nurse with some experience in neonatal or paediatric resuscitation should perform a rapid assessment of the newborn immediately after the delivery to ascertain the need for resuscitation.

Conduct of labour

Labour is divided into three stages: the first stage is from the onset of regular contractions to full (10 cm) dilatation of the cervix. The second stage is from full dilatation of the cervix to delivery of the baby and the third stage is from the birth of the baby until delivery of the placenta. A full description of the detailed management of the three stages of labour is beyond the scope of this chapter, but a brief summary of the management of a normal vertex delivery is described.

First stage

Examine the patient abdominally and vaginally as necessary to follow the progress of the labour. As mentioned earlier, regularly perform measurement and recording of maternal vital signs and fetal heart rate. Gently wash the perineum with a non-irritating solution Shaving, urinary catheterization or enema administration are not required.

The duration of the first stage of labour averages 8 hours in nulliparous women and 5 hours in multiparous women. During this time, frequent assessment of foetal well-being is important.

Analgesia

Analgesics are helpful for the patient with significant discomfort and are generally not injurious to the foetus. The timing and dose of analgesia must be decided with due regard to the stage and rate of progression of labour in addition to the mother's wishes and birth plan.

Inhaled nitrous oxide is simply delivered, acts quickly, is rapidly eliminated and does not affect the foetus. It is usually provided initially in a dose of 50% N_2O mixed with 50% oxygen, but the N_2O dose can be increased to 70% maximum by delivery systems available in many EDs.

Opiate analgesia is also commonly used, although is generally not recommended within 4 hours of predicted delivery, meaning that it is unlikely to be used in a precipitous delivery in the ED. Morphine is preferred to pethidine, as the active metabolite of intramuscular pethidine has a longer half-life in the newborn compared with intramuscular morphine. Major opiate side effects include maternal drowsiness, nausea and vomiting. Although there is no clear evidence of major adverse effects at birth, the timing of any opiates given during labour should be considered and the newborn assessed for possible secondary respiratory depression or hypothermia.

Second stage

The second stage of labour is characterized by a fully dilated cervix and accompanied by the mother's urge to bear down and push with each uterine contraction. The median duration of this stage is 50 minutes in nulliparous women and 20 minutes in multiparous women, with the anticipation of a more rapid progression for low-birth-weight premature infants.

Spontaneous delivery of the foetus presenting by vertex is divided into three phases: delivery of the head, delivery of the shoulders and delivery of the body and legs. The second stage of labour begins when the cervix is fully dilated and delivery will occur when the presenting part reaches the pelvic floor.

As the second stage of labour progresses, preparations for delivery should be under way. A radiant warmer should be available and heated. Neonatal resuscitation adjuncts should be available and a suitably experienced staff member tasked and prepared to provide immediate assessment and care of the newborn. A nurse

should be at the bedside to coach and provide reassurance to the mother.

The vulva and perineum are cleared and gently washed with sterile water or saline. A repeated sterile examination to assess labour progression and confirm presentation may be performed. Drape the patient in such a manner that there is a clear view of the perineum.

Maternal position

Either a dorsal lithotomy or lateral Sims position may be used for delivery. The dorsal lithotomy position is recommended for inexperienced operators as it is easier to visualize and to manually control the delivery process or perform an episiotomy. In the dorsal lithotomy position, the mother should be tilted over to the left side, using a pillow or soft wedge, to avoid compression of the inferior vena cava by the gravid uterus and possible maternal hypotension and fetal hypoxia.

Episiotomy

When the presenting part distends the perineum, delivery is imminent. Consider an episiotomy at this time, but this should not be routine with a controlled delivery. It should be routinely performed only for specific indications, such as shoulder dystocia or breech delivery. The term *episiotomy* refers to a surgical incision of the perineum performed by the birth assistant just prior to delivery. The primary reason for this is to prevent a larger spontaneous, irregular laceration of the perineum, particularly one that extends into the rectum. It is performed with scissors when the perineum is stretched and distended, just prior to crowning of the fetal head, following infiltration of a posterior area of the peritoneum with 5 to 10 mL of 1% lignocaine (lidocaine) between contractions.

A mediolateral perineal incision is recommended, beginning at the posterior fourchette and extended towards the ischiorectal fossa. A midline episiotomy is no longer recommended due to an increased risk of tears extending through to the rectum. The patient should be encouraged to bear down during contractions and to rest in between.

Delivery of the head

Calm communication between the physician and mother is the best way to maintain control of the delivery. Delivery of the head must be controlled by the birth assistant so that the head extends slowly after crowning and does not 'pop out' of the vagina, which would increase the risk of perineal injury. Placing the palm of one hand over the head to control its extension most easily achieves this. At this point, the patient should cease actively pushing and may have to be instructed to pant or breathe through her nose in order to overcome a desire to push. The birth assistant's second hand, covered with a sterile gauze pad or towel, may be used gently to lift the baby's chin, which can be felt in the space between the anus and the coccyx.

As the occiput descends under the symphysis pubis, extension of the head occurs and progressively the forehead, nose, mouth and finally chin emerge. Suctioning of the nasopharynx and oropharynx prior to birth of the shoulders and trunk is not required even in the presence of meconium-stained liquor.[2] In 25% to 30% of patients, the umbilical cord is looped around the neck (nuchal cord); this should be checked. Usually, it is only loosely looped and can be drawn over the head. If that is unsuccessful, another method is to bring the cord caudally over the shoulders and deliver the baby through the cord and then unwind it after delivery. If this is not possible (e.g. it is too tight or has too many loops), double clamp the cord 2 to 3 cm apart and divide the cord between the clamps. Release of additional loops is now straightforward by unwinding the clamped ends around the neck. Recheck the neck, because the cord may be wrapped more than once. Then deliver the infant expeditiously.

Restitution and delivery of the shoulders

The baby's head, having been delivered face down in the most common occipito-anterior position, is allowed to 'restitute' (or correct) to one or the other lateral position. Once the head has restituted, the shoulders will lie in an antero-posterior plane within the pelvis. Delivery of the shoulders is now affected, taking great care not to allow the perineum to tear. Usually the anterior shoulder slips under the symphysis pubis with the next contraction. Gentle downward traction on the head promotes delivery of the anterior shoulder. Do not use excessive force, as this may result in a brachial plexus injury.

On delivery of the anterior shoulder, lifting the baby up will deliver the posterior shoulder, followed by the body and lower limbs. If delay occurs in delivery of the shoulders, the potential for shoulder dystocia should be considered.

Grasp the baby firmly with one hand, securing the infant behind the neck, with the other hand encircling both ankles; then place the baby on the mother's abdomen. The baby is slippery as a result of being covered with vernix and should never be held with one hand alone. Dry the baby and wrap it in a warm blanket to minimize heat loss; also record the time of birth.

As the infant clears the perineum, attention focuses on the umbilical cord. The infant should be kept low or at the level of the perineum to promote blood flow into the infant from the placenta. The cord is now clamped and cut. Clamps should be placed 4 or 5 cm apart, with the proximal clamp 10 cm from the infant's abdomen. An adequate umbilical stump is important for venous access if the neonate should require resuscitation.

Clamping the cord

There is no need to cut the cord immediately if the baby appears vigorous and breathes spontaneously. Delayed cord clamping, defined as waiting to clamp the umbilical cord for 1 to 3 minutes after birth or until cord pulsation has ceased, is associated with benefits, as more blood is transferred from the placenta to the baby. Benefits include higher birth weight, higher haemoglobin concentration, improved iron stores at 6 months, and improved respiratory transition.[3,4]

Delayed cord clamping is indicated with all deliveries unless urgent resuscitation is needed. Clamps should be placed 2 or 3 cm apart, with the proximal clamp more than 5 cm from the infant's abdomen. An adequate umbilical stump is important for venous access if the neonate requires resuscitation.

Immediately following birth, the vigorous newborn should be placed directly in contact with the mother's skin and covered with a blanket. Skin-to-skin contact is associated with decreased time to the first feeding, improved breastfeeding initiation and continuation, higher blood glucose level, decreased crying, and decreased hypothermia.[5] Maintain warmth by drying the baby with pre-warmed towels or blankets.

If the baby requires resuscitation, then the evidence favouring delayed cord clamping over rapidly commencing resuscitation is less clear. Quickly clamp the cord following delivery and transfer the baby for further assessment and resuscitation to a resuscitation trolley that has a radiant heat source.

Apgar score

Apgar scoring is used to provide a rough estimate of the baby's immediate adaptation to extra-uterine life. The score allows easy communication of a baby's status between providers and indicates a basic prognosis for the newborn. It is obtained at 1 minute and 5 minutes after birth, with a score from 0 to 10.

The following acronym approach can be used to remember the five categories, with each scored on a scale from 0 to 2:

A: **A**ppearance (0: pale or blue; 1: pink body, blue extremities; 2: pink body and extremities)

P: **P**ulse (0: absent; 1: less than 100 beats/min; 2: more than 100 beats/min)

G: **G**rimace (0: absent; 1: grimace or notable facial movement; 2: cough, sneezes, or pulls away)

A: **A**ctivity (0: absent; 1: some flexion of extremities; 2: active and spontaneous movements of limbs)
R: **R**espiration (0: absent; 1: slow and irregular; 2: good breathing with crying)
Note that if the baby requires resuscitation, waiting to do an Apgar score at 1 minute is not indicated.

The Apgar score can be calculated after delivery and resuscitation are complete.

Use of oxytocics

After every ED delivery, particularly deliveries that are precipitous or that occur in an out-of-hospital setting, the mother should be examined for the possibility of twins. Ongoing labour may be confused with postpartum cramping, only to have twin B and all the potential complications surprise the emergency clinician. This is particularly relevant for women with inadequate prenatal care and low-birth-weight infants.

Following the birth of the baby, when an antenatal ultrasound result is unavailable, palpate the mother's abdomen to exclude the possibility of a second foetus and administer an oxytocic agent if no such foetus is present.

Oxytocics aid in placental separation and reduce post-partum bleeding. The most common is oxytocin at a dose of 10 units given intramuscularly or 5 units intravenously as a slow bolus. An alternative is ergometrine in a dose of 250 μg intramuscularly or administered slowly intravenously. However, because this agent is associated with nausea, vomiting and hypertension, it is unsuitable for use in pre-eclampsia, eclampsia or hypertension. There is no significant advantage to the combination of oxytocin and ergometrine, and its use is associated with increased adverse effects relating to ergometrine.[4]

Third stage

The third stage of labour involves the delivery of the placenta and frequent checks of the tone and height of the uterine fundus. After administration of the oxytocic agent, look for signs of separation of the placenta from the uterine wall. Three classic signs of placental separation are (1) lengthening of the umbilical cord; (2) a gush of blood from the vagina, signifying separation of the placenta from the uterine wall; and (3) a change in the shape of the uterine fundus from discoid to globular, with elevation of the fundal height.

These signs usually occur within 5 to 10 minutes of the delivery of the infant but may extend to 30 minutes. Beyond 18 minutes, the risk of postpartum haemorrhage increases, and it is up to six times more likely after 30 minutes. Any attempt to deliver the placenta before it separates is contraindicated. Following separation and once the uterus is firmly contracted, apply controlled traction on the cord in a backward and downward direction with one hand while the other is placed suprapubically to support the uterus. Cease traction if the cord feels as though it were tearing.

Placental inspection

As the placenta appears at the introitus, traction is applied in an upward direction and the placenta is grasped and gently and rotated to ensure that the membranes are delivered without tearing. Examination of the umbilical cord and placenta is an essential part of the delivery process, and any abnormalities should be noted at this time.

Inspect the placenta and membranes to look for any missing segments or cotyledons, or evidence of a missing succenturiate 'accessory' lobe; these may prevent the uterus from contracting properly if they remain within the uterus.

The umbilical cord is normally a three-vessel structure, with two umbilical arteries on either side of the single umbilical vein.

Uterine tone

The first hour after delivery of the placenta is a critical period during which postpartum haemorrhage is most likely to occur. The uterus is evaluated frequently for tone and massaged trans-abdominally if any sign of relaxation exists.

Rub over the uterus to facilitate contraction and expulsion of clots. A common cause of postpartum haemorrhage is incomplete uterine contraction as a result of clots or tissue remaining within the cavity, which may be expelled by massaging the fundus or by manual removal under anaesthesia. Further oxytocics may be necessary.

Bleeding may also occur from other sites, so always perform a careful examination of the cervix, vagina, episiotomy wound and perineum following delivery. Full examination of the cervix for ongoing bleeding will require anaesthesia. The episiotomy wound and any other lacerations may be repaired using a continuous technique with a synthetic absorbable suture.

Observations

Observations taken following the birth of the baby should include the following:

- Maternal—temperature, pulse, blood pressure, uterine tone, lochia and fundal height
- Examination of placenta and membranes—assessment of their condition and structure, cord vessels and completeness
- Maternal emotional/psychological condition in response to labour and birth
- Successful bladder emptying

Newborn care

Keep the baby warm and dry and record the baby's vital signs, Apgar scores and weight. If vitamin K is available, administer it to the baby as a deep intramuscular 1-mg injection for prophylaxis of haemorrhagic disease of the newborn.

Disposition

Disposition of mother and baby to an obstetric unit either within the hospital or at a distant hospital should then be made once both are stable. The important information that should be provided includes the time of birth, drugs given to mother or baby, estimated maternal blood loss and the Apgar scores of the baby. Include the results of any blood tests and a copy of the observations. If either mother or baby is unstable, early consultation with the appropriate referral service is mandatory regarding the optimum timing and nature of the transfer.

Complications of delivery

Breech delivery

When a foetus is in a noncephalic or nonvertex presentation, it is considered a malpresentation.

Breech presentation refers to a foetus with the feet or buttocks presenting in the pelvic inlet; this is the most common type of malpresentation.

Breech presentation occurs in 3% to 4% of all deliveries, reducing in incidence with advancing gestation. It is associated with a morbidity rate three to four times greater than that of a normal cephalic delivery.

Breech presentation is more common with prematurity, as the final natural rotation in the pelvis may not have occurred. Therefore this and is associated with a greater incidence of foetal distress and umbilical cord prolapse. The most feared complication of a vaginal breech delivery is head entrapment, which can lead to foetal asphyxiation and death.[5]

In the normal cephalic presentation, the head maximally dilates the birth canal, allowing the rest of the body to descend unobstructed. However, with a breech presentation, the head emerges last and can become entrapped by incomplete cervical dilatation. Delivery of a breech presentation is often performed by caesarean section when available.

Circumstances such as precipitous delivery, lack of prenatal care, prematurity and the mother's preference for vaginal delivery can place an emergency medicine physician in the situation of managing a breech delivery. The following is relevant to the ED when vaginal delivery is imminent without obstetric backup or if the physician is concerned about foetal demise.

Management of breech delivery

Immediate obstetric expertise should be requested urgently while preparations are made for neonatal resuscitation. It is critical for the emergency physician to avoid manipulating the

foetus but rather to allow the delivery to occur spontaneously as far as possible.

Perform an episiotomy as the foetal anus is climbing the perineum. Allow maternal effort to deliver the baby spontaneously to the umbilicus, delivering the legs with knee flexion. Do not apply traction to the foetus, as this may cause foetal head extension, which leads to entrapment of the head and greatly increases the risk of asphyxiation.[6]

A loop of umbilical cord may be pulled down and allowed to hang. The mother is encouraged to bear down until the trunk becomes visible up to the scapula. Then rotate the trunk until the anterior shoulder delivers. Subsequent rotation of the trunk in the opposite direction results in delivery of the posterior shoulder.

Once the shoulders have been delivered, an assistant should provide downward pressure in the suprapubic area to keep the foetal head flexed while the assistant delivers the head either with the application of forceps or by placing the left hand into the vagina and pressing on the maxilla to cause further neck flexion while the other hand grasps a shoulder and applies firm traction in the line of the baby's hips, taking care not to extend the head. The combined neck flexion, traction on the foetus toward the hip/pelvis and the suprapubic pressure on the mother/uterus allows for delivery of the head of a breech infant (Mauriceau Smellie Veit manoeuvre).

Shoulder dystocia

Shoulder dystocia is a relatively uncommon and unpredictable obstetric emergency. From a clinical standpoint, a shoulder dystocia is most often diagnosed when the typical gentle downward traction on the foetal head that is used to deliver the anterior shoulder is unsuccessful in delivering the anterior shoulder under the pubic symphysis.

It is one of the more frightening complications of vaginal delivery and, while some at-risk patients may be identified, it is frequently unexpected. Estimates of its incidence are between 0.2% and 3.0%, depending on the exact definition used.[7] Important steps in management are recognizing the at-risk patient, calling for assistance early and understanding the manoeuvres to deliver the foetus. At-risk patients may have a large baby or gestational diabetes or be experiencing a precipitous birth.

One risk factor for shoulder dystocia that deserves attention is the mother's history of a shoulder dystocia, because recurrence rates are increased in a subsequent pregnancy, particularly when the foetus is of similar or greater size.

Investigators have attempted to determine whether, using known risk factors, shoulder dystocia can be accurately predicted. Their conclusion was that although a number of factors are associated with an increased risk of shoulder dystocia, none are of sufficient sensitivity or positive predictive value to allow their use clinically and thus to reliably and accurately identify the occurrence of shoulder dystocia.

Notably, the most relevant risk factor for an emergency physician performing emergency delivery is in fact a precipitous delivery—which is frequently the antecedent to the mother delivering in the ED in the first place. However, in many cases there are no predisposing factors.

Recognizing shoulder dystocia

As it is not possible to predict which deliveries will be complicated by shoulder dystocia, the emergency physician must be prepared for it.

Normally the shoulders negotiate the maternal pelvis in sequential fashion, anterior shoulder first. With shoulder dystocia, both shoulders attempt to clear the maternal pelvis simultaneously.

Following delivery of the foetal head, the anterior shoulder either does not deliver spontaneously or with gentle traction by the birthing assistant. Instead, the anterior shoulder becomes caught immediately above the symphysis. The first sign of shoulder dystocia is retraction of the foetal chin into the perineum, following the delivery of the head (the 'turtle sign').

In addition to the turtle sign, examination often reveals that the foetal shoulders are on a vertical axis rather than oblique. These findings, in combination with an arrested delivery, confirm the diagnosis of shoulder dystocia.

Delivery in less than 5 minutes is essential to prevent asphyxia as a consequence of compression of the umbilical cord, compression of the carotid vessels and potential premature separation of the placenta.

Adverse events with shoulder dystocia

Reported maternal complications related to shoulder dystocia have included third- or fourth-degree perineal lacerations, postpartum haemorrhage, vaginal or cervical lacerations, and symphyseal separation with lateral femoral cutaneous neuropathy.

Self-limiting neonatal complications include clavicular and humeral fracture, which occur in approximately 5% to 10% of shoulder dystocia cases. In addition, brachial plexus palsies resulting from lateral traction on the foetal head during delivery – predominantly of the Erb-Duchenne (C5 through C6) or the Klumpke (C8 through T1) type – occur in 10% to 20% of neonates born after a shoulder dystocia. Fortunately most of these neurological conditions resolve over time, with an estimated rate of persistence of 1% to 5%.

Other long-term neonatal complications that have been reported to occur, albeit infrequently, include permanent central neurologic injury and death.[8]

Treatment of shoulder dystocia

Once shoulder dystocia is recognized, either by a 'turtle' sign or the lack of delivery of the anterior shoulder after typical gentle downward traction on the foetal head, alleviating manoeuvres should be used.

An episiotomy may be considered if not already performed. Although an episiotomy is not a mandatory procedure, many operators may decide, given the individual circumstances, that an episiotomy will allow other manoeuvres to be accomplished more easily or effectively.

These manoeuvres include some combination of the McRoberts manoeuvre, suprapubic pressure, foetal rotation or delivery of the foetal posterior arm.

The McRoberts manoeuvre is generally recommended as the first technique and describes the exaggerated abduction and hyperflexion of the maternal thighs upon the abdomen. When a woman is placed in this position, the actual dimensions of the maternal pelvis are not changed; instead, the symphysis pubis is caudally rotated and the sacrum is flattened; these changes in pelvic orientation are believed to facilitate delivery.[7,8]

The addition of downward suprapubic pressure applied just proximal to the symphysis by an assistant—either continuously or in a rocking motion—is commonly used in association with the McRoberts manoeuvre. Suprapubic pressure adducts the shoulders and disimpacts the baby from the pubic symphysis into an oblique position. These two manoeuvres result in successful shoulder delivery in over 50% of episodes.

Additional manoeuvres include the Woods corkscrew and the Rubin II manoeuvres, which seek to rotate the shoulder girdle into a different orientation and free the anterior shoulder from under the symphysis pubis. Both these rotational manoeuvres require the physician's hands to be placed into the vagina and a large episiotomy.

Another type of alleviating action is the delivery of the posterior arm. To perform this manoeuvre, the clinician should apply pressure at the antecubital fossa to flex the foetal forearm and then sweep the arm across the foetal chest, with ultimate delivery of the arm over the perineum. After delivery of the arm, there is a 20% reduction in shoulder diameter, thereby allowing the dystocia to be relieved.

Further alternatives include placing the mother 'on all fours' in a hands and knees position, which can facilitate spontaneous delivery. The Zavanelli manoeuvre involves replacing the head in the birth canal and proceeding to immediate emergency caesarean section.

Postpartum haemorrhage

Postpartum haemorrhage (PPH) is the most common complication of labour and delivery, with primary PPH defined as excessive bleeding in the first 24 hours after birth. In an emergent situation, diagnosis generally occurs through estimation of blood volume loss and haemodynamic changes in response such as hypotension, tachycardia and oliguria.

PPH of more than 500 mL after vaginal delivery affects 5% to 10% of all deliveries and accounts for up to 25% of obstetric deaths.[4]

PPH is divided into two categories; the primary category includes blood loss that occurs within the first 24 hours and the secondary category is haemorrhage 24 hours to 6 weeks after delivery.

Other definitions of PPH include blood loss in excess of 500 mL after vaginal birth or more than 1000 mL after caesarean section. Severe PPH is blood loss greater than or equal to 1000 mL while a critical or major PPH is blood loss of greater than 2500 mL.[4]

The consequences of postpartum haemorrhage are related to the degree of blood loss and the timeliness of resuscitative measures. The uterus at full gestation receives 600 mL of blood per minute, placing the woman at risk for massive amounts of blood loss in a short time. Therefore this is a true obstetric emergency.

Pregnancy has a couple of advantages when compared with other clinical scenarios, both related to maternal age and pregnancy-related maternal adaptation; these include volume expansion. The average maternal age at delivery is 24 years, and occurs at a time in life when women are at their peak physiological condition.[4] Women at this age are typically healthy and do not have significant comorbidities.

Unlike other patient populations, women who are pregnant handle moderate amounts of haemorrhage well and usually recover unscathed. More importantly than this, the adaptation of blood volume to pregnancy confers a protective advantage against excessive blood loss that is unique.

This volume expansion begins at the end of the first trimester and results in a 50% increase in the blood volume, which leads to an additional 1000 to 1500 mL of circulating blood at the time of delivery. Considering that the average blood loss at vaginal delivery is 500 mL and at caesarean delivery is 1000 mL, most women have ample reserve at term for routine blood loss and moderate amounts of haemorrhage.

Bearing these facts in mind, it is important to remember that blood loss is frequently underestimated and PPH may be first detected by haemodynamic compromise. Once the patient shows signs of haemodynamic compromise, more than 1500 mL of blood volume may have been lost.

Table 19.7.2 Risk factors for PPH

Risk factors	*Aetiology*
Antenatal	
Increased maternal age—more than 35 years	Tone
Asian ethnicity	Tone/trauma
Obesity—body mass index (BMI) of more than 35	Tone
Grand multiparity—uncertain as mixed findings	Tone/tissue
Existing uterine abnormalities (e.g. anatomical anomalies, fibroids)	Tone
Maternal blood disorders: von Willebrand disease, idiopathic thrombocytopaenic purpura, thrombocytopaenia caused by pre-eclampsia/ gestational hypertension, disseminated intravascular coagulation (DIC)	Thrombin
History of previous postpartum haemorrhage or retained placenta	Tone/tissue
Anaemia of less than 9 g/dL at onset of labour	No reserve
Antepartum haemorrhage associated with suspected or proven placental abruption, known placenta praevia	Tissue/tone/ thrombin
Over-distension of the uterus: multiple pregnancy, polyhydramnios, macrosomia—greater than 4 kg	Tone
Intrauterine fetal death	Thrombin
Intrapartum	
Prolonged labour—first, second or third stage	Tone/tissue
Chorioamnionitis, pyrexia in labour (e.g. prolonged membrane rupture)	Tone/thrombin
Amniotic fluid embolism/DIC	Thrombin
Uterine inversion	Trauma/tone
Genital tract trauma (e.g. episiotomy, ruptured uterus)	Trauma
Postnatal	
Retained products (e.g. placenta, cotyledons or succenturiate lobe, membranes or clots)	Tissue
Amniotic fluid embolism/DIC	Thrombin
Drug-induced hypotonia (e.g. anaesthetic, magnesium sulphate)	Tone
Bladder distension preventing uterine contraction (e.g. obstructed Indwelling Catheter (IDC), unable to void)	Tone

(Modified from Queensland Maternity and Neonatal Clinical Guideline: PPH, with permission from the Queensland Maternity and Neonatal Clinical Guidelines Program).

The role of permissive hypotension in the maternity patient is uncertain because there is concern that it may compromise foetal well-being and uterine contractility in the postpartum period.

The common causes of PPH are referred to as the 'four Ts', which, in order of decreasing frequency, are as follows:

- Tone (70%)
  - atonic uterus
- Trauma (20%)
  - Laceration of the cervix, vagina and perineum
  - Uterine rupture or inversion
  - Non-genital tract trauma (e.g. subcapsular liver rupture)
- Tissue (10%)
  - Retained products, placental (cotyledons or succenturiate lobe), membranes or clots, abnormal placenta
- Thrombin (<1%)
  - Coagulation abnormalities

Management of postpartum haemorrhage

Prevention is essential by identifying the at-risk patient (Table 19.7.2). The aggressive use of oxytocin along with active management of the third stage of labour are important. These measures reduce the incidence of PPH by 40%. The initial response to PPH requires a multidisciplinary team approach to restore the woman's haemodynamic state while simultaneously identifying and treating the cause of bleeding.

The first key to management of PPH is to recognize its occurrence in a timely fashion. Bleeding often begins at the time of placental separation, and although it can be brisk and obvious, it is sometimes more subtle and can be steady and relentless. In the face of other bodily fluids associated with delivery, including amniotic fluid and urine, the amount of blood loss is often underestimated.[9]

It is important to factor in blood-loss volumes in blood-soaked linen and dressings. The steady bleeding seen initially may appear moderate but can persist until serious hypovolemia has occurred. Further complicating this is the failure of the pulse and blood pressure to change significantly until large amounts of blood have been lost. Once PPH has been identified, resuscitative measures should be quickly taken, including obtaining intravenous access with two large-bore intravenous lines for rapid infusion of crystalloid and blood, placement of a Foley catheter to monitor urine output, and an effort made to identify the cause (i.e. uterine atony, genital laceration, or other diagnoses). Surgical and anaesthesia teams should be mobilized as needed.

Blood should be taken for measurement of haematocrit, electrolytes, renal and hepatic function, coagulation testing, fibrinogen levels and blood cross-matching.

Intravenous crystalloid up to 1 to 2 L may be used initially and will be effective in mild cases of haemorrhage. Colloid fluids may also be used but have no demonstrable advantage over crystalloids. Very brisk haemorrhage or significant haemodynamic compromise should prompt consideration of the early use of blood rather than repeated doses of crystalloid. If bleeding or haemodynamic instability is ongoing following up to 2 L of intravenous crystalloid, blood should be given. O-negative blood may be required initially, followed by group-specific or fully cross-matched blood. Fresh frozen plasma (FFP), platelets and cryoprecipitate may all be indicated in severe PPH, with initiation of the department's massive transfusion protocol (MTP).

The purpose of the MTP is to trigger a multidisciplinary response to critical bleeding. Transfusion support must occur simultaneously with measures to arrest bleeding. Obstetric haemorrhage is often underestimated and may be concealed by delays in recognition and response, thus contributing to the severity of haemorrhage and to maternal morbidity and mortality. Profound coagulopathy and DIC may develop rapidly and early.

Currently there is no evidence or consensus to guide the optimal ratio of blood component replacement in obstetric haemorrhage; the usual practice is to use similar ratios as for trauma.[10]

The Queensland Maternity Clinical Guidelines for Management of Primary Postpartum Haemorrhage[4] advocate the use of a massive haemorrhage protocol in situations where there is

- Active bleeding and the use of four units of red blood cells (RBCs) within 4 hours plus haemodynamic instability
- Estimated blood loss greater than 2.5 L
- Clinical or laboratory signs of coagulopathy

The massive haemorrhage protocol incorporates early administration of intravenous tranexamic acid (1 g IV over 10 minutes), multiple units of RBCs and the use of other products. FFP is given to correct coagulopathy (target international normalized ratio [INR] <1.5), platelets to keep platelet count above 50 × 10^9/L, and fibrinogen concentrate or cryoprecipitate to maintain serum fibrinogen above 2.5 g/L.

Tranexamic acid may be beneficial in reducing the risk of death due to post-partum haemorrhage. Recombinant activated factor VII may also be used, although generally after discussion with a haematologist. There is no evidence to suggest that dose and timing of rFVIIa in the critically bleeding maternity patient should differ from that of standard massive haemorrhage protocols.[10]

Before massaging the fundus, ensure that the placenta has been delivered and is complete. An adherent or incomplete placenta in the setting of PPH may necessitate transfer to the operating suite for operative removal. If the placenta is delivered and complete, check that third-stage oxytocin has been given and massage the uterine fundus to promote contraction. Expel any uterine blood clots and make sure that the bladder is empty.

Make sure that a careful inspection of the vagina, cervix and perineum has been made to confirm or exclude genital trauma as a cause of ongoing bleeding. Clamp obvious arterial vessels and repair lacerations. Transfer to an operating suite may be necessary to allow a full inspection of the vagina, cervix and uterus and effective repair. Suspect uterine rupture in a patient with severe abdominal pain.

Uterine atony

Accounting for approximately 70% of cases, the most common cause of serious immediate postpartum haemorrhage is laxity of the uterus after delivery. Normally, postpartum bleeding from the placental implantation site is limited by contraction of the myometrium, constricting the spiral arteries. If the uterus does not contract, ongoing haemorrhage will occur.

On examination, the uterus is palpable as a soft boggy mass. The treatment of uterine atony is usually medical and consists of administration of oxytocin and/or prostaglandin derivatives. In addition, bimanual compression is performed, a relatively easy technique that controls most uterine haemorrhage. In this technique, the posterior aspect of the uterine fundus is massaged through the abdomen while the anterior wall of the uterus is massaged through the vagina with the other hand. This should be done while medical treatment is being given.

Give five units of oxytocin IV over 1 to 2 minutes followed by an infusion of 5 to 10 IU/h (30 units of oxytocin in 500 mL of 0.9% saline at 83–167 mL/h). Other drugs used for uterine atony include misoprostol 800 to 1000 µg PR and/or ergometrine 250 µg by the intravenous or intramuscular route.

Second-line drugs, such as PGF_2-α 250 µg IM or intramyometrially may be used up to a maximum of 2 mg, which is successful in 60% to 85% cases of refractory uterine atony. Side effects include nausea, vomiting, diarrhoea, pyrexia, hypertension and bronchoconstriction. Its use is therefore contraindicated in women with asthma and hypertension.

Persisting uterine atony necessitates immediate transfer to theatre to identify and remove retained products; whilst also employing bimanual uterine compression as a temporizing measure.

Additional measures in the operating theatre include the use of a Bakri balloon—a 24-Fr 54- cm silicone catheter with a filling capacity of 500 mL, which acts as an intra-uterine balloon tamponade.

Coagulopathy

Coagulopathies must be considered and should be specifically looked for with testing and managed with products as described earlier.

All women with severe PPH should be evaluated for disseminated intravascular coagulation (DIC). DIC can occur as a consequence of placental abruption, eclampsia, amniotic fluid embolism, postpartum infections, and dilution of clotting factors caused by aggressive volume resuscitation.

Other surgical causes

Continuing severe PPH and haemodynamic instability after management of all of reversible causes requires urgent surgery with possible laparotomy. Causes include uterine rupture or inversion and persistent atony, or causes such as subcapsular liver rupture or amniotic fluid embolism. Surgical procedures for intractable bleeding include placement of B-Lynch compression sutures to the uterus, bilateral uterine artery ligation, angiographic embolization of bleeding vessels and hysterectomy.

NEONATAL RESUSCITATION

Approximately 10% of infants require some assistance to begin breathing at birth, although less than 1% require extensive resuscitation. Of those requiring some assistance, the majority simply

require basic manoeuvres, such as stimulation, airway positioning and transient mask ventilation. Few require intubation and ventilation, and the need for chest compressions and medications is uncommon.[11]

The need for resuscitation may be completely unexpected; therefore prior preparation to manage a newborn requiring resuscitation is essential. This includes suitable equipment and training and an appropriate location to conduct resuscitation. Early contact should be made with the neonatal or paediatric team to plan for transfer or retrieval if necessary.

Neonates in need of resuscitation

The need for resuscitation in the newborn is more likely in circumstances such as preterm birth, absent or minimal antenatal care, maternal illness, complicated or prolonged delivery, antepartum haemorrhage, multiple births, previous neonatal death and a precipitate birth. This suggests that all ED deliveries should be treated as possibly of high risk, with appropriate preparations made to provide neonatal resuscitation.

Assessment and resuscitation of the newborn

The initial assessment should focus on tone, breathing and heart rate; subsequent assessment during resuscitation is based on the infant's heart rate, breathing, tone and oxygenation. The Australian Resuscitation Council Neonatal Resuscitation Flowchart illustrates the assessment and resuscitation of a newborn baby (Fig. 19.7.1).

Infants who are born at term, have had low or no risk factors for needing resuscitation, are breathing or crying and have good tone should be dried and kept warm. These actions can be provided on the mother's chest and do not require separation of mother and baby. Poor tone and minimal response should be managed with brisk but gentle drying with a soft towel to stimulate the infant to breathe.

Oxygenation

Oxygenation is assessed using pulse oximetry, noting that the healthy term newborn takes up to 10 minutes to achieve oxygen saturations of 85% to 90%. Although insufficient oxygenation can impair organ function or cause permanent injury, there is increasing evidence that even brief exposure to excessive oxygenation is harmful to the newborn during and after resuscitation. Emergency physicians should recognize this aspect of a newborn's normal respiratory physiology and not provide high-dose oxygen in an attempt to attain unnecessarily high oxygen saturations. A guide to expected oxygenation saturations in the first 10 minutes after birth is listed on the Australian Resuscitation Council Neonatal Resuscitation Flowchart (see Fig. 19.7.1).

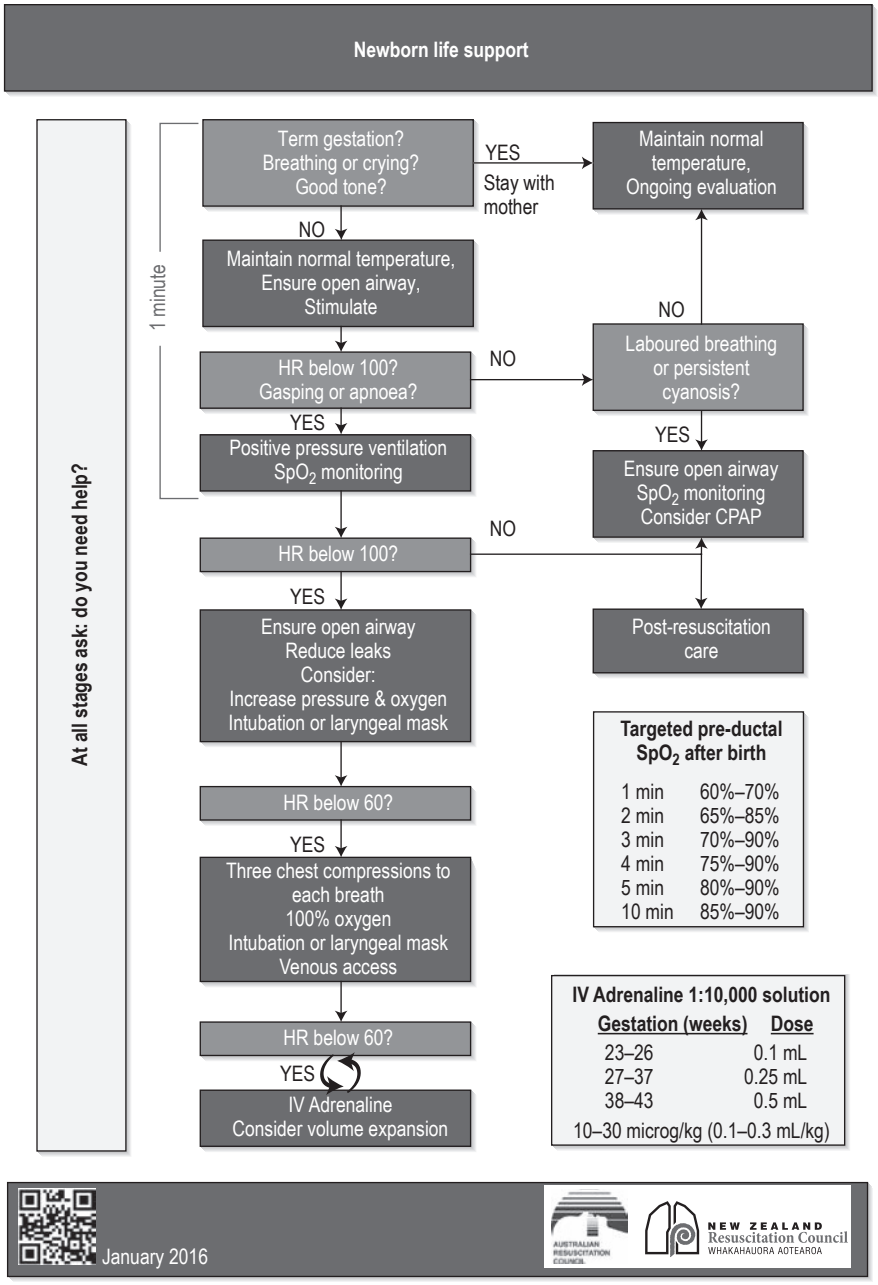

FIG. 19.7.1 Neonatal resuscitation flowchart. (From the Australian Resuscitation Council ANZCOR Neonatal Guidelines.)

Air should be given initially for ventilation of the term infant while pulse oximetry is commenced. Supplemental oxygen delivered by a blender with air is used when the infant's oxygen saturations do not reach the lower end of the target saturations despite effective ventilation. Increased concentrations of oxygen should be used if the infant's heart rate fails to increase or oxygenation as measured by oximetry remains lower than expected.

Attempting to increase the oxygen saturation over 90% in a newborn is potentially harmful. In all cases, the first priority is to ensure adequate inflation of the lungs followed by increasing the concentration of inspired oxygen only if needed.

Positive-pressure ventilation

If the infant remains apnoeic or its breathing is inadequate, positive-pressure ventilation is started using a self-inflating bag, T-piece device or a flow-inflating bag via a face mask or even an endotracheal tube. Persistent apnoea, particularly associated with hypotonia and a heart rate below

100 beats per minute, is an ominous sign. The main measure of effectiveness of ventilation is a prompt and sustained improvement in heart rate. This can be determined by listening to the heart with a stethoscope or initially by feeling for pulsations at the base of the umbilical cord. It should be consistently above 100 beats per minute within 1 minute of birth in a non-compromised infant. Rates below 100 beats per minute are managed with ventilation, whereas a rate below 60 per minute requires both positive-pressure ventilation and chest compressions.

There are few indications for intubation and ventilation in the newborn population. If adequate ventilation is being obtained with a bag and mask, intubation is generally not needed.

Endotracheal tube (ETT) internal diameter in millimetres can be calculated as gestational age in weeks divided by 10. Typically a 2.5-mm tube is appropriate for infants weighing less than 1 kg; a 3.0-mm tube is suitable for infants weighing 1 to 2 kg; a 3.0-mm tube is used for infants weighing 1 to 2 kg; a 3.5-mm tube is used for infants weighing 2 to 3 kg; and a 3.5- or 4.0-mm tube is used for infants weighing more than 3 kg.

Newborn intubation is generally performed using uncuffed tubes, but the use of a 3.5- or 4.0-mm cuffed tube is acceptable for larger babies.

Chest compressions

The preferred technique for chest compression is an 'encircling technique' with two thumbs on the lower third of the sternum, with the fingers surrounding the thorax to support the back. A chest compression should be performed each half second with a half-second pause after each third compression to deliver a breath, resulting in a 3:1 ratio with a total of 90 compressions and 30 breaths per minute.[11]

Once chest compressions have been commenced, they should be performed with as little interruption as possible. Do not stop unless assessment is needed to make treatment decisions. Signs of improvement in spontaneous cardiac output may include improvement in spontaneous heart rate, a rise in oxygen saturation, and commencement of some spontaneous movement or breaths. Chest compressions should continue until it is obvious that the heart rate is greater than 60 per minute.

As soon as a decision has been made to perform chest compressions, preparation should commence to establish vascular access and administer intravenous adrenaline.[11]

Adrenaline

Medications and fluids are rarely indicated for the resuscitation of newborn infants. Bradycardia is usually caused by hypoxia and inadequate ventilation. Apnoea is due to insufficient oxygenation of the brain stem. Therefore establishing adequate ventilation is the most important step to improve the heart rate. However, if the heart rate remains below 60 per minute despite adequate ventilation (the chest is seen to move with inflations) and chest compressions, adrenaline (epinephrine) may be needed. Because this will exert part of its effect by action on the heart, it is important to give it as close to the heart as possible. An umbilical vein catheter is the most rapidly accessible intravascular route for adrenaline (epinephrine) and it can also be used for fluid administration.

Ventilation and chest compressions must be delivered continuously during preparation to administer intravenous medication or fluids.[11]

Adrenaline is recommended if the heart rate remains below 60 beats per minute despite effective ventilation and chest compressions. The recommended intravenous adrenaline dose is 10 to 30 µg/kg (0.1–0.3 mL/kg of a 1:10 000 adrenaline solution) followed by a small saline flush. This dose is repeated if the heart rate remains below 60 beats per minute despite effective ventilation and cardiac compressions. Higher doses of adrenaline are not recommended.

The preferred route of administration of adrenaline is via the umbilical vein through an umbilical catheter.

If umbilical catheters are not available, a nasogastric feeding tube (size 6) or an 18-gauge cannula without a needle are suitable alternatives. In circumstances where umbilical vein catheterization fails, intraosseous access or peripheral vein access are valid alternatives; however, these are more technically challenging in the newborn.

There is little research to support the use of endotracheal adrenaline and there are concerns that even in higher doses it may still result in lower levels of adrenaline than if it were delivered via the intravenous route. If vascular access cannot be obtained, endotracheal adrenaline (epinephrine) may be considered. If the endotracheal dose fails to increase heart rate to more than 60 beats per minute, an intravascular dose should be given as soon as feasible.

If the endotracheal route is used, a dose of 50 to 100 µg/kg (0.5 to 1 mL/kg of a 1:10 000 solution) is recommended.

Intravenous fluids

Consider intravenous fluids when there is suspected blood loss and/or the infant appears shocked (pale, with poor perfusion and a weak pulse) and has not responded adequately to the other resuscitative measures already outlined. Isotonic crystalloid (e.g. 0.9% sodium chloride or Hartmann's solution) should be used in the first instance, but in the setting of critical blood loss, this may have to be followed with red cells and other blood products suitable for emergency transfusion.

The initial dose is 10 mL/kg given by intravenous push. This dose may be repeated after observation of the response.

Naloxone

Naloxone is not used routinely as part of the initial resuscitation of newborns with respiratory depression in the delivery room. It may be considered in continuing respiratory depression following restoration of heart rate and colour by standard resuscitation methods if it is thought that this may be secondary maternal opioid medications—especially if administered within the previous 4 hours. The current recommended dose of naloxone is 0.2 mg given intramuscularly in a full-term baby. Smaller doses of 10 µg/kg given intravenously will also reverse opioid sedation, but the effect will last only a short time compared with the larger intramuscular dose.[2]

Meconium-stained liquor

Meconium-stained liquor (light-green tinge) is relatively common, occurring in up to 10% of births. Notwithstanding this, meconium aspiration is a rare event and has usually occurred in utero before delivery. Suctioning the infant's mouth and pharynx before delivery of the shoulders makes no difference to the outcomes of babies with meconium-stained liquor and is not recommended. Similarly, routine endotracheal intubation and endotracheal suctioning of babies with meconium-stained liquor who are vigorous (breathing or crying, good muscle tone) is discouraged, as it does not alter the outcome and may cause harm.

In the non-vigorous baby with depressed vital signs, the emphasis should be on initiating respiration rather than on clearance of meconium. In a non-vigorous infant and the presence of thick meconium with the potential to block the airway, endotracheal intubation and suction of meconium may serve to clear the airway and allow respiration or ventilation, but it should not delay the initiation of ventilation. If the endotracheal tube is then removed there is no need to repeat this intervention and efforts should then be directed to establishing respirations.

Blood glucose and temperature must be checked in any baby undergoing resuscitative measures. Neonatal hypoglycaemia (Blood Sugar Level (BSL) <2.6 mmol/L) may be corrected by the administration of a bolus of 2.0 mL/kg of 10% glucose solution. Although it is important to avoid hypothermia in newborns by employing a radiant heat source, drying the baby and

wrapping in a warm, dry towel or blanket with the head covered, ideally by a hat or beanie, is also important.

Neonatal transfer

Neonates requiring resuscitation following emergency delivery will have to be referred to a regional or tertiary neonatal unit for ongoing care. Transfer of these babies requires careful communication and coordination between the two centres, with transport usually undertaken by a specialized neonatal transport team.

SECTION 20 PSYCHIATRIC EMERGENCIES

Edited by *Biswadev Mitra*

20.1 Mental state assessment

Blair Hobbs

ESSENTIALS

1 **The number of patients presenting to the emergency department (ED) with mental health problems is increasing.**

2 **Regardless of diagnosis and presentation, an initial assessment must be performed within the first few minutes of an individual's arrival in the ED, taking into account the risk of**

- **Suicide and self-harm**
- **Violence or other forms of assault**
- **Absconding**

3 **The role of organic illness presenting as a mental disorder should not be forgotten.**

4 **Substance use/misuse resulting in presentations to EDs appears to be increasing.**

Epidemiology

Mental health disorders are among the three leading causes of total burden of disease and injury in Australia, alongside cancer and cardiovascular disease.[1,2] These mental issues are among leading causes of non-fatal disease burden in the Australian population. Mental health disorders are highly prevalent, with 4 million Australians estimated to have experienced a common mental disorder in 2015. Mental illness can be disabling and costly in both human and socioeconomic terms.[1,3]

In terms of disability, it has been estimated that having a major depressive disorder is the equivalent of having congestive cardiac failure or chronic severe asthma. The prevalence of this is projected to increase significantly over the next decade.[3]

Suicide is the third overall leading cause of death for men across all age groups.[2] The prevalence of suicide is approximately 16 for every 100,000 men and approximately and 5 per 100,000 women. The highest rate of suicide occurs in men over the age of 85 years (37.6 per 100,000). A significant proportion of people who commit suicide have had contact with a health provider in the preceding 12 months, often in an ED.[4]

Over the 8 years to 2014, ED presentations rose 14.8% in the United States, whereas mental health presentations for the same time period rose 44%, contributing significantly to ED overcrowding.[5] This trend has been mirrored in Australia.

Contributing to this may be the following:

- Lack of private health insurance
- Rising substance use
- Lack of social supports including suitable housing
- Lack of alternatives to care
- Round-the-clock accessibility of the ED[5]

The Australian Institute of Health and Welfare report into Mental Health Services 2016-17 revealed 276,954 presentations to Australian EDs in which the primary problem was thought to be a mental health disorder.[3] A little under 4% of Australian public hospital ED presentations are due to a mental health complaint, correlating well with other studies and US figures, which estimate that 2% to 6% of emergency medicine presentations are primarily due to mental health disorders, although this figure is likely to underrepresent the overall number of people presenting to an ED with a mental health problem.[3-6]

Two-thirds of these people are between the ages of 15 and 44 years (compared with 42% for the general population presenting to a suburban ED); 29% have anxiety and neurotic disorders; 21% mental and behavioural disorders due to psychoactive substance abuse; 19% mood disorders and 17% schizophrenia or delusional disorders.[5] It is estimated that 17.7% of adult Australians admitted to hospital report a mental health issue in the previous 12 months. An estimated 0.4% to 0.7% of the adult population suffer from a psychotic episode in any given year.[1-2]

Mental health issues are highly prevalent and relevant to the work of emergency clinicians. In many cases, these patients' mental illness goes unrecognized, or they may present with an active medical condition and a mental health diagnosis may not be recorded by hospital data collection methods.[6]

Introduction to the mental state examination

It is common for emergency department staff to report a lack of confidence and skill dealing with a population of patients unfamiliar to them.[7-9] Recent Australian studies have shown ED clinicians are most concerned about knowledge gaps in risk assessment, particularly related to self-harm, violence and aggression, and distinguishing psychiatric from physical illness.[9] ED clinicians routinely report the need for more education on mental health–related presentations.[10-11] A high proportion of mental health–related presentations to EDs involve drug and alcohol intoxication. This may complicate the assessment and treatment of mental health problems, often lengthening the stay of these patients within the ED and delaying their disposition.[5-7]

There is a risk of mental health patients being assigned to lower triage categories and experiencing longer waits to be seen by staff than mainstream patients, and there is more variation in triage categorization for mental health patients.[11] With this in mind, there has been much work over recent years to improve the quality of care and experience for people presenting to an ED with a mental health problem.[12]

Bias, Stigma and Discrimination

People with mental illness experience discrimination and difficulties accessing necessary treatment. An interviewer needs to be aware of their own values and beliefs and how this may influence a mental state assessment. If a health professional notices their decision-making is affected by a negative attitude toward the patient, they should seek assistance from a senior colleague. (Box 20.1.1).

ABCs of the mental state examination

At the point of triage, initial risk assessment should be conducted to identify any imminent and/or life-threatening risks to the patient or staff. The triage nurse and treating doctor should obtain a brief collateral history from emergency services and/or significant others and devise an initial treatment plan in order to ensure the safety of the patient, staff and others in the ED. Regardless of risk or patient behaviour, all assessments and interventions should balance the safety of patient and staff with respect and dignity.[13-15]

The ABC of Mental Health Assessment is based on[13]:

- **A**ppearance, affect and mood
- **B**ehaviour
- **C**ommunication, conversation and cognition

If the situation is relatively controlled, the formal mental health assessment should then take place. Further information is gathered from community-based resources such as a general practitioner. A provisional assessment and management plan is developed in conjunction with the mental health team and appropriate disposition is arranged (Fig. 20.1.1).

Box 20.1.1 Factors that may drive bias and discrimination

- Religious beliefs
- Race/ethnicity/cultural beliefs and practices
- Political opinion
- Philosophical beliefs
- Sexual preference or orientation
- Intellectual disability
- Drug and alcohol use

Triage

The Mental Health Triage Scale (Table 20.1.1) has been developed and modified to be included in the Australian Triage Scale (ATS).[13-15] It provides symptom and behavioural descriptors for the triage nurse to determine the level of risk or urgency required to manage risks such as suicide and self-harm, violence and absconding. It is also important for the triage nurse to determine whether the patient is intoxicated, as this is a significant contributing risk factor. From this, the triage nurse determines the ATS category, urgency of initial treatment and most appropriate clinical area for the patient to receive further treatment. Having timely access to the patient's clinical file with reference to previous psychiatric history, risk and past behaviours is also helpful. The local mental health service may be able to provide further information or tell you whether the patient is known to them.

Many hospital EDs have developed a triage risk-assessment form or screening tool. For ease of use, many of these have included 'tick box' areas designed to identify risk factors for dangerous behaviour. A compilation of multiple assessment tools used throughout Australia is shown in Boxes 20.1.2 to 20.1.4.[7,13-15]

It is recommended that any patient who presents as a high or imminent risk be seen in a timely manner. Some EDs have teams specifically assigned to respond to high-risk behavioural disturbance in a co-ordinated and standardized manner. These teams may include a mental health clinician, security or police, depending on the resources available to the hospital. As a last resort, the use of sedation or restraint may be required and used according to legislation and local policy. A collaborative approach to assessment and treatment by ED and mental health clinicians will help to ensure a streamlined and safe pathway of care through an often chaotic and congested department.

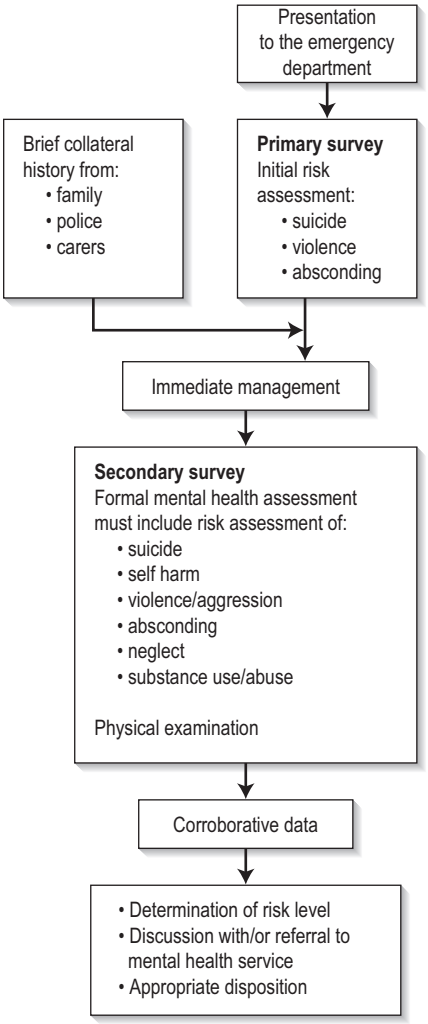

FIG. 20.1.1 The mental health assessment process.

Aims of the mental health assessment

The aims of the formal mental health assessment are to determine the following:

- Does the patient have a mental illness?
- Is there a question of safety for the patient or for others?

Table 20.1.1 The mental health triage scale

ATS 2	Patient is violent, aggressive or suicidal or is a danger to self or others Requires police escort/restraint
ATS 3	Very distressed or acutely psychotic Likely to become aggressive May be a danger to self or others
ATS 4	Long-standing or semi-urgent mental health problem and/or has supporting agency/escort present
ATS 5	Patient has a long-standing non-acute mental health disorder but has no support agency Many require referral to an appropriate community resource

Box 20.1.2 Brief screening suicide risk template

Mental state
☑ Active disease
☑ Psychosis
☑ Hopelessness/despair/guilt/shame
☑ Anger/agitation
☑ Impulsivity

Suicide attempts/thoughts
☑ Continual/specific thoughts
☑ Formulated plan
☑ Intent
☑ Past history of attempt with high lethality
☑ Means
☑ Suicide note
☑ Risk of being found
☑ Organizing personal affairs

Substance abuse
☑ Current misuse

Supports
☑ Lack of or hostile relationships

Loss
☑ Recent major loss (even perceived): significant relationship, job, housing, financial difficulties, independence
☑ Recent/new diagnosis of major illness or chronic illness

Patients then stratified into high, medium or low risk

Box 20.1.3 Aggression risk tool

☑ Alert on chart
☑ Previous history of violence/threatening behaviour, verbal or physical
☑ Aggressive behaviour/thoughts
☑ Homicidal ideation
☑ Use of weapons previously
☑ Access to weapons
☑ Intoxicated

Patients then stratified into high, medium or low risk

Box 20.1.4 Risk of absconding

Mode of arrival
☑ Police
☑ Handcuffed
☑ Family/carer coercion
☑ Voluntary
☑ Past history of absconding behaviour
☑ Alert on chart
☑ Verbalizing intent to leave
☑ Lack of insight into illness
☑ Poor/non-compliance with medication

Patients then stratified into high, medium or low risk

- What is the patient's view of his or her health problem or illness?
- What is the patient's view of treatment and how willing is he or she to cooperate?
- Can the treatment be provided in the community or is hospitalization required?

The formal psychiatric interview

Introduction

The central components to a psychiatric assessment are the patient history and the mental state examination (MSE).

Taking a patient's history requires gathering all the relevant details pertaining to the patient's current presentation to the ED and doing this succinctly. Obtaining a history enables the clinician to identify what the problem is; the nature, duration and severity of any symptoms; and what has precipitated the presentation to the ED at this time. While taking a history, it is imperative to observe and listen, demonstrating empathy, establishing rapport and endeavouring to develop a collaborative approach to treatment. Using skills of observation, listening and enquiry, the clinician can construct an MSE in order to identify possible diagnoses and risks. By identifying the main problem or problems and themes in the first few minutes of the interview, the ED clinician can identify the possible diagnosis and then focus the questioning on exploring this further.

The environment in which the MSE is conducted is an important consideration. Behaviourally disturbed people are often fearful and overwhelmed; they may find the highly stimulating environment of an ED to be threatening. The interview space should be quiet and private, making the patient feel safe, and the interviewer should avoid interruptions as much as possible. These prerequisites are difficult to attain in an increasingly busy ED. Wherever appropriate, the interviewer should sit at the same level as the patient, although depending on the context or level of risk, standing may be reasonable. The interviewer must demonstrate respect, genuineness and empathy. His or her voice should be quiet and calming, especially when seeking to calm the hyper-aroused patient. The interviewer should use non-judgmental language and open-ended questions.[13,16] It is important that the interviewer also feel safe and secure. If any risk is felt, the interviewer should have security or police present in the room or just outside. The interviewer may ask to have the patient searched for items of potential risk, according to legislation and hospital policy; this may include weapons or medications that the patient is at risk of ingesting. The interviewer should also note the nearest duress alarm and may choose to wear a personal alarm if available. The interviewer should sit within easy access of an exit and should never be boxed into a corner. If the interviewer begins to feel uncomfortable, there is always the option of leaving and returning to complete the assessment at a later stage. All threats, attempts and gestures suggestive of violence should be treated seriously.

Aspects of the interview: direct questioning

Basic demographic information

The formal interview aims to identify a diagnosis and the necessary treatment for that diagnosis. Traditionally, patient care has been problem-based and centred on the alleviation of distressing symptoms and returning patients to baseline functioning. In recent years there has been a shift in focus from paternal models of care that are historically risk-averse and bio-medically directed to a recovery-orientated approach to care. A recovery focus has been adopted in policy at hospital, state and national levels. Recovery promotes the self-advocacy and empowerment of patients to make decisions about their treatment. Clinicians should have a collaborative discussion with each patient to identify the goals of his or her treatment and desired health outcome. In some cases advanced care directives or statements will have to be considered in treatment decisions.

It is wise to establish rapport with the patient with a personal introduction and an explanation of the purpose of the interview. The interviewer can begin by asking a series of non-threatening questions, for example, regarding demographics. This information is often required, as many mental health services rely on a patient's residential location to determine follow-up services.

These questions help by building a profile of lifestyle, relationships and thought processes. Likelihood of success or failure of particular treatment modalities may be assisted by knowledge of previous hospital admissions, both general hospital and mental health (Box 20.1.5).

The process of MH assessment differs slightly from that of a general medical assessment. In a MH assessment, as well as noting the content of responses, the interviewer also assesses how thoughts are processed and what meaning they may have. The interviewer attempts to interpret the patient's thought patterns to help formulate a diagnosis and understanding of the patient's experience.

Presenting complaint

The patient is asked to recall the sequence of events leading to presentation to the ED. The interviewer should explore the circumstances of the behaviour, reasons for it, degree of planning or impulsivity and its context. Were drugs and alcohol involved? Was there a recent precipitating event? It is often useful to get the patient to recall the previous 48 to 72 hours leading up to the event.[17]

This usually leads to questioning regarding current difficulties. The interviewer should explore the nature of current problems. There may be financial

Alcohol
Drug use
Tobacco use
Gambling

or legal problems, isolation, bereavement, impending or actual loss, or diagnosis of major illness. Have there been any recent changes and who are the patient's usual support people? An exploration of significant relationships is important, along with the depth and duration of these relationships. It is useful to gain an understanding of the patient's usual coping methods and personality style.

Mood and affect

There should be formal questioning regarding the patient's mood (inner feelings) and whether it is in keeping with affect (outer expression). The mood may be incongruent with affect, swing wildly between extremes (labile) or be inappropriate.

Mood is assessed by asking the patient to subjectively describe it (e.g. sad, happy, angry); and it may be helpful to obtain a subjective rating out of ten. Mood can also be objectively assessed by asking about the patient's ability to cope with activities of daily living, such as eating, weight loss or gain, sleep (early morning wakening or trouble getting to sleep) and general hygiene. The patient's ability to concentrate may also diminish with increasing mood disturbance, reflected by the ability to perform usual activities.

This may lead to direct questioning regarding future outlook and thoughts of suicide. It is important to be direct in asking the patient about suicide and whether there is a formulated plan to accomplish this. A well thought out plan with clear means of carrying it out requires further exploration and intervention by a mental health professional.

Delusions and hallucinations

Delusions and hallucinations are features of psychotic disorders. The patient may be reluctant to disclose intimate thoughts and beliefs to the interviewer, especially if he or she is suspicious or mistrustful owing to a psychotic illness.

Hallucinations may be auditory, visual, tactile, olfactory, somatic or gustatory. The context in which they occur should be explored. Visual and tactile hallucinations are more commonly associated with organic pathology or drug-related presentations. Auditory hallucinations are common in chronic forms of psychosis, such as schizophrenia. Hypnagogic (occurring just before sleep) and hypnopompic (occurring on wakening) hallucinations are more benign than others. Common hallucinatory or delusional themes are persecutory, paranoid, religious, grandiose, controlling, somatizing and suicidal.

Insight and judgement

Insight involves the person's view and understanding of what is happening and why. This may include the following:
- Denial of illness
- Awareness of being sick and needing help but denying it at the same time
- Awareness of being sick but blaming it on external factors
- Awareness that illness is due to something unknown within the patient
- Intellectual insight: understanding of illness but reluctance to apply this to personal circumstances
- Insightful: good awareness of motives and feelings, illness, treatment and implications of decisions

It is important to gain an understanding of the patient's attitudes, views and motives in relation to his or her illness and proposed treatment. This will help to determine appropriate treatment and management, level of supervision required and the likelihood of adherence with treatment.

Aspects of the interview: observation

Key elements

Undertaking an MSE relies on the interviewer actively observing the patient's behaviour and conversation and interpreting his or her thoughts and comments. A summary is given in Box 20.1.6.

There are a multitude of acronyms for remembering the various elements of the MSE. Listed here are two.

The ABCs of the MSE[14]:
- Appearance
- Affect and mood
- Behaviour
- Conversation and communication

GFCMA – 'Got four clients on Monday afternoon'[16]:
- General appearance
- Form of thought
- Content of thought

Box 20.1.6 Overview of mental state examination

General description:
- appearance
- behaviour
- attitudes

Mood and affect:
- mood
- affect
- appropriateness

motivation/energy
appetite
sleep

Speech:
- rate
- volume
- tone

Perception:
- hallucinations

Thought process:
- form fluency, organised or disorganised

Thought content:
- delusions
- suicidal or homicidal ideas
- hopeless/helpless/guilty

Cognition:
- consciousness
- orientation
- memory
- attention
- insight and judgement

- Mood and affect
- Attitude

Appearance, attitude and behaviour

This considers the patient's ability to care for himself or herself. Box 20.1.7 lists features that may require particular attention. Attitude is important, as it may indicate how cooperative a person will be with care and treatment. Abnormal posturing and unusual or repetitive behaviours should be noted. These may indicate increasing thought disturbance. With increasing aggression and agitation, there may be motor restlessness, pacing and hand wringing. Tension may escalate rapidly and steps should be taken early to defuse the situation.

The interviewer should note the rate, volume and rhythmicity of speech. This can range from being completely mute through monosyllabic answers to rapid, loud speech indicative of pressure of speech. The tone, inflection, content and structure of speech should be noted. The interviewer should determine if the speech is fluent, if the thoughts behind it are logical and whether it flows appropriately for the situation.

Box 20.1.7 Appearance, attitude and behaviour

General:
- clothing
- application
- appropriate for climate?

Cleanliness:
- general grooming (hair, nails)
- tattoos, track marks on arms

Eye contact:
- intense stare
- avoids direct gaze
- decreases with increasing anxiety

Facial expression:
- variation in facial expression, voice, use of hands and body movements

Reaction to interviewer:
- aggressive, submissive, cooperative, guarded, evasive, passive or hostile

Motor:
- restless
- repetitive behaviour (e.g. rocking, hand wringing)
- tremor
- posturing
- tics
- tardive dyskinesia

Speech:
- rate, volume and rhythm
- mute
- poverty of speech (slow, monosyllabic responses)
- pressure of speech (extremely rapid, loud speech)
- normal inflection or flat and monotonous

Thought disorder

This is characteristic of psychosis. It is conversation that is illogical or lacks cohesion, sequence or connection of ideas. It varies in severity from milder forms of circumstantiality to derailment and word salad at the severe end of the spectrum. Flight of ideas is a common characteristic of mania, whereas poverty of thought or thought blocking can occur in schizophrenia or catatonia. A list with explanations is given in Table 20.1.2.

Thought content

The interviewer identifies the prominent themes being expressed by the patient. These may revolve around feelings of hopelessness or helplessness, suicide, grief and loss, persecution, being controlled or under surveillance, religious or grandiose ideas, delusions of poverty or nihilism (the belief that part of the self does not exist, is dead or is decaying).

Table 20.1.2 Thought disorders

Circumstantiality	Delays in reaching goals by long-winded explanations, but eventually gets there
Distractible speech	Changes topic according to what is happening around the patient
Loosening of associations	Logical thought progression does not occur and ideas shift from one subject to another with little or no association between them
Flight of ideas	Fragmented, rapid thoughts that the patient cannot express fully as they are occurring at such a rapid rate
Tangentiality	Responses that superficially appear appropriate but are completely irrelevant or oblique; never arrives at the point
Clanging	Speech where words are chosen because they rhyme and do not make sense
Neologisms	Creation of new words with no meaning except to the patient
Thought blocking	Interruption to thought process where thoughts are absent for a few seconds and are unable to be retrieved

Perception

Auditory hallucinations are the most common form or hallucinations in mental illness. A patient may be actively hallucinating despite denying this on questioning. It is important to note if the patient's eyes suddenly switch direction for no apparent reason or if he or she appears to be listening to a voice. These movements are often quite subtle and easily missed if observation is not active. Note the content or type of voice being heard, such as command hallucinations, where the patient may feel compelled to act on a specific instruction that could lead to dangerous actions.

Cognitive assessment and physical examination

Screening of cognitive function and a physical examination are an integral part of the psychiatric assessment. The interviewer should ensure that the patient does not have an acute confusional state secondary to a physical condition that may account for a behavioural problem.

A number of tools are available to assess cognitive functioning.[13,17] These comprise assessments of orientation, concentration, attention, memory, language and abstraction. The presence of impaired cognitive function or an intellectual disability will influence decisions about diagnosis, treatment and disposition. Approximately 20% of mental health patients have a concurrent active medical disorder requiring treatment and possibly contributing to the acute behavioural disturbance.[6] Investigations depend on patient history and physical examination but may include electrolytes, liver and renal functioning, CK, thyroid functioning, drug toxicology, computed tomography and lumbar puncture. Only after this can an emergency medicine practitioner plan the most appropriate management.

Conclusion

A good mental health assessment is vital for timely and appropriate treatment and disposition for what is an increasingly large group of patients in the ED. Formulating an accurate assessment of a person's mental state and risk, enables appropriate provision of treatment and intervention. This may include referral to specialist mental health services for treatment planning. The mental health professional is then able to conduct a more detailed assessment to assist in determining appropriate treatment and disposition.

CONTROVERSIES

- Most hospitals now have specialized mental health teams placed within the ED. There is a trend towards the development of short-stay psychiatric beds (with varying models of care) with a purpose-designed area within or attached to the ED where mental health patients receive care after initial assessment. Increased specialization has the potential to de-skill emergency medicine personnel, both nursing and medical. On the other hand, a greater presence of mental health staff can help to build capacity and serve as a role model to ED clinicians. To date it is uncertain which particular model of care is more effective in the short-term treatment of mental health patients.
- Despite the improved presence of mental health teams within EDs, mental health patients are exposed to access block and overcrowding in EDs. This has resulted in mental health patients spending prolonged periods of time in the ED while waiting for inpatient beds to become available. This has the potential for poor quality of care and the unnecessary use of sedation and restrictive practices. ED and mental health teams must work collaboratively to ensure good outcomes for mental health patients.

20.2 Distinguishing medical from psychiatric causes of mental disorder presentations

David Spain

ESSENTIALS

1 **Morbidity and health costs are reduced by distinction of medical from psychiatric causes of mental disorder presentations to emergency departments.**

2 **Always ask if any medical condition exists in addition to the psychiatric complaints. This will identify most medical causes of mental disorder.**

3 **Missed medical diagnosis is most commonly associated with failure to undertake an adequate medical history, mental state examination and physical examination.**

4 **Substance-related disorders are most easily identified on direct or collateral history.**

5 **The presence of delirium or new cognitive defects makes an organic or substance-related illness almost certain.**

6 **The diagnosis of delirium may require repeated assessments over time.**

Introduction

Emergency physicians (EPs) often assess patients with suspected mental disorder. The critical question posed is: What is causing this? Causes broadly include psychiatric, medical, intoxication and behavioural. Identifying the likely cause and careful consideration of the capability of local facilities usually leads to correct disposition, reduced morbidity and costs.[1] EPs need a simple classification defining the principal diagnosis of the presenting mental disorder consistent with the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-V) terminology. This allows us to communicate with psychiatric colleagues and should assist diagnostic, management and disposition accuracy. Table 20.2.1 is such a suggested classification.

Medical issues are traditionally called organic. That terminology persists but is increasingly challenged by a postulated medical basis for some psychiatric disorders.

Medical clearance has been used for over 40 years, but there is still no accepted universal agreement of what that means or should entail.[2] As a minimum, it aims to identify medical conditions causing, aggravating or co-existing with an apparent mental disorder that require medical rather than psychiatric care. Overall, the process should be considered an imperfect risk reduction strategy.

General approach

Patients with abnormal behaviour labelled as psychiatric after routine medical and psychiatric assessment frequently have a final diagnosis of a medical cause or precipitant for the mental disorder. The incidence ranges between 19% and 80%.[2] Deciding whether a particular presentation of mental disorder is medical or psychiatric is often difficult, as there are very few absolutes that distinguish medical from psychiatric illness. Careful collection and weighting of appropriate information commonly only leads to a differential diagnosis.

Some diagnoses and dispositions can be determined quickly after a medical and psychiatric history, with the addition of a mental state and full physical examination. This sometimes takes place without diagnostic procedures. Other presentations require extensive and intensive evaluation, repeat evaluation, observation in hospital and significant investigations before the diagnosis is clear.

Medical clearance in emergency departments (EDs) can be inaccurate due to the presence of intoxicating substances or patient factors that limit assessments. A non-judgemental approach with prudent intervention based on known or likely risks, close monitoring in a safe environment and repeated assessment of physical and mental state over time are often necessary to obtain an accurate diagnosis and optimal outcome.

Studies on medical clearance by ED staff and psychiatrists have repeatedly shown a poor ability to discover medical conditions. This failure is commonly due to one or more of the following factors: inadequate history; failure to seek collateral history; poor attention to physical examination, including vital signs; absence of a reasonable mental state examination; uncritical acceptance of medical clearance by receiving psychiatric staff; and failure to re-evaluate over time.[3] Medical conditions were most easily identified in the ED by the triage nurse or medical officer when asking whether any medical conditions existed in addition to the psychiatric complaints.[4]

Table 20.2.1 A simple classification of principal diagnosis of mental disorder for emergency physicians

DSM-V *terminology*	*Broad traditional clinical grouping*	*Likely principal management and disposition*
Axis 1		
Clinical disorder due to a general medical disorder	Organic	Medical
Delirium, dementia and amnestic and other cognitive disorders	Organic	Medical
Substance-related disorder—intoxication or withdrawal disorder	Organic	Medical
Substance-related disorder—substance induced persistent disorder	Organic	Psychiatric
Clinical disorder (not identified to above or axis II principal diagnosis)	Psychiatric	Psychiatric

Box 20.2.1 Triage safety questions[5]

Is the patient a danger to him- or herself?
Is the patient at risk of leaving before assessment?
Is the patient a danger to others?
Is the area safe? Does the patient need to be searched?

(From Pollard C. *Psychiatry Reference Book – Nursing Staff.* Hobart: Department of Emergency Medicine Royal Hobart Hospital; 1994 with permission.)

Evaluation requires a thorough approach and a commitment of time and effort. Special skills are required for medical clearance and psychiatric interview. A coordinated and focused medical and psychiatric assessment has the highest yield of correct diagnoses.[1] Proformas or clinical pathways may improve compliance and documentation of important details, but have not demonstrated improved patient outcomes.

National Emergency Access Targets (NEAT) in Australia have changed the management in some situations. Approaches vary depending on institutional capabilities and local agreements. Detailed medical clearance for every patient is no longer universally practiced in ED. Many known psychiatric patients are now triaged directly for psychiatric assessment. Inpatient psychiatric services have, in response, taken the responsibility for medical assessment for those incompletely or not assessed in EDs. Triage screening still leaves a volume of complex patients requiring detailed medical assessment in the ED.

Triage

Triage is vital, as many apparent psychiatric presentations have medical conditions. Correct identification by nursing staff facilitates correct management and reduces morbidity and mortality. Many patients with psychiatric illness are also a significant risk to themselves or to others and require urgent intervention. Questions regarding safety should always be raised (Box 20.2.1).[5]

Nursing staff can use a triage checklist to identify presentations with high yield for organic illness (Box 20.2.2). These require ED medical assessment. With local service agreement these also allow streamlined psychiatric referral without ED medical clearance for those with a known mental disorder and a low medical risk. These are based on consensus guidelines previously developed by EPs and Psychiatrists.[6] They require vigilance by the psychiatric team to consider that a low risk of medical cause remains. They have been operating for some years without obvious increase in adverse outcomes. They are yet to be validated.

If a psychiatric diagnosis is likely, then an appropriate urgency rating by the Australasian Triage Scale for psychiatric presentations should be applied. This triage categorization for psychiatric presentations has been developed and verified and allows reasonable waiting time standards for urgency to be applied in Triage Category 2–5 (Box 20.2.3).[7] A Triage Category 1, when there is severe behavioural disturbance with immediate threat of serious violence, has been sensibly added to that scale by the Australasian College for Emergency Medicine.

Triage should consider privacy issues to obtain an accurate history. Collateral information, if available, should be obtained, considered and documented. This information should allow the patient to be placed in an appropriate and safe environment with continuing visual and nursing observations while further assessment occurs.

Box 20.2.2 High-yield indicators of organic illness identified at triage

Emergency department triage and referral of adult patients to psychiatry

1. Does the patient have a **new psychiatric condition**? ☐ Yes ☐ No
   If Yes please specify:
2. Any history of **active medical illness** needing evaluation? Explore patient concerns re new medical issues or concerns of current medical illness or regards co-morbid medical conditions. ☐ Yes ☐ No
   If Yes please specify:
3. Any **abnormality of vital signs**? Please document observations below. ☐ Yes ☐ No
   Pulse: ..... BP: ..... Temp: ..... Resp Rate: ..... O^2 Sat: .....
   Values considered abnormal are:
   - Temp ≥38°C
   - Pulse <50 or >120 beats/min
   - Blood Pressure: systolic <90 or >200 mm Hg; diastolic >120 mmHg
   - Respiratory Rate >22 or <10 breaths/min
   - O^2 saturation <90% on room air
4. Any physical complaint or sign? (Any trauma, abnormal gait, abnormal speech, pallor, cyanosis, sweatiness, irregular pulse, unequal pupils, headache, chest pain, abdominal pain) ☐ Yes ☐ No
   If Yes please specify:
5. Any acute ingestion, misuse, chronic abuse or withdrawal of any substance? (e.g. illicit drugs, alcohol, overdose.) ☐ Yes ☐ No
   If Yes please specify:
6. **Any features of delirium** such as: lethargic, stuporose, fluctuating or altered level of consciousness, inattention or disorientation to time, place or person? ☐ Yes ☐ No
   If Yes please specify:
7. Is the person aged <15 years old or >55 years old? ☐ Yes ☐ No

Outcome:
If the answer is No to all the above questions, no further evaluation is necessary and the patient can be directly referred for psychiatric assessment. If the answer is Yes to any question, the patient needs ED medical assessment before any referral is initiated.

Box 20.2.3 Guidelines for Australasian Triage Scale coding for psychiatric presentations[7]

Emergency: Category 2
Patient is violent, aggressive or suicidal, or is a danger to self or others, or requires police escort

Urgent: Category 3
Very distressed or acutely psychotic, likely to become aggressive, may be a danger to self or others. Experiencing a situation crisis

Semi-urgent: Category 4
Long-standing or semi-urgent mental health disorder and/or has a supporting agency/escort present (e.g. community psychiatric nurse[a])

Non-urgent: Category 5
Long-standing or non-acute mental disorder or problem, but the patient has no supportive agency or escort. Many require a referral to an appropriate community resource

[a]It is considered advantageous to 'up triage' mental health patients with carers present because the carers' assistance facilitates a more rapid assessment.
(From Smart D, Pollard C, Walpole B. Mental health triage in emergency medicine. *Aust NZ J Psychiatr* 1999;33:57–66 with permission.)

The interview environment

A climate of trust is very important, as many details of the psychiatric interview are sensitive. The psychiatric interview should take place in as quiet and private an environment as possible. The choice of the interview site may be limited in emergencies to ensure safety for both the patient and the staff.

History

A careful traditional medical history is the most common identifier of medical illness causing a mental disorder presentation. Substance-related disorders are most easily identified on history. Drug history should check compliance and detail prescribed, recreational and over-the-counter medications. Gradual onset and a previous psychiatric history are more commonly associated with psychiatric illness. Conversely, abrupt onset, no premorbid decline and no past psychiatric history favour a medical cause.

Family history is often a key indicator of psychiatric or medical cause. For example, a newly depressed 30-year-old man with a family history

of Huntington disease or porphyria is more likely organic. Conversely, an 18-year-old man with a hypomanic presentation plus strong family history of bipolar disorder is more likely psychiatric. Suicidal and homicidal risk should be assessed routinely to ensure safety. The system review is a useful screen for organic illness.

HIV-related illness is the new great mimic of modern psychiatry and medicine. Risk behaviours should be explored. Positive HIV status always warrants assessment for an organic cause of any new behavioural disturbance. Clinically, these problems often initially present with symptoms of mild anxiety or depression. Many treatable medical causes are only evident after significant investigations.

Delirium, a highly specific but not absolute indicator of medical or substance-induced disorders, should always be sought. By definition, this requires a history of recent onset and of fluctuation over the course of the day. Classically, there will be subtle changes in the level of consciousness or the sleep–wake cycle. Patients may have poor recent memory or not be able to attend sufficiently to give a history if delirious. The psychiatric history, including life profile, may give evidence of the presence or absence of premorbid decline. An abrupt onset of abnormal behaviour with no premorbid decline is more suggestive of an organic cause.

Collateral history

Collateral history is important as the patient is not always capable of, or willing to give, full information. This history often crystallizes a diagnosis that would otherwise be uncertain or missed. Previous discharge summaries may provide information regarding alcohol and drug use, previous behaviour and diagnosis. The family should be asked to bring in all medications, including over-the-counter items. Family, friends and caregivers may give rapid access to collateral history. Collateral may be the only source for a history of a patient's fluctuating mental status, suggesting delirium, even when the patient appears quite lucid in the ED.

Examination

Lack of attention to important details of the examination is a frequent cause of missed medical illness. Areas that commonly yield positive findings, but are frequently omitted, are: the neurological examination; appearances of endocrine disease; toxidromes; signs of malignancy; stigmata of drug or alcohol abuse; and vital sign examination. Poor cooperation can prevent detailed examination and should be documented so that future consulting clinicians are aware of a deficient entry examination.

Vital signs

Abnormal vital signs are frequently the only abnormality found on examination of patients with serious underlying medical disease. They must always be acknowledged and explained. Pulse oximetry should be included rapidly to exclude hypoxia. A bedside blood sugar level should be routine.

Mental state examination

This is an account of objective findings of mental state signs made at the time of interview. It is the psychiatric equivalent of the physical examination and specifically details the current status. It should be performed by the EP as part of medical clearance. Observations made by other staff, such as hallucinations, may be significant and can be included with the source identified. Careful consideration of the mental status frequently clearly distinguishes medical from psychiatric illness, guiding further investigation and management. For example, the presence of delirium or other new cognitive defects make an organic illness almost certain. Disorientation is highly suggestive of delirium. Delirium can be very subtle. Due to the fluctuating nature, the delirious patient may appear normal on a single interview. Other less obvious features, such as lability of mood, variability of motor activity or lapses in patient concentration making the interview difficult, can be the only clues and are easily overlooked. The importance of formulation using collateral history and repeated mental state examination is stressed. Documentation is important so that mental status changes on repeat assessment can be appreciated.

Examination tools

Elderly patients with delirium or cognitive defects are frequently not recognized by EPs. These patients are at high risk of morbidity and mortality. Cognitive defects may be rapidly and reliably identified by EPs during mental status examination by the use of Folstein's Mini Mental State Examination (MMSE).[8] A score of less than 20 suggests an organic aetiology. A fall of two or more points on serial MMSE is highly suggestive of delirium. Other screens suitable for EP use are the Quick Confusion Scale,[9] the 4AT test and the 6-Item Cognitive Impairment Test.[10]

Elderly patients with possible dementia or delirium may require more detailed screening with the confusion assessment method as a recognized standard. However, assessors with special training are required.

The tests above are suitable screening tools for EDs but are not intended to replace formal neuropsychological assessment.

Proformas of medical history, mental state examination and physical examination may improve the thoroughness of assessment and documentation.

Investigations

Investigations always should be guided by clinical findings and be tailored to each individual presentation.

First presentations and suspicion of a medical cause or co-morbid illness aggravating mental disorder are the major indications for emergency investigations. Baseline blood tests, such as full blood profile, blood sugar level, electrolytes, liver function tests, calcium and thyroid function tests, may at times detect clinically unsuspected problems. Examination and culture of urine and cerebrospinal fluid should be undertaken if occult infection is considered. A urine drug screen may confirm clinical suspicions of drug-related illness when collateral and patient history of misuse is absent. HIV and syphilis testing should be done on all patients with significant risk. Mandatory brain computed tomography (CT) is not indicated, but the threshold for imaging in first presentations of altered mental state without obvious cause or after head trauma should be low. Herpes encephalitis may not produce imaging changes on CT but should be considered when fever, delirium or cognitive changes are present with sudden alterations in behaviour. Magnetic resonance imaging and electroencephalogram examination will rarely be indicated in the ED for this group of patients.

Diagnostic formulation

EPs providing medical clearance of clients who do not meet low-risk criteria at triage should suspect organic disease until proved otherwise. In particular, reversible medical causes of an abnormal mental state should be sought. Proformas improve documentation and summation. Consideration of the factors in Table 20.2.2 may help to determine doubtful cases. There are few absolutes that distinguish organic from psychiatric patients. Use of the five-axis DSM-V system improves the ability to consider the patient's presentation in the context of total functioning. It also allows EPs to communicate with psychiatric peers in the recognized language.

Some patients require observation, re-examination and further investigations before a definitive answer is obtained. Intoxicated patients usually require observation until sober when valid mental health assessments can occur. Interim care and disposition vary depending on the presentation, the past history and the facilities available. A common expectation of EPs for patients referred to psychiatrists is to

Table 20.2.2 Factors influencing the likelihood of medical or psychiatric illness as the principal diagnosis

Organic	*Psychiatric*
Abnormal vital signs	Family history of psychiatry disorder
Age >40 with first psychosis	Past psychiatric illness
Delirium	Fully orientated
Conscious level fluctuates	Clear sensorium
Inability to attend	
Memory impaired	
Impaired cognitive abilities	Intact cognition
Neurological signs, e.g. dysarthria	
Abnormal physical signs	
Abrupt onset	Slow onset
Dramatic change in general status (hours to days)	Premorbid slow deterioration in employment/family/socially
Recent medical problem	Recent significant life event
Medication, drugs/alcohol/withdrawal	Non-compliance psychiatric medication
Marked new personality changes	
Visual, tactile or olfactory hallucinations more common Agitation/irritability HIV/AIDS Failed psychiatric treatment	Auditory hallucinations more common especially: Voices arguing Voices commentary Two voices discussing Audible thoughts
Disorganized delusions	Structured delusions
Movement disorders	Somatic passivity experiences
Perseveration	
Confabulation	
Illusions or misinterpretations	
Circumstantiality	
Concretism	Thought withdrawal, insertion or broadcasting
FH degenerative brain disease	FH psychiatric illness
FH heritable metabolic	FH: family history psychiatric illness

FH, Family History

document that the patient is 'medically cleared'. The assessment is known to be imprecise and difficult.[1,2] Better documentation is to state that the ED assessment has revealed no evidence of an emergent medical problem that would preclude admission to psychiatric care and further medical evaluation.

Conclusion

A thorough medical history, psychiatric history, collateral history, physical examination, mental state examination and judicious specific investigation will identify most patients likely to have an underlying physical cause for a mental disorder presentation. Omission of any of these steps may lead to missed medical diagnosis and incorrect disposition.

CONTROVERSIES AND FUTURE DIRECTIONS

- Where and when the assessment of a mental disorder ideally occurs is somewhat controversial. Urgent assessment in the traditional hospital-based general ED with strict medical clearance is ideal and is the safest for abrupt onset of a new mental disorder illness. Patient volume and time demands with resource constraints are forcing alternative models for entry to care. Many EDs are triaging patients as likely medical, emergent psychiatric or non-emergent psychiatric. Depending on local service availability, early streaming based on this triage allows many psychiatric clients (most non-emergent) to be directed away from the ED to appropriate community mental health services. Additionally, community-based psychiatric services are increasingly managing acute episodes of behaviour disorder in the community without the need for hospitalization or emergency department involvement. Hard outcome studies are yet to be undertaken on these new models.
- NEAT was expected to increase pressure on ED and psychiatric services to respond in a timely fashion. There is an absence of data on quality related to NEAT for mental disorder attendances. Despite the new targets, services commonly have not been able to approach or consistently meet targets for admitted psychiatric patients.
- Providing adequate resources and a safe physical environment for assessment, management and disposition of the rapidly escalating number of patients with a substance-related disorder is a major ED challenge. Assessments during intoxication are typically unhelpful. Intoxication may last hours to days and require medical therapy or brief admission. While the ED may be an appropriate resource for the initial care of severe behavioural disturbance, no universally applicable model has been found to manage patients who need a safe place to sober up from intoxications before reassessment. Larger EDs in heavily populated areas have been trialling short-stay acute behavioural units that combine emergency, psychiatric, toxicology, and alcohol and drugs services.

20.3 Deliberate self-harm/suicide

Jennie Hutton • Grant Phillips • Peter Bosanac

ESSENTIALS

1 Deliberate self-harm is a frequent presentation to emergency departments and is a symptom of diverse underlying problems, be they biological, social or psychological.

2 Patients with deliberate self-harm form a heterogeneous group, most of whom do not have ongoing suicidal behaviour.

3 Assessment of suicide risk following deliberate self-harm is to inform treatment and to identify risks amenable to intervention and protective factors. It involves assessment of background demographic, psychiatric, medical and psychosocial factors as well as the presenting crisis. The patient should feel listened to and understood following the assessment.

4 There is no 'gold standard' for suicide risk assessment and the level of risk can change quickly.

5 The most consistent factors predicting fatal and non-fatal repetition following deliberate self-harm are psychiatric illness, personality disorder, substance abuse, multiple previous and types of attempts, hopelessness, social disconnectedness and intoxication.

6 A planned strategy to deal with these patients should address triage, restraint and observation, medical and suicide risk assessment, treatment, disposition and follow-up.

7 Management requires coordinated care with emergency, mental health and primary care clinicians, as well as carers.

8 Treatment decisions should be collaborative wherever possible and take into account any advance statement that may have been made. The next of kin should be contacted wherever practicable for both collateral information and collaboration.

9 The legal framework for the location in which individuals practice should be known and considered.

Introduction

Suicide is a deliberate act of intentional self-inflicted death. It is the most extreme manifestation of deliberate self-harm (DSH), where the spectrum spreads from superficial lacerations through to actions intended to end life. Although suicide is uncommon, 10% of people who complete suicide are seen in an emergency department (ED) in the month prior to death, with a substantial proportion not having psychosocial assessment, thus providing an opportunity for intervention.[1] Regardless of the presentation to ED, about 8% of patients have experienced recent suicidal ideation or behaviour, which they may not disclose unless specifically explored.[2] However, the major ED impact is in the identification and assessment of large numbers of patients potentially at risk of suicide, with initial management of co-morbidities and modifiable risk factors.

DSH is a maladaptive response to internal distress and may not have suicidal intent; however, it may indicate a risk for suicide. DSH is a common ED presentation (approximately 0.4% of all ED visits) and the goals of management include treating the physical health sequelae, assessing the risk of non-fatal or fatal repetition and prevention, and diagnosing and commencing treatment of potentially reversible psychosocial causes.

Epidemiology

In Australia there were 3128 deaths from intentional self-harm in 2017, with age standardised rates of approximately 19.1 per 100,000 in males and 6.2 in females (fig. 20.3.1).[3] Intentional self-harm accounted for 1.9% of all deaths in 2017. However, with a median age at death of 44.5 years, intentional self-harm (11.4%) was responsible for the most Years of Potential Life Lost (YPLL) of all diseases and trauma. As a comparison Ischemic Heart Disease which contributed 7.4% of YPLL in 2017 has a median age at death of 85 yrs.

Across OECD (Organisation for Economic Cooperation and Development) countries, suicide rates were lowest in South Africa, Greece, Mexico, Israel and Brazil, at less than 7 deaths per 100,000. They were highest in Lithuania, Hungary, Japan and Latvia, at more than 17 deaths per 100,000. The World Health Organization estimates that the low- and middle-income countries account for 78% of global suicides.

Hospital presentations for DSH are at least 10 times higher than suicide rates. The 2007 Australian National Survey of Mental Health reported 1.9% of males and 2.7% of females experienced suicidal ideation within 12 months.[4] This rate may be as high as 25% in certain populations and age groups.

Risk of suicide

An episode of DSH is one historical risk factor predictive of future suicide behaviours. Approximately 1% to 2% of patients complete suicide during the year following an attempt, and in approximately 40% of suicides there is a history of a previous self-harm. A systematic review of fatal and non-fatal repetition of self-harm reported a suicide rate of 2% at 1 year and 7% after 9 years.[5] Hospitalization and aftercare decrease the short-term risk of suicide, but have little impact on the long-term risk of suicide. However, this may be due to undertreatment of psychiatric illness.

Repeated episodes of deliberate self-harm

DSH usually invokes help from friends, family and the medical profession so the patient's social situation and psychological well-being tends to improve. This effect is prominent in younger patients, but may not occur in patients aged over 60 years. The risk of repetition is 12% to 16% in the following year, with 10% of these occurring in the first week.[5] This is more likely in females who are unemployed, have cluster B (e.g. borderline, narcissistic and histrionic) personality traits or have substance-abuse problems. A younger age at first attempt, the presence of long-standing affective disorders, drug/alcohol misuse disorders and anxiety all correlate with repeated attempts. Some patients have chronic suicidal ideation and multiple repetitions of DSH. They often suffer from personality disorders, psychotic disorders, chronic medical conditions, alcohol or drug use, a history of childhood sexual

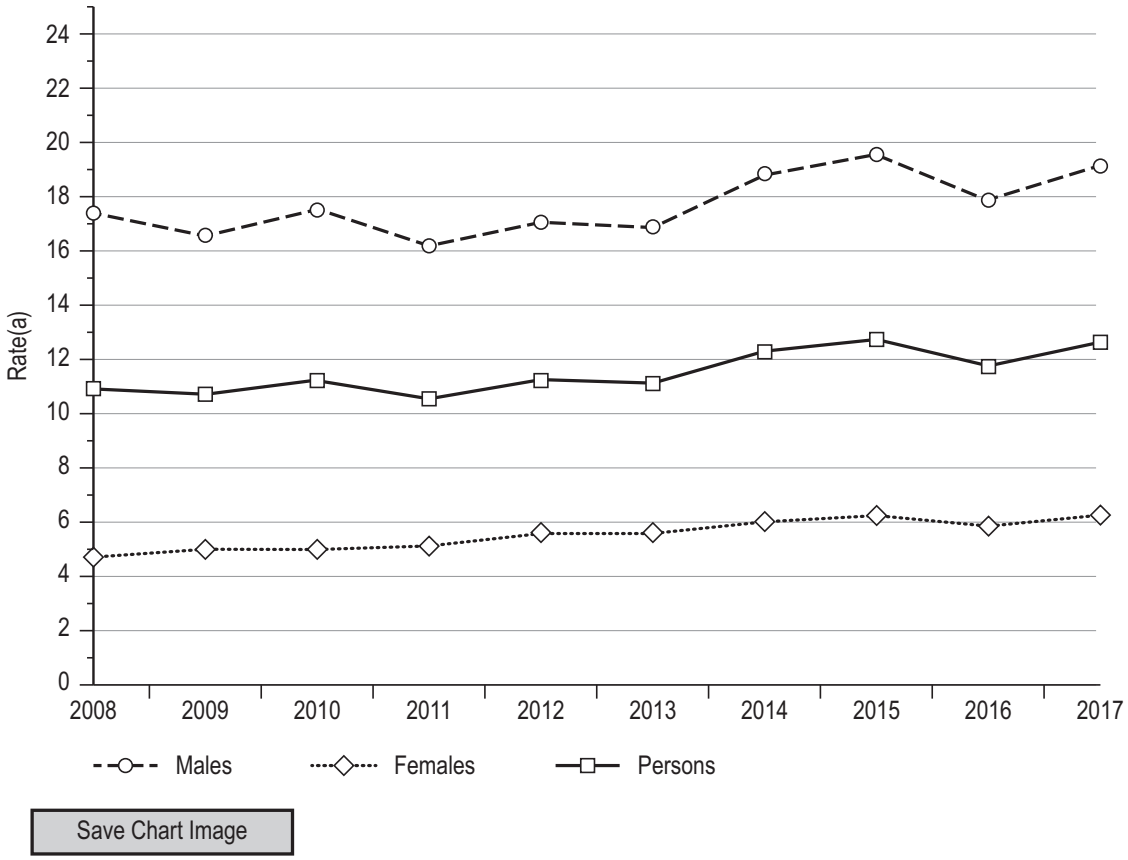

FIG. 20.3.1 Suicide rates Australia (2008–2017). (From Causes of Death, Australian Bureau of Statistics, 2017. Accessed Jan 2019)

abuse and violent behaviour. They use DSH as a means of fighting off anxiety, hopelessness, loneliness or boredom, as well as subjective experiences of emptiness or extreme distress. They may also be maladaptive ways of eliciting assistance from family, friends or health carers. These patients are at increased risk of eventual suicide. Reversible potentiating factors should be addressed where possible.

Patients with DSH who leave the ED prior to a psychosocial assessment may have a higher risk for repeat DSH, probably associated with lack of specialist follow-up and treatment of reversible factors.

Patient characteristics

Demographic factors

Age

Suicide and DSH are rare in children under 12 years of age. Australian data suggest a peak at 30 to 34 years in males (27.5 per 100,000) and 50 to 54 years in females (10.4 per 100,000).[3] There is another peak in the elderly, with suicide rates increasing with age from 65 years.

The incidence of DSH increases throughout puberty, reaching a peak at 15 to 24 years of age and decreasing thereafter. The ratio of rates of DSH to suicide decreases markedly with age. DSH is uncommon in the elderly, who have a high ratio of successful to unsuccessful attempts.

Gender

In Australia, the overall rate ratio of M:F suicide is 3.4 in 2010 compared with 2.7 in New Zealand.[6,7] The rate for male DSH has been increasing in Western countries recently with the male to female ratio approximately 1:2. Females choose methods that are less likely to be fatal and may be more likely to present to hospital following DSH.

Social and cultural factors

Suicide rates are higher in those who live alone or are in a lower social group, especially in urban areas characterized by social deprivation and overcrowding. Being single, separated, divorced or widowed increases the risk of suicide two- to threefold in the high-income countries. In these countries, being partnered reinforced by children decreases the risk of suicidal behaviour.

Recent data in Australian aboriginal people reports substantially higher suicide rates that commence at a lower age than in the non-aboriginal population.[3] The suicide rate for Aboriginal or Torres Strait Islander People in 2017 (25.5 per 100,000) is twice as high as non-indigenous people (12.6 per 100,000). In addition, 76% of these deaths are attributed to male indigenous people.[3] A higher suicide rate is seen in indigenous groups of other developed countries for example, in New Zealand, the age-standardised rate was 197.7 per 100,000 Maori in 2013 compared with a rate of 172.2 per 100,000 non-Maori.

Rural areas in Australia and New Zealand and remote areas in the UK have a higher rate than urban areas.[3,6,7] Incarceration is a risk factor for suicide; in any form of custody the suicide rate is three times that of the general population.

Some social groups, such as doctors, dentists, musicians, lawyers and law-enforcement officers, are more prone to suicide. Most adults (75%) with DSH have relationship problems with their partners, and teenagers with their parents. A perceived or potential loss, such as a major argument or separation, often precedes the act on a background of ongoing social difficulties or substance use.

Unemployment increases the risk of DSH by 10 to 15 times, with the risk increasing with duration of unemployment. This may not be a cause or effect, but may be due to some underlying factor, such as psychiatric illness, personality disorder or substance abuse.

Medical factors

There is an increased risk of suicidal ideation in people with chronic ill health; the majority of such patients have sought medical advice in the 6 months before suicide.

Psychiatric factors

There is a pre-existing psychiatric disorder in 90% to 100% of cases of suicide, with depression accounting for 66% to 80%, but this rate may be based on retrospective psychological autopsy and therefore be open to dispute. The lifetime rate of suicide among psychiatric inpatients is 3 to 12 times higher than in the general population and involves a greater proportion of more violent methods, such as jumping from buildings, or hanging. One-third of these episodes occur after self-discharge from hospital, with another third occurring during approved leave. The high-risk time is the first week of admission and during the first 3 months after discharge.

Psychiatric disorders are present in up to 60% of patients who complete DSH, but may be transient and secondary to acute psychosocial difficulties. Da Cruz et al. examined the cases of 286 individuals who died within 12 months of mental health contact in North West England; 43% of the sample attended the ED on at least one occasion and 12% of the sample attended an ED on more than three occasions and could be considered 'frequent attenders'. Most frequent attenders had a history of self-harm (94%), 68% had a history of alcohol abuse, 63% were unemployed at the time of death and 49% had a history of drug abuse.

The psychiatric diagnosis that carries the greatest risk of suicide is mood disorder, particularly major depressive disorder if associated with borderline personality disorder, anxiety or agitation. Fifteen percent of these high-risk patients complete suicide over a lifetime. Depression correlates well with the occurrence of suicidal ideation, but may not be as strong a predictor of planning and preparation (intense thoughts, plans and capability) and, therefore, suicide completion. Hopelessness is the most important factor associated with suicide completion and may be of greater importance than suicidal ideation or depression itself.[8] Therefore depressed patients should have their attitudes towards the future carefully assessed. Patients with cluster B personality disorders are at a high risk of DSH and suicide, especially if associated with labile mood, impulsivity, alienation from peers and associated substance abuse.

Up to 10% of people with schizophrenia die by suicide. Young adult males are at high risk, especially if there is associated depression with feelings of hopelessness, previous DSH or suicide behaviours, unemployment or social isolation.

Individuals with alcohol use disorders have an overall approximately 7% lifetime risk of dying by suicide, with women being at greater risk than men. Fifteen percent of alcohol-dependent persons eventually complete suicide. The majority of these are also depressed. Young males dependent on heroin have 20 times the risk of the general population.

Chronic alcohol dependence is uncommon in DSH, but alcohol intoxication is involved in 50% to 90% of suicide attempts. Acute alcohol ingestion is found in approximately 35% of people who die by suicide.

Frequent attenders

Frequent attenders to EDs (defined as more than three presentations in a year) are also at high risk. This group has seven times the risk of the general population and rates of suicide similar to clinical psychiatric populations. This risk is particularly pronounced in patients who present with panic attacks, especially if associated with depressive symptoms.

Aetiology

No specific psychological or personality structure is associated with suicide and patients who complete suicide or DSH do so for many unrelated reasons. The precipitant may be a personal crisis or life change amplified by poor social support, substance abuse or psychiatric disorder. Intoxication may decrease inhibitions enough to allow an act to proceed. A study by Wyder interviewed 112 people following a DSH. She found that 51% had considered DSH for 10 minutes or less, but of those who had been affected by alcohol that number jumped to 93%.[9]

The most frequent methods of suicide in Australia are hanging, strangulation and suffocation, with these modes being used in 56% of all suicide deaths in 2010 in Australia. Poisoning by drugs was used in 12% of suicide deaths in 2010, followed by poisoning by other methods including alcohol and motor vehicle exhaust (10%). Firearms accounted for 7% of suicide deaths in Australia in 2010, a rate which has declined from 20% a decade earlier, possibly due to firearm restriction legislation. Proportions due to each method vary according to region, residence, age and sex. In the United States, firearms accounted for 57% of male and 32% of female suicide deaths.

One-third of patients with DSH express a wish to die, but most do so to communicate distress. DSH may serve many functions for the person. At its most simple, it serves an integrative function calming the person at a time of great distress. It may also be a way of mobilizing assistance for someone who is feeling overwhelmed by circumstances. Many patients threaten suicide or magnify being at risk of suicide to increase the likelihood of admission to hospital. These patients are more likely to be substance dependent, have personality diatheses (e.g. marked borderline, antisocial or dependent traits or disorder) or homelessness, and be single and in legal difficulty. However, these instances of goal-directed behaviour should not be discounted, and the behaviour should be taken seriously. A presentation to an ED is a declaration that the person is in a self-defined crisis for which they are using maladaptive coping measures.

Most cases of medically serious DSH are due to self-poisoning, with 90% associated with alcohol intoxication. The most common drugs are non-prescription analgesics and psychotropic drugs. Many overdoses are related to alcohol or illicit substance intoxication and may be accidental rather than deliberate, although this distinction is often difficult to ascertain. Self-injury may involve cutting of the skin in various sites about the body but may also involve self-inflicted cigarette burns, excoriation of the skin or hitting themselves or other objects. More violent forms of self-injury are less common and suggest serious suicidal intent. Bizarre self-mutilation may occur in psychotic patients who may not necessarily have an intention to die but are acting in accordance with delusional beliefs or in response to command hallucinations.

Assessment

A person who expresses suicidal ideation or engages in DSH is sending a distress signal that emergency physicians must acknowledge. Suicidality should also be assessed in patients with symptoms or signs of depression, unusual behavioural changes, substance abuse, psychiatric disorders and complainants of sexual violence.Those who present with injuries of questionable or inconsistent mechanism, such as self-inflicted lacerations and gunshot wounds or motor vehicle accidents involving one victim, should also be considered for assessment. Many would argue that assessment of self-harm should be a routine part of any ED assessment. A retrospective study by Da Cruz et al. found that 40% of persons who died by suicide had presented to the ED at least once during the year prior to their death. Assessment in the ED ideally will contain elements that provide the person with the opportunity to discuss psychosocial aspects of their life. Within this discussion, it may be that suicidal ideation or thoughts of DSH may be elicited. This may allow early referral to psychosocial support, thereby providing the person with holistic care to help address their needs.

Assessment requires a systematic, multidisciplinary approach involving prior staff education, appropriate triage, observation and restraint procedures (in the setting of imminent risk and the absence of less restrictive options), and a planned strategy for assessment followed by treatment and disposition. The priorities are to define the physical sequelae of the act, risk of further DSH behaviour, psychiatric diagnoses and acute psychosocial stressors. These aspects are those that can then be targeted for short-term interventions. However, assessment tools and scales designed to give an overall indication of the magnitude of risk (low, medium or high) are not clinically helpful in identifying patients at imminent risk of suicide, as the predictability of completion of suicide is bedevilled by the low prevalence of suicide with

false positives in the 'high-risk' groups. Moreover, most of those who go on to completion of suicide will be categorized as 'low risk', as this group is far greater in number than the high-risk group.

Triage

In a patient who has attempted DSH, initial management involves resuscitation, treatment of immediate life threats and preventing complications. The patient should be triaged according to the physical problem as well as current suicidality, agitation, aggression and mental state. The mental health triage scale can be used for this purpose. A triage score of 2 or 3 should be applied if patients are violent, actively suicidal, psychotic, distressed or at risk of leaving before full assessment can occur. Constant observation is required at this point and nursing staff, security or police may be needed. In Australia, a number of different triage scales can be used. There is some evidence that a mental health triage scale improves outcomes; however, the accuracy of the assessment can be limited by a number of environmental, staff and patient factors.

Medical assessment

The patient's safety in the ED should be optimized by limiting the availability of drugs, removing sharp implements, removing car keys, ropes, belts or sheets, and securing nearby windows. Other concurrent and concealed methods of self-harm should be sought. This may be facilitated by changing into hospital gowns, whereby the patient is more easily identified if they abscond. In addition, other means to increase visibility, such as security cameras, high-visibility cubicles or assigning a special nurse, should be considered. Assessment of the patient may be difficult, either due to a general medical cause or being unsettled from the precipitant of the act, or from not wanting to be in hospital or allow medical intervention. This may necessitate the therapeutic utilization of anxiolytic medication; the use of physical restraint may be considered if at high risk or unable to be fully assessed and wanting to self-discharge. This may be done under a duty of care to the patient or the local mental health act may be utilized in extreme situations. Emotional support of the patient, friends and relatives is required during and after this phase, with clear explanation of the rationale and the procedures. Distinguishing medical from psychiatric causes of mental disorder presentations is discussed elsewhere in this book (see Chapter 20.2).

Suicide risk assessment

Initially, an assessment needs to be done in the ED to determine patient disposition, but a more comprehensive psychiatric assessment may need to wait until substance or anxiolytic medication effects wear off. Collateral sources of information need to be accessed since patient history can be unreliable or incomplete. Friends, family, local doctor, ambulance officers, helping agencies already involved and previous presentations documented in the medical record can all add useful information in order to advise an assessment. A therapeutic relationship should be formed and the clinician should be non-judgemental, non-threatening and clearly willing to help. A positive attitude has been shown to improve outcomes with this group of patients. It is the responsibility of the clinician to establish rapport with the patient, and all patients benefit from feeling that they have been listened to and understood.

People presenting in crisis are hypersensitive to any negative transference. This may intensify the patient's already low self-esteem, increasing future self-harm potential and making a therapeutic relationship difficult to establish. When managing a patient who may be expressing self-harm ideation, the ideation should be discussed openly. Expressions of self-harm carry individual meaning for each person. It is important, in a therapeutic relationship, to explore the meaning that this carries for the person, and alternatives.

Risk factors may be divided into two main categories: static and dynamic. Static factors have been historically identified by Durkheim who showed that some less socially integrated groups within society were at greater risk of suicide than others. These static factors are enduring and in the context of a person's developmental history and social circumstances. Hence, being male, unemployed, single, socially isolated, poorly educated, from a lower socioeconomic group, with a history of mental disturbance and substance-use disorders would all place someone in a higher risk group.

Dynamic factors are the more fluid day-to-day factors that intensify the risk posed by the static factors. Flewett divides these factors into internal and external factors. The internal factors include current feelings of abandonment, desperation, hopelessness, co-morbid depression, current drug use or physical illness. External factors are those of increased social dislocation, including homelessness, bereavement, intoxication, and an adverse life event, such as the recent loss of a job or relationship.

The role of dynamic risk is highlighted by Rosenman when he states: 'for conditions with multiple risk factors… each factor adds a little to the risk, but only when it interacts with other factors. No single predictor or combination of predictors is present in every individual, and membership of the high-risk group changes from moment to moment. Half a bottle of whiskey may create a high suicide risk within an hour'.

Assessment of suicide risk involves assessing background demographic, psychiatric, medical and social factors; these are the static factors that underlie any presentation and will determine the chronic suicidal risk that the person presents. Dynamic risk factors as well as the current circumstances and risk of suicidal behaviour itself are outlined in Table 20.3.1. There are epidemiological differences between people who self-harm and those who complete suicide. Although the groups are different, there is an important overlap. The more an individual's characteristics resemble the profile of a suicide completer, the higher the risk of future suicide or suicide behaviours. Despite this, in long-term follow-up studies very few of these factors have been shown to be good independent predictors of suicide following DSH. The most consistent factors are psychiatric illness, personality disorder, substance abuse, multiple previous attempts and current suicidal ideation and hopelessness.

Moreover, contemporary risk assessment is focussed on prevention rather than prediction-oriented assessment and the centrality of engagement with the patient and their individual predicament and concerns. It is important to engage the patient in identifying strengths, and supports as part of the interview. In many situations the precipitating stressors are relieved with intervention or time.

Use of scales

Many screening tools have been devised to identify high-risk groups within those presenting with DSH. PATHOS, the Suicidal Intent Scale, the Sad Persons Scale and other scoring systems have been devised to complement medical assessment of suicide risk. However, many of these scales use outdated risk factors and patient populations unrepresentative of EDs. Scales need to be sensitive, but this misclassifies a large number of individuals as potentially at risk of suicide. These deficiencies need to be considered when applying suicide risk scales in the ED and these scales should not be used as an absolute assessment of suicide risk or of the need for psychiatric admission. In addition to validated questionnaire assessment, there are a number of validated interview assessment tools, such as the Suicide Attempt Self-Injury Interview. Problems that clinicians report in using these tools is that of the time taken to administer them. In any event, these tools have been shown to be as accurate as a mental health clinician's global assessment, although they predominantly utilize demographic risk factors replete in the general population and without a sound evidence base.

The problems associated with suicide-risk assessment are summarized in Box 20.3.1.

An example of useful questions that can be used in assessment are given in Box 20.3.2.

Table 20.3.1 Factors associated with suicide

Variable	*High risk*	*Low risk*
Static factors		
Gender	Male	Female
Marital status	Separated, divorced, widowed	Married
Employment	Unemployed or retired	Employed
Medical factors	Chronic illness, chronic pain, epilepsy	Good health
Psychiatric factors	Depression, bipolar, schizophrenia, panic disorder, previous psychiatric inpatient, substance abuse	No psychiatric history
Social background	Unresponsive family, socially isolated or chaotic, indigenous background, refugee from conflict areas, past history of trauma, developmental trauma	Supportive family, socially stable and integrated
Dynamic factors		
Suicidal ideation	Transient, intense suicidal ideation, plan and intent, intoxication and impulsivity with impaired judgement	Infrequent, transient
Attempts	Multiple	First attempt
Lethality	Violent, lethal and available method	Low lethality, poor availability
Planning	Planned, active preparation, extensive premeditation	No realistic plan, telling others prior to act
Rescue	Act performed in isolation, event timed to avoid intervention, precautions taken to avoid discovery	Rescue inevitable, obtained help afterwards
Final acts	Wills, insurance, giving away property	
Coping skills	Unwilling to seek help, feels unable to cope with present difficulties	Can easily turn to others for help, can plan to overcome present difficulties, willing to become involved in aftercare
Current ideation	Admitting act was intended to cause death, no remorse, continued wish to die, hopelessness or helplessness	Primary wish to change, pleased to recover, suicidal ideation resolved by act, optimism
Precipitant	Similar circumstances can recur, acute precipitant not resolved	Stressful but transient life event, acute precipitant addressed

Definitive treatment and disposition

Following necessary medical treatment and suicide-risk stratification, disposition may involve compulsory or voluntary admission to a psychiatric or medical ward, short-term observation or discharge with appropriate follow-up. Restraint and compulsory admission may be necessary for the high-risk patient who wishes to self-discharge. Approximately 30% of DSH patients are admitted for psychiatric inpatient care, but the factors involved in the decision for psychiatric hospitalization following DSH involve a complex evaluation of risk, potential for treatment and social supports.

Patients who are intoxicated with alcohol can be both behaviourally disinhibited and emotionally labile and, as discussed, are at higher risk of intentional self-injury. Short-term observation allows intoxication to resolve so that more comprehensive and longitudinal psychiatric assessment can take place. A short-term stay in hospital can also help to resolve many acute areas of conflict and make psychiatric evaluation more accurate. ED short-stay wards or psychiatric assessment and planning units are appropriate for these admissions, especially if a multidisciplinary team is available to review the patient and to initiate management and follow-up.

Important elements of management involve addressing the modifiable elements of the precipitating problem, treating psychiatric illness and environmental interventions, such as family counselling, encouraging a support network and developing coping and problem-solving skills. Adaptive solutions to the current crisis should be reinforced utilizing short-term

Box 20.3.1 Problems in assessing suicide risk

Suicide is rare, even in high-risk groups, so it cannot be predicted without a high rate of false-negative or false-positive errors.

Suicidality presents in heterogeneous ways that may not be recognized.

Suicidality is transient and affected by intoxication, stress and being in hospital.

The patient may be reluctant, oppositional or manipulative.

The patient may present in an atypical fashion, especially the elderly with physical complaints.

Suicide risk factors identify high-risk subgroups but not individuals.

The demographic factors associated with suicide have changed recently, thus changing the make-up of risk groups.

Risk factors are based on studies of long-term follow up and, therefore, long-term risk.

Subtle changes in mental status and behaviour may be missed if not assessed by the usual doctor.

Unexplained improvement in psychological status may be the result of increased motivation to die.

Patients may deny their true intentions due to embarrassment, fear of being stopped in carrying out their own wishes, fear of being institutionalized or fear of the confidentiality of the interview.

Patients may say life is not worth living or that they feel they would be better off dead, but not necessarily have an increased risk of suicide unless they have made suicidal plans or attempts, or if they have pervasive hopelessness.

Correlation between medical danger and suicidal intent is low unless the patient can accurately assess the probable outcome of their attempts if treatment has not been received.

Box 20.3.2 Useful questions

I have seen some paperwork, but I wonder if you could let me know what happened?
While you were taking the tablets, what was going through your mind?
Did you think you had any other options?
What did you think was going to happen?
How long have you been thinking about this?
If you could change a couple of things in your life, what would they be?
How are you feeling now?
What has changed that means you are no longer feeling suicidal?
How are you coping in the emergency department?
Who is important to you? Do they know what has happened?
Are you thinking you need to be in hospital?
If you went home now do you think you'd be OK?
Do you have any plans as to how to address the issues that led you to feel suicidal?
How can we help?

(From Ryan C, Large M, Gribble R, et al. Assessing and managing suicidal patients in the emergency department. *Aust Psychiat.* 2015;23(5):513–516, with permission.)

solutions. Factors that should be addressed while patients are in hospital include referral to services to help address the dynamic risk issues, such as problems with relationships, employment, finances, housing, legal problems, social isolation, bereavement, alcohol and drug abuse, and dependence. In this regard, social workers or mental health nurses are invaluable. For greatest effect, these should be available after hours and on weekends since the majority of DSH presentations are after hours. For repeat attenders who are often socially isolated, hospitalization should not be a substitute for social services, substance-abuse treatment and legal assistance, although admission may be necessary while appropriate supports are put in place.

Dispositional decisions need to be taken, weighing up the relative and potential iatrogenic harm generated by hospitalization and the now common legal mandate for treatment in a least restrictive environment. Discharge will be with referral to community agencies with responsibility for supporting the person in the community and, according to risk assessment, may include community mental health teams, general practitioners (GPs), non-government support agencies, etc. The aim of disposition is to minimize risk factors while empowering the person to develop more positive and capable coping styles for future crises, and for timely follow-up following discharge from hospital. The plan should be clear to each patient and includes details such as how they keep their environment safe and potentially disable any plan. Safety plans may also include identifying the warning signs for the patient, internal coping strategies or social strategies to help distract them. This is in addition to contact details for professionals and agencies available in a crisis.

A number of brief contact interventions, such as postcards and single telephone calls, have been proposed following a patient's discharge from the ED. The common mechanism of action for these is suggested to be enhanced social support and suicide prevention literacy. Currently there appears to be no clear evidence to uniformly employ these for all patients with suicidal behaviour in the ED.

Pharmacotherapy has been shown to be useful in addressing the debilitating symptoms of a major depressive disorder and, along with psychotherapy, can help the person regain their previous level of functioning. Once risk and disposition have been addressed, the pharmacotherapeutic management and ongoing assessment can be by the local medical officer, who can refer as necessary to mental health specialists. Pharmacotherapy involves the treatment of the underlying psychiatric disorder. Overall, antidepressants decrease the risk of attempting suicide, although the lethality of suicide attempts is increased if tricyclic antidepressants are taken in overdose. Selective serotonin reuptake inhibitors and other newer classes of antidepressants (including Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs), Noradrenergic and Specific Serotonergic Antidepressant (NaSSa), Norepinephrine Reuptake Inhibitor (NRI) etc.) may have a more selective effect in decreasing suicidal behaviour and are less toxic in overdose than tricyclic antidepressants—the latter are no longer prescribed as first-line antidepressant medications by psychiatrists. These factors make the newer class of drugs an attractive choice for depressed patients who are suicidal. An increase in aggression in young patients initiating fluoxetine had been associated with a transient increase of suicidal behaviour. However, there is ongoing controversy surrounding the risks of different types of antidepressants.

Prevention

Comprehensive strategies for the prevention of suicide have been or are being developed in Finland, Norway, Sweden, Australia and New Zealand. Suicide prevention focuses on psychiatric, social and medical aspects, and usually involves public education, media restrictions on reporting of suicide, and school-based programmes with teacher education. Other prevention methods include the training of doctors in the detection and treatment of depression and other psychiatric disorders, alcohol and drug abuse information, enhanced access to the mental health system and supportive counselling after episodes of DSH. Decreasing the availability of lethal methods may involve legislative changes, such as more stringent gun control, restricting access to well-known jumping sites, or changes to the availability or packaging of tablets. Overall, studies into the effectiveness of suicide-prevention strategies have shown inconsistent reductions in suicide rates following interventions. Approaches to reduce DSH repetition have also shown disappointing results. Improved recognition and treatment of mental illness, improved social services and drug and alcohol-support services may be of greater benefit than specific suicide-prevention strategies.

Ethical and governance considerations

In assessing and managing patients with DSH and suicidality, the patient's desire for autonomy and self-determinism (e.g. declining recommended or reasonable treatment options, follow-up or support) must be considered in terms of their mental state, the static and imminent dynamic risk factors, the protective factors and the available support (e.g. social, family, carer, accommodation, financial, etc.) These considerations must also be balanced with the patient's capacity to provide informed consent and their human rights and dignity, against that of the paternalism of clinicians initiating immediate treatment or restricting immediate care to the ED or other inpatient setting (e.g. psychiatric inpatient unit).

Often, in circumstances of imminent risk to self, the patient's requests or demands for confidentiality may not be absolute, in so far as it is often necessary to obtain collateral history from others (e.g. GPs, psychiatrists, family, carers, etc.) and communicate with others about the immediate assessment and management of risk. Other aspects of confidentiality include local governance around accessing electronic mental health databases or clinical records that record service contact data about patients.

The disposition of ED patients who have presented with DSH or a suicide attempt must also be considered through the prism of the health service's key performance indices. For example, such key performance indices may cover response times for triage and target times for disposition from the department. Accordingly, the patient's disposition must also be considered in terms of balancing non-maleficence with utilitarianism (the 'greater goods' of accessibility, responsiveness and quality of healthcare for a community). Adapting services to most effectively assess and support these patients is an ongoing challenge for ED and requires ongoing evidence review.

The framework of care in which the above issues and dilemmas are considered is also informed by relevant local mental health, medical treatment and human rights legislation. ED clinicians should familiarize themselves with the relevant local legislation and the processes of invigilation. Health services require written policies with regard to care of suicidal patients in the ED, which cover clinical pathways with evidence-based content and the support of clinical action, including constant observation, scope of searches by staff and bodily restraint.

Conclusion

Assessment of suicide risk is an important skill in emergency medicine, since many patients present to EDs with suicidal thinking or behaviour. Although the risk of suicide for an individual patient is difficult to predict, emergency physicians can provide a system for assessment and identification of risk groups. Acute interventions can attempt to prevent short-term completion of suicide or repetition of DSH, since emergency physicians are predominantly involved in the care of these patients, often using short-stay wards. It is during this period in the ED that linkage to ongoing support services can be affected. A team approach involving psychiatry and social work is necessary

in most cases, with many problems resolved by a short-term hospital admission, brief crisis intervention and intensive short-term follow up.

20.4 Depression

Evan Symons

ESSENTIALS

1 **Clinical depression is common, affecting 2% to 5% of the population at any time.**

2 **Depressive symptoms can be accurately assessed through a systematic interview and mental state examination.**

3 **The diagnosis of depressive syndrome depends on the severity, pervasiveness and persistence of the symptoms.**

4 **Commonly comorbid conditions need to be identified, including anxiety and addictive disorders.**

5 **In the majority of cases, depressive illness can be treated appropriately in a primary health care setting. The need for specialist input and/or hospital admission reflects increasing severity and risk.**

Introduction

The need to determine the presence and severity of a depressive syndrome is a very frequent task in the emergency department (ED). Assessment of depression is necessary in relation to a variety of patient presentations. The classic ED situation is the overdose or other attempted suicide or self-harm, where the assessment of depression forms part of further evaluation after the patient has been medically stabilized.

It is also becoming more common for patients to present to the ED complaining of depression (often on the advice of family, friends or crisis help lines) without having harmed themselves. Patients with a variety of medical conditions, especially conditions that are chronic or disabling, also often develop a depressive syndrome that can form a major part of the reason behind an ED attendance. Some patients who present to EDs with personal crisis or self-harm may have been identified as suffering from a personality disorder. They are at high risk of co-morbid depression. The evaluation of depressive symptoms is also an important aspect of the assessment of patients seen in the ED with alcohol and drug abuse problems.

In these assessments, it is very important to have a clear concept of the syndrome of 'clinical depression'. This syndrome is called 'Depressive Episode' in the *International Classification of Disease*—10th edition[1] (ICD-10) and 'Major Depression' in the *Diagnostic and Statistical Manual of Mental Disorders*—5th edition (DSM-5).[2] The importance of diagnosing a depressive episode lies principally in determining the presence of a clinical syndrome, which is in need of treatment, is likely to respond to treatment and is likely to persist without treatment. The clear delineation of a depressive episode is also an essential basis for differential diagnosis from other medical and psychiatric conditions and for distinguishing between the clinical syndrome of depression and the day-to-day fluctuations of mood and states of dejection, pessimism, frustration and disappointment, which are the lot of all human beings.

The diagnosis of a depressive episode depends on the pervasive presence of enduring mood change, marked loss of interest in usual activities or marked loss of energy and drive, as well as a number of other associated symptoms. The list of symptoms contributing to the depressive episode syndrome in ICD-10 is shown in Box 20.4.1. The DSM-5 syndrome of major depression has the same list of symptoms, with the exception of 'loss of confidence or self-esteem'. An adequate number of these symptoms must be present for at least 2 weeks before the diagnosis of depressive episode can

Box 20.4.1 Symptoms contributing to the diagnosis of a depressive episode in ICD-10

1. Depressed mood, most of the day, nearly every day, largely uninfluenced by circumstances
2. Markedly diminished interest or pleasure in all, or almost all, activities, most of the day, nearly all day
3. Loss of energy or fatigue, nearly every day
4. Loss of confidence or self-esteem
5. Unreasonable feelings of self-reproach, or excessive or inappropriate guilt, nearly every day
6. Recurrent thoughts of death or suicide or any suicidal behaviour
7. Diminished ability to think or concentrate, or indecisiveness, nearly every day
8. Psychomotor agitation or retardation, nearly every day
9. Insomnia or hypersomnia, nearly every day
10. Change in appetite (decrease or increase with corresponding weight change)

be made. The pervasiveness of the symptoms is defined principally by the specifications that they must be present 'most of the day' and for 'nearly every day'.

ICD-10 further classifies depressive episodes into mild, moderate and severe, according to the total number of symptoms present (mild = 4/10 symptoms, moderate = 6/10 symptoms and severe = 8/10 symptoms). However, it is important to note that, even in mild or moderate depression, the patient must have at least two of the first three symptoms; that is, the patient must have two of depressed mood, loss of interest or loss of energy, most of the day, nearly every day, for at least 2 weeks. The diagnosis of severe depressive episode requires the presence of all three of the first three symptoms.

The diagnosis of a depressive episode does not in any way depend on the presence or absence of a precipitating life event or situation. The ICD-10 also has a category of brief depressive reaction (one of the 'adjustment disorders'), which forms part of the differential diagnosis of a depressive episode. This syndrome is defined by the presence of a precipitating life event and depressive symptoms. However, if the depressive symptoms are of sufficient number, pervasiveness and duration to qualify for the description of a depressive episode, then this diagnosis should be made regardless of the presence of a precipitant. The notion that 'this patient's depression is understandable given the circumstances' should never detract from a proper evaluation of the severity and duration of the symptoms.

Epidemiology

Clinical depression, defined as 'Major Depression' or an ICD-10 'Depressive Episode', is a very common condition. Extensive epidemiological community surveys in many populations around the world have established that the 6-month prevalence rate of major depression is in the range of 2% to 5% in any population.[3] The epidemiological research has also shown that only a minority of persons with current depressive syndromes are receiving active treatment.[3]

The age onset of the first depressive episode is typically in the third decade, but can be at any age. The male to female ratio is 1:2. A person who has had one episode of clinical depression has an 80% chance of recurrence, and patients with recurrent depression have an average of four episodes in their lifetime.[4]

Incomplete recovery is common. Studies of hospitalized patients have shown that, while at least 50% of patients recover from an index episode within 6 months, 30% remain symptomatic for more than 1 year and 12% for more than 5 years.[5]

There is some evidence for an increase in the prevalence of Major Depression and a younger age of onset, over the last 40 years.[6]

Aetiology

The aetiology of depression is complex, involving both genetic and environmental factors. Important environmental factors include childhood experiences of adversity or neglect and stresses in adult life. The effect of genetic factors may be mediated, in part, through inherited predispositions to excessive worry and anxiety.[3]

Precipitating life events, especially those involving loss, are known to play a part in triggering individual episodes of depression.[7] This effect is greatest for the first episode of depression. Second and subsequent episodes are more likely to occur without identifiable precipitating events,[8] suggesting that the first episode has a neurobiological priming effect.[9]

Neurobiological changes in depression are also complex. Based, in part, on the supposed mechanism of action of antidepressant medication, early work focused on evidence of depletion of amine neurotransmitters in the central nervous system.[10] More recent research has suggested depression may involve alterations in neural cell populations, especially in the hippocampus.[11]

Prevention

Depression is a major public health problem. The World Health Organization has recently estimated that 322 million people are living with depression worldwide. Depression is responsible for 7.5% of all years lived with disability, making it the 'single largest contributor to non-fatal health loss' globally.[12] Public health measures have included campaigns to raise awareness of depression both in the general public and in health care providers. ED staff can play a very significant role in case identification and in ensuring referral for effective treatment.

Clinical features

The syndrome described as a 'Depressive Episode' (or 'Major Depression') is defined principally by its symptoms and, to a lesser extent, signs. As the severity of the depressive episode is also dependent on specific characteristics of the individual symptoms and signs (as well as the total number of symptoms), it is also important to understand the varieties of their manifestations.

Symptoms

It is useful to start the history with an exploration of the problem that has brought the person to the ED. This problem may be an overdose or other attempted suicide or self-harm, a personal or relationship crisis, a period of alcohol or other drug abuse, an exacerbation of a chronic medical condition or chronic pain or some other complaint. It is also important during the clinical assessment to begin to form some picture of who the patient is, including whether he or she lives alone or with others, the nature and quality of his or her personal relationships and his or her daily occupation, interests and activities. These inquiries not only assist in building rapport through demonstrating an interest in the patient, but also elicit information that is necessary for understanding the patient's symptoms in context.

At some point, the patient can be told that the interviewer would now like to explore the symptoms of depression in more detail. It may be helpful to group the symptoms of the depressive episode (see Box 20.4.1) into various domains of the patient's experience. The first group ('depressed mood', 'markedly diminished interest' and 'loss of energy') refers to the pervasive mood state and the quality of the patient's spirits or enthusiasm for life. The second group ('loss of self-esteem', 'unreasonable self-reproach or guilt' and 'recurrent thoughts of death or suicide') refers to the cognitive contents of the patient's thoughts. The third group ('diminished concentration' and 'psychomotor agitation or retardation') refers to the degree of agitation or lethargy associated with the patient's thought processes and physical activity. The final group ('insomnia or hypersomnia' and 'change in appetite') refers to physiological changes.

Both the pervasiveness and duration of these symptoms should be assessed. The syndrome is, by definition, one in which the symptoms have become persistent and inescapable, not the occasional or sporadic experience of these symptoms that nearly everybody endures sometimes. Duration is important because the syndrome must be present for at least 2 weeks before the diagnosis can be made, although often the patient may have been unwell much longer than this.

The timing of onset of a depressive episode can be difficult to establish because the onset is often very gradual and insidious (although it can be relatively rapid). The patient may have experienced previous episodes, which become confused with the present one, and patients often confuse long-term feelings of low self-esteem with the current episode. Hence, the question 'How long have you been feeling like this?' is often unproductive. It is more useful to ask the patient to describe the presence and pervasiveness of each of the symptoms 'during the last 2 or 3 weeks or so' and, in particular, to try to identify some recent time at which there has been a change in the clinical state or function of the patient.

The pervasiveness and duration criteria taken together imply a diminished ability to carry out normal activities and to meet responsibilities. Although many depressed patients push themselves to keep going, careful enquiry reveals that this has become more arduous. Difficulty in attending to tasks may range from diminished effectiveness at work, child care or study to, eventually, neglect of self-care and nutrition. Thus impairment in function is another indicator of the severity of the episode.

'Depressed mood, most of the day, nearly every day' is perhaps the most difficult of the symptoms to characterize. 'Mood' refers to a person's underlying emotional state, the emotional baseline that permeates each day. It is useful to ask not only 'Do you feel depressed?' but also 'What is that like for you?' Some patients describe feeling much more unhappy than usual or sad all the time or unexpectedly tearful; others report feeling more irritable with others or more inclined to worry. The severity of the mood change may be shown in a loss of mood reactivity, which can be elicited by asking 'Can you cheer yourself up, take your mind off your worries?' and 'Do you find that the things that normally make you happy don't seem to cheer you up as much as usual?'

'Markedly diminished interest or pleasure in all, or almost all, activities, most of the day, nearly every day' is somewhat easier to assess, especially if the interviewer takes the time to build up a picture of the patient's usual day. With careful inquiry, a nuanced picture can be built up of the extent of the patient's withdrawal from his or her usual activities. Included within this criterion is a lack of pleasure or interest in sexual activity.

'Loss of energy or fatigue, nearly every day' is an important symptom, which is sometimes overlooked. The emphasis should be on the loss of energy; that is, whether the patient is aware of having much less energy or drive than usual. In severe cases, the patient may describe feeling the body is heavy or thoughts are sluggish, at which point this symptom overlaps with 'psychomotor retardation'. Loss of energy is an important symptom in differential diagnosis, which may point to such conditions as anaemia, hypothyroidism, diabetes or other undiagnosed medical conditions.

The cognitive symptoms of depression ('loss of self-esteem', 'unreasonable self-reproach or guilt' and 'recurrent thoughts of death or suicide') can to some extent be observed in listening to the patient's spontaneous comments and, as such, form a part of the mental state examination. However, patients who are more introspective have some awareness of a change in thought processes and are able to describe the ways in which their thoughts have become more gloomy than usual. This insight is lost when depression becomes more severe and the patient tends to regard the self-reproach or thoughts of suicide as entirely justified.

In assessing 'loss of confidence or self-esteem', the emphasis should be on the loss or change in the person's self-concept. It can be helpful to approach the issue with suggestive questions, such as 'Tell me about a time when you felt better about yourself', 'Did you used to feel more confident at work?' or 'Was there a time when you felt more adequate as a parent?'

'Unreasonable feelings of self-reproach or excessive or inappropriate guilt, nearly every day' is probably one of the most consistently reliable symptoms pointing to a diagnosis of depressive episode. Sometimes, a very conscientious person may habitually find fault with him- or herself without being clinically depressed. However, a person who is not depressed will usually be able to consider other points of view, to debate the sense of culpability internally and to consider whether the sense of guilt may be 'excessive', 'inappropriate' or 'unreasonable'. This capacity to rationalize about thought processes becomes progressively more impaired as the patient becomes more severely depressed, until the patient's guilt appears unquestionable.

In psychotic forms of depression, the sense of guilt may take on bizarre dimensions in which the patient can feel responsible for all the evil in the world or for distant events. A not uncommon experience is for the patient to see a report on the television of a calamity, such as an earthquake, and to feel responsible for the event.

'Recurrent thoughts of death or suicide' can arise in a depressive episode in a variety of ways. Not uncommonly, the thoughts may simply come into the patient's mind; the patient reports having thoughts of being dead, wanting to be dead or thoughts of suicide that are uncharacteristic, unbidden and unwanted, without any intention to act on these thoughts. Sometimes the suicidal thoughts are directly linked to excessive or delusional guilt, in which the patient feels his or her death to be necessary and inevitable; here the risk of suicidal action is very high.

In other cases, the suicidal thoughts are a logical consequence of a sense of hopelessness, a lack of faith in the future. This last type of suicidal ideation is less specific for the diagnosis of depressive episode, as it may also reflect an apparently realistic appraisal of life circumstances, an attitude of philosophical pessimism or poor coping skills in a person with impaired personality function. These distinctions are important because the suicidal ideation, which is a part of a depressive episode, may be expected to resolve with treatment of the depression, whereas the other forms may not.

'Diminished ability to think or concentrate or indecisiveness, nearly every day' is a relatively straightforward symptom to assess and is useful as an indicator of the severity of the depressive episode. It can be assessed by asking about ability to focus on work or a recreational activity, such as watching television or reading a book. Some patients report that their mind is easily distracted or restlessly inattentive. Many report the intrusion of negative ruminations (concerning lack of worth, sense of failure or guilt, thoughts of suicide or other worries), which go round and round in their minds. Progressive impairment in the capacity to concentrate will demonstrate increasing severity of depression; a severely depressed patient may not even be able to focus on one newspaper story and take in the contents.

'Psychomotor agitation or retardation, nearly every day' refers to abnormalities of movement, facial expression, speech and thought processes, which are directly assessed in the mental state examination and are discussed more fully below. However, this can also to some extent be assessed through the history from the family. 'Psychomotor agitation' includes restless, fidgety behaviour, the inability to sit still or attend to a task, and anxious, repetitive speech or even perseveration. 'Psychomotor retardation' includes lack of spontaneous bodily movement, lack of facial expression, lack of verbal communication and slowness of response. Retardation is the more common and the patient or family may report progressive withdrawal and decrease in activity to the point where the patient sits for long hours apparently doing nothing. The presence of significant psychomotor agitation or retardation is usually indicative of a severe depressive episode.

Changes in sleep pattern ('insomnia or hypersomnia, nearly every day') are very common in depression, even in mild episodes. It is worth enquiring in detail about the specific changes in sleep pattern, as these relate to the severity of the depressive episode. Initial insomnia or delay in the onset of sleep is not specifically associated with depression, as it can be strongly associated with anxiety or primary insomnia. Middle insomnia (waking after 2 or 3 hours of sleep) and early morning waking are more specific to depression. The extent of difficulty the patient has in going back to sleep and the mood and thought content when awake during the night are also relevant.

Change in appetite may involve an increase or decrease with corresponding weight change. Severe loss of appetite with marked loss of weight, in the absence of medical illness or deliberate dieting, is associated with severe depression.

Signs

The most important signs are:

- signs of psychomotor agitation or retardation
- the affective state of the patient

- the thought content
- the degree of insight.

The patient with psychomotor agitation demonstrates, in milder forms, fidgety or repetitive behaviours, such as hand wringing or sighing. This can progress to an inability to sit still and, eventually, continuous pacing. The patient may say little while looking very apprehensive and preoccupied or may importune all the staff with repetitive, anxious questions, apparently seeking reassurance, which is never achieved. In severe cases, speech becomes perseverative.

By contrast, the psychomotor-retarded patient maintains a relative immobility, lying in bed or sitting in a chair for long periods, with infrequent changes in posture. The face may be relatively expressionless, look sad or show an anxious dread. Both the facial expression and the body language show diminished reactivity during interview. There is little spontaneous speech and, if responses to questions can be elicited, the responses lack richness, depth or elaboration. Slowness of thought processes is shown especially by a marked increase in the time taken to supply an answer to a question. In severe cases, the patient may be mute.

The affective state of the depressed patient during the interview is most often sad, but sometimes anxious or even hostile. As the depression becomes more severe, the patient tends to show a diminished range of affects and has an impaired affective reactivity (e.g. the patient does not smile in response to social cues).

During the interview it is important to observe the themes evident in the patient's spontaneous conversation. Themes of despair, failure, guilt and death are typical of a depressive episode. The degree of insight may be a marker of the severity of the depressive episode.

Variants

Melancholic depression

Some severe depressive episodes can be distinguished, which have severe mood symptoms, marked changes in physiological function and significant psychomotor agitation or retardation.

This form of the depressive syndrome is designated 'Major Depression with Melancholic Features' in DSM-5 and 'Depressive Episode with Somatic Syndrome' in ICD-10. The ICD-10 criteria for the 'somatic syndrome' are shown in Box 20.4.2. At least four of the eight symptoms must be present to make the diagnosis. Most 'depressive episodes with somatic syndrome' are also likely to meet the criteria for 'severe depressive episode'.

The clinical significance of making the diagnosis of melancholic depression is that this form of depression is likely to require intensive biological treatment.

Box 20.4.2 ICD-10 criteria for the 'somatic syndrome' (melancholia)

1. Marked loss of interest in activities that are normally pleasurable
2. Lack of emotional reactions to events or activities that normally produce an emotional response
3. Waking in the morning 2 hours or more before the usual time
4. Depression worse in the morning
5. Objective evidence of marked psychomotor retardation or agitation
6. Marked loss of appetite
7. Marked loss of libido

(From World Health Organization. *The ICD-10 Classification of Mental and Behavioural Disorders.* Geneva: WHO; 1993.)

Most of the symptoms contributing to the diagnosis of the 'somatic syndrome' are more severe and are more specific forms of the symptoms of a 'depressive episode.' It is not just any sleep disturbance, but marked early morning waking which is important. Similarly, it is not just a change in appetite, but a significant (more than 5% of body weight) loss of weight, which is important. The presence and severity of the psychomotor agitation or retardation is the most important sign, since these phenomena can be objectively and systematically observed and rated.[13]

Psychotic depression

This is discussed in Chapter 20.5. The patient with a psychotic depression will usually meet the criteria for a severe depressive episode, often with the 'somatic syndrome'.

Mild and moderate depressive episodes

In clinical practice, it is usually not difficult to recognize a 'severe' depressive episode.

Greater uncertainty may be associated with making the diagnosis of 'mild' or 'moderate' depressive episode, especially in patients who have a long-term history of poor self-esteem or are temperamentally inclined to worrying, moodiness or irritability. Some research evidence[14] suggests that these temperamental factors can affect the presentation of the depressive syndrome. Thus a person who is a habitual worrier who develops a depressive episode is likely to worry more and perhaps to withdraw from social contact or abuse alcohol or anxiolytic drugs. A person who tends to be moody or irritable is likely to become more so in a depressive episode and may appear demanding, complaining and unreasonable.

Nevertheless, the essential and salient characteristic of even a mild or moderate depressive episode is that the patient has a persistent mood change for at least 2 weeks. The interviewer should focus on the symptoms of depressed mood, loss of interest and loss of energy because it is the enduring presence of these symptoms, which makes the diagnosis clear. Of the additional symptoms contributing to the diagnosis of depressive episode, probably the most common are difficulty with sleep and diminished ability to think and concentrate.

A patient with persistent depressed mood and impaired concentration almost certainly has some functional impairment. A useful approach to this question is to ask the patient about normal daily activities and then assess the extent to which these activities are disrupted by the symptoms. Can the patient do household chores? Does this require unusual effort? Can the patient go to work? Is the patient functional at work? Are even simple leisure activities like watching television disrupted by the patient's mood state? It is this evidence of change in function that permits the identification of a mild or moderate depressive episode, regardless of pre-existing temperamental vulnerabilities.

Depression in the elderly

The symptoms of depression in older people are generally very similar to those in younger age groups and should be assessed in a similar way.[15] Symptoms, such as loss of energy, insomnia or change in appetite, also may be influenced by co-morbid medical illness, but a persistent mood change or loss of interest should prompt consideration of a depressive episode. Older people may tend to minimize their feelings of depression and, in these cases, a collateral history of loss of interest in usual activities may be found. Not uncommonly older people are seen in the ED following an overdose that may appear medically trivial. These patients should always be carefully assessed for the presence of a depressive syndrome.

'Pseudo-dementia' is a term used to describe patients with a depressive syndrome who present with an apparent change in cognitive function. The patient with depressive pseudo-dementia is likely to have a relatively recent and relatively abrupt change in concentration and memory. In contrast to the patient with dementia, the patient with pseudo-dementia usually shows a great awareness of having memory difficulties and will tend to demonstrate the impairment to the interviewer with considerable anxiety. In addition, the patient with depressive pseudo-dementia manifests other symptoms of a depressive episode.

Differential diagnosis

The differential diagnosis of the depressive syndrome is important because there are several other clinical disorders involving depressed mood or other symptoms of depression, which have a different prognosis and treatment.

Brief depressive reaction

A brief depressive reaction (also called 'Adjustment Disorder with Depressed Mood' in DSM-5) can be diagnosed when a person experiences some depressive symptoms without meeting the full criteria for a depressive episode, following stressful life events. Typically, the person describes a depressed mood which is not persistent; that is, there are good days and bad days and the depressed mood can be relieved by distraction or pleasant activities. Common stressful life events include relationship crises or other interpersonal conflicts.

This is often the diagnosis in patients who are seen in the ED following an overdose, although care should be taken to inquire about symptoms of a depressive episode. Treatment involves brief psychotherapy aimed at helping the person achieve some resolution of the personal crisis. If the hospital has a crisis counselling service, the patient can be referred to that service for brief therapy. Alternatively, the patient can be referred to their general practitioner (GP) or other community counselling service. Social work staff in the ED often have good knowledge of local crisis counselling services.

Grief

The symptoms of acute grief can be mood disturbance, guilt, impaired concentration, sleep and appetite disturbance, impaired function in daily activities and preoccupation with memories of the deceased.[16] There is a considerable overlap with the symptoms of a depressive episode. However, it is customary to respect the feelings of the bereaved and to recognize that it is usually beneficial for the person to be supported through the natural process of grief, preferably by family, friends or other familiar persons, such as the family GP.

However, if the symptoms become more severe or more prolonged (such as beyond 6 months), it is appropriate to consider the diagnosis of a depressive episode. Symptoms suggestive of the development of a depressive episode include persistent and progressive lowering of self-esteem, persistent thoughts of death and suicide, markedly impaired concentration and psychomotor retardation.

Bipolar depression

ICD-10 specifies that in a person who has a history of bipolar disorder, a diagnosis of 'depressive episode' should not be made even if the patient meets the criteria for a depressive episode. Instead, the diagnosis of 'bipolar affective episode, current episode mild, moderate or severe depression' should be made. The distinction is important because of the treatment and prognosis. In particular, antidepressant medication should be used very cautiously in the person with bipolar disorder because of the risk of provoking a switch to mania.

Box 20.4.3 Signs contributing to the diagnosis of a manic episode in ICD-10

1. Increased activity or physical restlessness
2. Increased talkativeness ('pressure of speech')
3. Flight of ideas or subjective experience of thoughts racing
4. Loss of normal inhibitions, resulting in behaviour that is inappropriate to the circumstances
5. Decreased need for sleep
6. Inflated self-esteem or grandiosity
7. Distractibility or constantly changing activity or plans
8. Behaviour that is foolhardy or reckless
9. Marked sexual energy or sexual indiscretions

(From World Health Organization. *The ICD-10 Classification of Mental and Behavioural Disorders*. Geneva: WHO; 1993.)

The symptoms of a bipolar depressive episode are in themselves not consistently different from the symptoms of any other episode of depression. The distinction therefore rests on a previous history of treatment for bipolar disorder or a history of a manic episode that may not have been treated.

A manic episode, as defined in ICD-10,[1] involves an elevated or irritable mood sustained for at least a week and at least three (or at least four if the mood is only irritable) of the signs shown in Box 20.4.3. Mania is discussed in more detail in Chapter 20.5.

The depressed patient seen in ED who is suspected of having a bipolar disorder should usually be referred to a psychiatrist for assessment and treatment. Bipolar disorder is a life-long condition, with a high rate of recurrent episodes, which requires specialized pharmacological and psychological management.

Organic mood disorder

Many medical conditions (Box 20.4.4) are especially associated with a typical depressive syndrome. Because the medical condition is considered likely to have a pathophysiological significance in the development of the depressive syndrome, these conditions are termed 'organic mood disorders'.

Occasionally, the depressive syndrome may be the first presentation of a previously undiagnosed medical illness. Clinical or laboratory evidence of hypothyroidism was found in 5% of patients with a depressive syndrome in one series.[17] Hypercalcaemia due to unsuspected hyperparathyroidism very occasionally presents with depressed mood, lethargy or cognitive change as the presenting symptoms.[18] The first presentation of pancreatic cancer with a depressive syndrome is well recognized.[19] A depressive syndrome may be the first presentation of Huntington disease, before the onset of the movement disorder, and the diagnosis will only be suggested by the family history.[20] Some patients with HIV infection have been found to present with a mood disorder before manifesting other symptoms of AIDS.[21] Because many medical conditions associated with depressive symptoms involve central nervous system disease, any neurological signs should prompt investigation for an unsuspected cerebral tumour, for example.

Box 20.4.4 Medical conditions associated with depressive syndrome

Hypothyroidism
Hypercalcaemia
Pernicious anaemia
Pancreatic cancer
Lung cancer
Stroke
Alzheimer dementia
Vascular dementia
Parkinson disease
Huntington disease
AIDS
Central nervous system tumour
Multiple sclerosis
Neurosyphilis
Brucellosis

However, more commonly, the depressive syndrome presents in a patient with an already recognized medical illness. In these cases, it is important to evaluate carefully the severity and persistence of the depressive symptoms and not dismiss them as an understandable reaction to the illness. Symptoms, such as loss of energy, sleep disturbance and anorexia, may be difficult to evaluate as they may be related to other pathophysiological change, but the patient with persistent depressed mood, loss of pleasure in activities, marked loss of self-esteem and feelings of guilt or hopelessness is likely to be experiencing a depressive episode. If such a depressive episode is diagnosed and treated, the patient will experience relief of suffering and a greater ability to deal effectively with other medical problems.

Many drugs have been associated with depressive symptoms, often based on only a few case reports.[22] Medications with a particularly strong association with depression include interferon, isotretinoin, methyldopa, benzodiazepines, digitalis, β-blockers, oral contraceptives and corticosteroids. A useful approach is to consider drugs that have recently been introduced in relation to the time course of the depressive symptoms.

Mood disorder due to psychoactive substance use

Chronic alcohol misuse is frequently associated with depressed mood, low self-esteem and feelings of guilt and hopelessness. Severe sleep disturbance can also be precipitated by rebound wakefulness as blood alcohol levels

fall during the night. The person who regularly abuses alcohol is also likely to experience fatigue, impaired concentration, appetite disturbance and loss of sex drive. These symptoms may mimic those due to a depressive episode, such that it is not possible to make a differential diagnosis of a depressive episode while the patient continues to drink, nor is it likely that the depressive symptoms will remit without abstinence. Patients with alcohol-induced mood disorders should be encouraged to attend alcohol detoxification and rehabilitation programmes. There is some evidence that antidepressant medication may help to reduce both depressive symptoms and alcohol consumption.[23]

Amphetamine withdrawal is often associated with a markedly depressed mood, which usually improves within a few days if the patient remains abstinent.

The abuse of alcohol and other drugs is sometimes an attempt to self-medicate for a pre-existing depressive syndrome. This history should be especially sought in the patient whose abuse of alcohol or other drugs is of recent onset or follows important life change, such as bereavement or divorce. However, even if a pre-existing depressive syndrome is identified, the patient should be informed that treatment of their substance use problem is an important component of recovery.

Dysthymia

Dysthymia refers to a chronic form of depression in which the patient experiences symptoms, such as lack of enjoyment in life and a gloomy or pessimistic outlook, without meeting the full criteria for a depressive episode. The depressed outlook tends to become interwoven with the personality of the patient, who tends to be sombre, self-critical and lacking in confidence and motivation. Dysthymia often has onset in early adult life and can persist for many years. The disorder has been well characterized[24] and found to be relatively common (about 3% of the general population) in epidemiological studies.[25]

Sometimes, patients with a dysthymic disorder develop further symptoms indicating a superimposed depressive episode, which can be termed a 'double depression'.

Patients with dysthymia may present to EDs as a consequence of suicidal ideation or behaviour. The condition should be regarded as serious because of its chronicity. The patient should be referred to a psychiatrist or mental health service as treatment can be difficult.[26]

Anxiety

Anxiety disorders include panic disorder (recurrent panic attacks), generalized anxiety disorder (persistent worrying associated with muscular tension and autonomic symptoms), obsessive–compulsive disorder and phobic disorders, such as agoraphobia or social phobia. Any of the symptoms of each of these anxiety disorders may occur as part of the symptoms of a depressive episode if a person with a pre-morbid anxious temperament becomes depressed. However, primary anxiety disorders are also common. In these cases, the patient gives a history of typical anxiety symptoms usually extending over many months or even years. Many patients with primary anxiety disorder go on to also develop a depressive syndrome.

Because of both the overlap in symptoms and the frequent co-morbidity, it may be difficult to distinguish primary anxiety disorders from primary depressive disorders in the emergency setting. Probably the most important symptoms are persistent depressed mood and suicidal ideation, which may require inpatient treatment. Patients who do not have persistent depressed mood and suicidal ideation, but who have a mixture of other depressive symptoms and anxiety symptoms, can be safely directed to their GP or to an outpatient mental health service for further evaluation.

Personality disorder

The concept of personality disorder refers to enduring patterns of behaviour, including especially interpersonal behaviours, which are well outside the usually sanctioned range of behaviours in a particular culture and which are associated with substantial subjective distress or conflict with others. The diagnosis of personality disorder should only be made if the behaviour patterns are persistent, relatively inflexible and have been present since a young age, often beginning in childhood or adolescence.

Although a variety of specific personality disorders have been described, the two most common forms in the ED are antisocial personality disorder and borderline personality disorder.

Persons with antisocial personality have a long-term history of disregard for social rules, usually resulting in a chequered employment history, broken relationships and often violent or criminal behaviour. As a result of personal crisis precipitated by these behaviours, persons with antisocial personality not infrequently present to ED with acute brief depressive reactions, helplessness and suicidal ideation or behaviour. Assessment should be especially directed at clarifying if a superimposed persistent depressive episode is present and the severity of this episode.

Inpatient psychiatric treatment is problematic because the patient often has difficulty adhering to ward rules and expectations. If the depressive symptoms are not severe and seem to be reactive to recent stressors, it is preferable to try to engage the patient in a realistic discussion of the current problems and, if possible, make a referral to crisis counselling. However, in some cases, when the depressive symptoms are more severe and the risk of suicidal behaviour is high, it may be necessary to arrange inpatient admission.

The person with borderline personality disorder displays erratic interpersonal behaviour, as well as considerable impulsivity and recklessness. The interpersonal behaviours include a strong tendency to see others in 'all good' or 'all bad' terms, and to react dramatically to perceived rejection or abandonment. Reckless and impulsive behaviours include abrupt breaches in relationships, alcohol and other drug abuse, and self-damaging acts, such as cutting. Persons with borderline personality often describe chronic feelings of emptiness and loneliness, often associated with suicidal ideation. These features are sometimes misdiagnosed as depression when they may actually represent the patient's usual way of feeling rather than a discrete depressive episode. Because borderline personality disorder is a long-term condition, intervention with the patient who presents in the ED in crisis should, if possible, be directed towards facilitating or enhancing the patient's engagement with outpatient treatment services.

As many as 50% of patients with borderline personality may also meet the criteria for a depressive episode at any one time.[27] Although a diagnosis of borderline personality may have been made on the basis of the longitudinal history, it is therefore also important to try to assess the severity, persistence and duration of current depressive symptoms. If the patient is already engaged with an outpatient mental health clinician, it is useful to liaise with the therapist regarding recent symptoms and function.

Assessment

The assessment of the patient for depression should cover:

- the current social circumstances of the patient
- recent stressors or precipitating events
- thorough evaluation of the symptoms of the syndrome of clinical depression and their severity
- consideration of previous depressive or manic episodes
- mental state examination
- risk assessment
- consideration of possible medical illness as a cause of symptoms
- detailed evaluation of alcohol and other drug use
- identification of treatment services already available to the patient.

It is generally a good idea to start the interview with some basic social information. Does the

patient live alone? How is he or she occupied or employed? Is there a supportive relationship or other family? This information assists in understanding the context of the symptoms and helps with treatment planning.

Exploration of precipitating events is important partly because these worries are likely to be occupying the mind of the patient, and discussion of these issues helps to build rapport in the interview.

Identification of the presence and severity of the depressive symptoms is the most important part of the assessment. Unfortunately, it is often not done systematically and the 'diagnosis' of depression is made only on the basis of a patient's statement about 'being depressed' and one or two other symptoms, such as sleep and appetite disturbance. Systematic evaluation requires detailed exploration of the symptoms described above. Particular attention should be paid to the persistence, pervasiveness and duration of the symptoms. If this systematic approach is taken it is possible to determine:

- if the syndrome of clinical depression is present or not
- the severity of the syndrome.

The proper diagnosis of a depressive syndrome and the assessment of the severity of the syndrome are of major importance in treatment planning.

There may be insufficient time in an emergency interview to explore fully the previous psychiatric history. However, it is useful to ask if the patient has been depressed before, whether or not any previous episodes were treated and what was the response to previous treatment. It is also important to identify any previous episodes of mania in case the depressive episode may be a presentation of bipolar disorder.

Mental state examination focuses on the signs described above. Persistently sad affect and noticeable psychomotor agitation or retardation are indicators of more severe depression. Similarly, if the patient's conversation is very preoccupied with themes of failure, despair, guilt or death, the depression is likely to be more severe. Inquiry about these matters should be extended to look for delusional beliefs. Useful questions may include 'Do you feel responsible for bad things happening?', 'Do you feel there is something drastically wrong with you?' or 'Do you believe you deserve punishment?' Understanding the patient's level of insight into his or her condition is also important to treatment planning, particularly if involuntary treatment should become necessary due to the risk of suicide.

Risk assessment is multifaceted. If the patient has attempted suicide through overdose or other means, inquiry should be made about the circumstances of this attempt, the patient's understanding of the lethality of the attempt and whether or not the patient sought help afterwards or made an effort to conceal the attempt. The patient's current thoughts about suicide and his or her attitude to suicide are also relevant. Many patients admit to having thoughts of suicide but indicate that they would be deterred from suicidal action by, for example, having responsibility for dependent children. The disappearance of these 'protective factors' from a patient's considerations is an indicator of worsening risk. Patients with psychotic depression may be at higher risk because they lack such 'emotional' constraints on suicidal behaviour. Other factors associated with increased suicide risk include lack of supportive relationships, living alone, being unemployed and current alcohol abuse.

Risks of self-neglect, malnutrition and dehydration also need to be considered.

A primary medical condition causing depressive symptoms is likely to be suggested by other symptoms and signs or be pre-existing. There are no mandatory investigations for the assessment of a depressive episode, although checking haemoglobin and thyroid biochemistry is sensible.

Inquiry should be made about alcohol and other drug-use patterns and, especially, recent changes in pattern use. A person with long-standing alcohol or other drug abuse is likely to have a substance-induced mood disorder and needs to address this as the major focus of treatment. A recent marked increase in alcohol or other drug use may indicate an attempt to self-medicate for a depressive syndrome.

It is always useful to ask the patient if she or he is currently seeing a psychiatrist, psychologist or other mental health therapist or has a good relationship with a trusted GP. These existing health care professionals can often be the natural starting point in planning treatment interventions.

Treatment

Treatment for a depressive episode involves the prescription of specific antidepressant medication or a specific course of psychotherapy or both.

Medications

Commonly used first-line antidepressant medications are shown in Table 20.4.1. Because none of these medications has been shown consistently to have superior efficacy, the choice of medication is based on the acceptability of the side-effect profile and previous treatment response.

The selective serotonin re-uptake inhibitors (SSRIs) are usually well tolerated and are a good first choice. Some patients experience agitation, nausea or gastrointestinal hyper-motility when they start SSRI medications. These symptoms usually settle in a week or two. The most troublesome long-term side effect of SSRIs is sexual dysfunction (especially delayed ejaculation or anorgasmia). These side effects sometimes require a change of medication. The side effects of serotonin-noradrenaline reuptake inhibitors (SNRIs), such as venlafaxine and duloxetine, are similar to SSRIs, with the addition of excessive sweating and itch at high doses. Abrupt discontinuation of SNRIs is associated with a range of unpleasant symptoms (including headaches, nausea and emotional lability).

Mirtazapine has useful sedating properties and can be very helpful in a patient with marked insomnia or agitation. Because it stimulates appetite, its use is limited in patients with a weight problem. Mirtazapine, reboxetine and moclobemide are useful alternatives for patients

Table 20.4.1 Commonly used antidepressant medications

Drug	*Class*	*Usual daily oral dose range (mg)*	*Half-life (h)*
Fluoxetine	SSRI	20–60	24–144
Citalopram	SSRI	20–40	23–45
Escitalopram	SSRI	10–20	27–32
Fluvoxamine	SSRI	100–300	9–28
Paroxetine	SSRI	10–40	3–65
Sertraline	SSRI	50–200	22–36
Venlafaxine	SNRI	75–225	3–7
Moclobemide	RIMA	450–600	1–3
Mirtazapine	–	30–60	20–40
Reboxetine	–	8–10	12–13
Duloxetine	SNRI	60–120	12

RIMA, Reversible monoamine oxidase inhibitor; *SNRI*, serotonin and noradrenaline re-uptake inhibitor; *SSRI*, selective serotonin re-uptake inhibitor.

who experience sexual dysfunction with SSRIs or SNRIs.

Tricyclic antidepressants (e.g. imipramine, amitriptyline and dothiepin) and irreversible monoamine oxidase inhibitors (MAOIs; phenelzine and tranylcypromine) continue to be prescribed for some patients, but they tend not to be first-line drugs. The use of tricyclics has decreased because of side effects (especially anticholinergic) and because of their cardiac toxicity in overdose. Irreversible MAOIs are generally inconvenient to take because of the need for dietary restrictions.

Psychotherapy

The psychotherapies commonly used for depression include supportive psychotherapy, cognitive behavioural therapy (CBT), interpersonal psychotherapy (IPT), acceptance and commitment therapy (ACT) and mindfulness-based cognitive therapy. Most psychiatrists and clinical psychologists have appropriate training and skills to offer one or more of these therapies. Many GPs and other health professionals, such as social workers, nurses and occupational therapists, also have received training in these therapies.

Supportive psychotherapy is the least well defined of the psychotherapeutic treatments. The core of the treatment is a supportive relationship, education about the nature of depression and practical advice.

CBT is a structured psychotherapy, usually involving 10 to 20 sessions. The behavioural techniques include reversing social isolation, scheduling relaxing or pleasurable activities and working with family members to provide incentives for helpful behaviours. The main part of the therapy involves 'cognitive restructuring', a systematic exploration of the patient's unhelpful thought patterns, followed by collaborative work to help the patient substitute more positive responses.[28]

IPT is also a structured psychotherapy, typically of about 16 sessions. The therapy focuses on helping the patient to make changes in his or her interpersonal relationships, which may be contributing to the depressive syndrome.[29]

ACT is a mindfulness-based behavioural psychotherapy, which encourages individuals to accept negative experiences that cannot be avoided and to make decisions to establish an authentic and fulfilling life.[30]

Mindfulness-based cognitive therapy combines the principles of CBT with mindfulness-based stress reduction techniques.[31]

Evidence

All currently available antidepressants have been shown to achieve better symptom reduction than placebo, with no one antidepressant consistently demonstrating superior efficacy.[32] In drug trials, up to 40% of patients in the placebo arm have shown improvement, which may include the non-specific effects of supportive interventions as well as spontaneous remissions.[33] As the natural history of depression in a community sample (which includes relatively minor, untreated cases) shows a median episode duration of 12 weeks, spontaneous remission appears to be common.[34] Patients with psychotic depression respond better to the combination of an antidepressant and an antipsychotic medication than to an antidepressant medication alone.[35]

Both CBT and IPT have been shown to be effective in achieving symptom reduction compared to pill placebo control.[36,37] CBT and IPT have been shown to be as effective as medication for mild-to-moderate depression.[37] The treatment of severe depression with psychotherapy alone is supported by some evidence[38] but remains controversial.

There are no systematic data regarding supportive psychotherapy (as it is not a standardized treatment) but substantial clinical experience attests to its efficacy.

Mild-to-moderate depressive episodes

As long as the suicide risk is containable, the great majority of these patients can be treated as outpatients. Therefore the most important part of treatment planning in the ED is to identify an appropriate referral pathway. If the patient is already in contact with a mental health professional or has a trusted GP, it is preferable to refer the patient back to these persons and, if possible, make phone contact with that doctor or therapist with advice regarding the emergency presentation. If the patient does not have their own doctor or mental health professional, it is appropriate to refer the patient to an outpatient mental health service.

Patients with mild-to-moderate depressive episodes can improve with either medication or psychotherapy and can be advised to discuss these treatment options with the follow-up doctor. It is not essential to start the antidepressant medication in the ED; it is probably more appropriate to leave this to the follow-up doctor who can monitor for efficacy and side effects.

Some patients may only have mild-to-moderate symptoms but, nevertheless, be at significant suicidal risk, associated with recent suicidal behaviour and persistent suicidal ideation. The risk is increased if the patient lives alone. Such patients require admission to a psychiatry ward, where the options for medication and psychotherapy can be further explored.

Severe depressive episodes

Most patients with severe depressive episodes will be admitted because of significant suicide risk or substantial functional impairment. The evidence suggests that these patients require treatment with antidepressant medication and are often initially too symptomatic to engage in psychotherapy. Classical indications for electroconvulsive therapy are psychotic depression and severe retarded depression (especially if the patient has inadequate oral intake).

CONTROVERSIES AND FUTURE DIRECTIONS

- Population-based studies indicate that clinical depression is very common, possibly increasing in prevalence and significantly undertreated.
- A major challenge for all health services is to improve the rate of case identification.
- Equally important will be the further development of effective referral pathways to appropriate treatment.

20.5 Psychosis

Evan Symons

ESSENTIALS

1 **In the age of community mental health treatment, emergency departments have become major sites for the assessment of patients with psychosis.**

2 **An important responsibility of the emergency department clinician is to exclude delirium and 'organic' causes of psychotic symptoms, including intoxication with illicit substances.**

3 **Key risks associated with acute psychosis include self-harm/suicide, aggression, misadventure and homelessness. Disposition decisions, including community referral or hospitalization, depend on the collection of information about treatment history, community supports and risk assessment, as well as assessment of the mental state and the preference of the patient.**

4 **Patients with psychosis and their carers should be involved in treatment planning wherever possible.**

Introduction

Psychotic illness is a frequent cause of presentation to the emergency department (ED).[1,2] It is estimated that in excess of 64,000 people in Australia aged 18 to 64 years have had a psychotic illness and have been in contact with public specialized mental health services each year. This equates to 5 cases per 1000 population or 0.5% of the population. Because these patients are usually severely mentally unwell, they also account for a significant share of the workload of EDs.

The tasks of the ED staff in relation to patients with psychotic illness are complex and varied. Initially, there is usually a need for containment and stabilization of an aroused and frightened patient with impaired reality testing. The patient is often in the hospital unwillingly and frequently following a major crisis in the community or at home. Patient preference should be elicited and considered in treatment and disposition planning wherever possible. There is often a need to manage behavioural disturbance, potentially involving risk of harm to the patient, staff or others, while the patient remains in the ED for significant periods of assessment and for the implementation of disposition plans. It is also important to exclude medical causes for the psychotic symptoms and to consider the presence of co-morbid medical conditions. In determining disposition, consideration must be given to the need for voluntary or involuntary admission or, alternatively, referral to an array of community-based treatment services.

Box 20.5.1 Tasks of the emergency department in relation to the patient with psychosis

1. Stabilization of the aroused or frightened patient
2. Management of behavioural disturbance in the emergency department
3. Exclusion of medical causes for the psychiatric presentation
4. Assessing the presence of co-morbid medical illness
5. Determining the need for voluntary or involuntary admission
6. Arranging referral to community services
7. Liaison with family and other carers

Finally, it is important to involve families and other carers in both the assessment phase and in treatment planning. These tasks are summarized in Box 20.5.1.

Classification

Traditionally, psychotic illnesses were classified into 'functional' (i.e. non-organic) psychoses and 'organic' psychoses. Developments in psychiatric nosology have expanded this classification and the *ICD-10 Classification of Mental and Behavioural Disorders*[3] now contains at least 16 different diagnoses, many with several subtypes, which could be used to describe patients with psychotic symptoms.

However, in emergency practice, the differentiation of the specific psychiatric syndrome is not always possible. The pragmatic classification shown in Box 20.5.2 is based on:

- excluding medical causes for the psychotic presentation
- considering the role of alcohol and other drugs of abuse
- making a provisional psychiatric diagnosis as a guide to initial management and
- considering the possibility that the symptoms may be related primarily to psychological stress.

A description of each of these categories is given in the section on clinical features.

Box 20.5.2 Pragmatic classification of patients with psychotic symptoms

1. Psychotic symptoms due to general medical condition
   - Delirium
   - Dementia
   - Psychosis in clear consciousness without cognitive impairment
   - Psychosis caused by medications
2. Acute and chronic schizophrenia
3. Mania with psychosis
4. Depression with psychosis
5. Intoxication or substance-induced psychosis
6. Psychotic-like reactive states

Epidemiology and prognosis

The two principal 'non-organic' conditions, which involve psychotic presentations are schizophrenia and bipolar disorder (type 1).

The prevalence of schizophrenia is about 1% of the adult population. It is not a rare disorder. The male:female ratio is approximately 1:1. Onset can be at any age, but mostly before the age of 30.[4] Age of onset is slightly later on average for women than for men.

Schizophrenia is usually a chronic condition, but with a variable course. In the long term, about 20% of cases have a good recovery, 20% have recurrent episodes with good recovery between episodes, 40% have recurrent episodes with incomplete remission and 20% have a severe chronic course.[5] The 20-year suicide rate may be as high as 14% to 22%.[5]

The prevalence of bipolar I disorder (which, by definition, means that the patient has had at least one manic episode) is about 1.0% of the population. The male:female ratio is 1:1. The onset is often in late adolescence and 95% of cases have onset before the age of 26.[6]

A patient who has had one episode of mania has about an 80% chance of a recurrence within 5 years. Although there is usually a good recovery between episodes, there is a very high rate of recurrence, with an average of one episode of mania or depression every 2 years, although the frequency of episodes in the individual case varies greatly.[7] The 22-year suicide rate is 13%.[7]

Aetiology and prevention

The aetiology of schizophrenia and bipolar disorder is not well understood, despite intensive research. Both disorders involve genetic and environmental factors. A person who has one parent with schizophrenia has about a 10% chance of developing the disorder; this is similar for bipolar disorder. There is insufficient knowledge about the aetiology of either disorder to suggest effective strategies for primary prevention.

There is considerable scope for secondary prevention, which is early diagnosis and prompt treatment, especially in relation to recurrent episodes. Strategies include the education of patients and families, the identification of early warning signs of relapse and the use of maintenance and prophylactic medication.[8] ED staff can make a major contribution to this preventative work by emphasizing the importance of continuing treatment and facilitating engagement with generalist and specialist mental health services.

Clinical features

Psychotic symptoms due to a general medical condition

Delirium

Delirious patients often manifest psychotic symptoms. Visual illusions (misperception of real objects, such as mistaking an innocuous object for a malevolent figure or animal) and delusions of persecution (e.g. the patient believing he is being poisoned by the doctors and nurses) are particularly common. Other symptoms include auditory hallucinations, affective lability, apparent formal thought disorder and grandiose or religious delusions.

Delirium should always be considered in older patients and those who present with abrupt onset of psychotic symptoms. The pathognomonic features of delirium are disorientation (especially for time and place) and a fluctuating conscious state. Not uncommonly, the patient plucks at the air or the bedclothes in apparent response to visual illusions or hallucinations. The abnormalities of mental state can fluctuate widely over the course of a day from relative lucidity to marked disturbance.

The delirious patient usually has a history or symptoms of a medical disorder and manifests abnormalities of vital signs or other abnormalities on physical examination or laboratory investigation. However, the absence of abnormal investigation results does not exclude a diagnosis of delirium.

The differentiation of medical and psychiatric causes of altered mental state is discussed in detail in Chapter 20.2.

Dementia

Psychotic symptoms in dementia can include auditory and visual hallucinations, delusions (often persecutory) and delusional misidentification (e.g. the delusion that a person closely related to the patient has been replaced by a double). These psychotic symptoms are common in dementias of all types, including Alzheimer disease and vascular dementias. A mean prevalence of 44% has been found across several cross-sectional samples.[9] The diagnosis of dementia depends on the presence of multiple cognitive deficits and will usually be evident from other features of the history and presentation. A change in the mental state of a patient with dementia should prompt consideration of superimposed delirium.

Psychosis in clear consciousness without cognitive impairment

Occasionally, patients present with psychotic symptoms of organic cause, without features of delirium or dementia. The variety of medical conditions associated with psychotic presentations is shown in Box 20.5.3. Although these disorders are relatively rare as the cause of psychiatric presentation, they should be especially considered in relation to a patient with new-onset psychosis over the age of 40 (i.e. older than the usual age of onset of the much more common schizophrenia and bipolar disorder).

In emergency practice, the psychoses associated with epilepsy are probably those most likely to be associated with uncertainty in management. These psychoses are of two types. Some patients with established epilepsy develop chronic inter-ictal psychosis; that is, a psychosis without specific temporal relationship to seizure activity. The clinical picture is often like schizophrenia and the disorder should be treated in its own right with antipsychotic medication.[10] The second presentation is of a post-ictal psychosis, usually following a cluster of seizures and sometimes with a lucid interval of 1 or 2 days. The patient can present with both schizophrenia-like and mood symptoms. The mental state spontaneously returns to normal within a few days, as in the more common post-ictal delirium.[11]

Box 20.5.3 Medical causes of psychotic presentations

- Epilepsy
- Hypo- or hyperthyroidism
- Huntington disease
- Wilson disease
- Porphyria
- B12 deficiency
- Cerebral neoplasm
- Stroke
- Viral or autoimmune encephalitis
- Neurosyphilis
- Human Immunodeficiency Virus (HIV)-associated neurocognitive disorders

Psychoses caused by prescribed medications

A long list of medications, many based on sporadic case reports, can sometimes be associated with psychotic symptoms.[12] The two most common are corticosteroids and dopamine agonists.

Steroid psychosis usually presents a manic-like picture and can show florid psychosis. It is most often associated with doses greater than 40 mg equivalents of prednisolone per day.[13]

Dopamine agonists used in the treatment of Parkinson disease (e.g. levodopa and bromocriptine) are associated with auditory and visual hallucinations, persecutory delusions and hypomania. The psychotic symptoms are dose-related but dose reductions may be associated with severe exacerbation of parkinsonian symptoms.[14]

Acute and chronic schizophrenia

The symptoms of schizophrenia include the 'positive' symptoms of acute psychosis and the 'negative' symptoms, such as apathy and social withdrawal.

Positive symptoms involve delusions, hallucinations and formal thought disorder. The content of delusions may include beliefs that the patient is an important person (grandiose), that the patient has special communication with deities or spirits (religiose) or that there is something awry with the patient's body or the world (hypochondriacal and nihilistic). The most common delusions are beliefs that other persons or the TV or radio are making special reference to the person (delusions of reference) and beliefs that certain persons or agencies are engaged in conspiracies to harm the patient (delusions of persecution).

Hallucinations are usually auditory but can be in any sensory modality. The specific types of auditory hallucinations first described by Schneider,[15] although not specific to schizophrenia, are strongly supportive of the diagnosis. These include a voice making a running commentary on the patient's actions, two or more voices discussing or arguing about the patient and a voice repeating the patient's thoughts aloud.

Sometimes the most obvious positive symptom of psychosis is formal thought disorder. This usually takes the form of loosening of associations (lack of logical connection between

statements) and tangential (off the point) replies to questions. The effect of these symptoms is to make it difficult or impossible to take a sequential history. In more severe cases, the language itself becomes incoherent as grammatical conventions are abandoned and invented words ('neologisms') are used. In the emergency setting, the less severe forms of formal thought disorder may also be shown by highly anxious, delirious or intoxicated patients.

The negative symptoms include blunting of affect (lack of emotional response), apathy (loss of volition), poverty of speech (severely diminished verbal communication) and autistic withdrawal from social interaction. These symptoms can be difficult to distinguish in the acute setting from the effects of co-morbid depression or from the bradykinesia caused by antipsychotic medications.

In emergency practice, the three most common types of presentation of schizophrenia are the first psychotic episode, acute psychotic relapse of an established illness and a social crisis in a patient with chronic schizophrenia. It is useful to distinguish these types of presentation because of the management implications.

The patient with a first episode of psychosis is typically a young adult who has been brought to the ED by family or police often following months of concern about deterioration in the patient's mental state or behaviour. Sometimes there will have been an acute episode of bizarre, suicidal or aggressive behaviour. Exclusion of medical causes of psychosis is important in the first episode, especially in the older patient. It may be difficult to be certain whether the syndrome is one of mania (see below) or schizophrenia, but this distinction is not crucial in emergency assessment. More important is the fact that the patient is likely to be frightened and confused, as is the family also. The patient may require involuntary hospitalization.

The acute relapse of an established illness can also involve considerable distress to the patient and family. In these cases, it is useful to look for changes in medication, problems in compliance, changes in the treatment system (e.g. the absence of the treating doctor), alcohol and other drug abuse, and recent stressful events. It may be possible to avoid hospitalization.

Patients with chronic schizophrenia are now treated most frequently through community mental health services. They may present with an exacerbation of the psychosis for the reasons outlined above. However, the presentation is often related to social problems, such as conflict with family or difficulties with accommodation or finances. In these cases, it can be very useful to communicate with the community mental health services to clarify the patient's baseline level of function and current problems. Some patients with chronic illness are effectively homeless and have poor engagement with community services, irregular medication use and ongoing drug abuse. Although it is difficult in a busy ED, these patients ideally need some work towards establishment of continuity of care and long-term treatment plans.

The term 'schizoaffective disorder' has been used to describe an illness in which patients show typical symptoms of schizophrenia as well as having definite manic or depressive episodes. In practice, in the ED, such patients can be assessed and managed in a similar way to patients with schizophrenia.

Mania with psychotic symptoms

The manic syndrome is one form of presentation of bipolar disorder, the others being a depressive episode and mixed affective state.

The typical manic syndrome is very distinctive. The patient presents with euphoric or irritable affect, pressure of speech (rapid, continuous speech which is difficult to interrupt), distractibility and disinhibited or overfamiliar behaviour. If delusions are present, they are typically grandiose (that the patient has an important mission) or persecutory (e.g. that other persons are engaged in a conspiracy to prevent the patient fulfilling his or her destiny). Collateral history will usually show that the patient has been well until the last few days when the patient has become overactive and disorganized with a markedly decreased need for sleep.

In mixed affective psychosis, the patient often shows typically manic arousal and irritability, but may have a depressive theme evident in the content of speech. Depressive psychosis is discussed below.

Sometimes a delirious patient with affective lability, irritability, disinhibition and distractibility may be misdiagnosed as manic. The diagnosis should be considered in the older patient without a previous history of bipolar disorder. The distinction can be made on the basis of the impairment of cognitive function (disorientation, fluctuating conscious state and memory impairment) in delirium and clinical or laboratory evidence of medical illness.

It may be difficult to distinguish acute mania from acute schizophrenia in the emergency setting, especially in first episode cases. Being certain of the diagnosis is not crucial, as the short-term management is similar (see below).

Major depression with psychotic features

Patients who exhibit psychotic features during a depressive syndrome are severely depressed. The content of delusions and hallucinations relates to the patient's feelings of worthlessness or guilt and may include the conviction that the patient should die. Because the patient is unable to evaluate these beliefs rationally, the risk of suicidal actions is high and these patients should be closely supervised.

The patient with a depressive psychosis will show the other typical features of a depressive syndrome. Most often, the mental state assessment will show a patient who lacks spontaneity and is withdrawn and sad. Occasionally, however, the patient may be agitated and irritable.

The differential diagnosis and management of depressive syndromes are discussed in Chapter 20.4.

Substance-induced psychosis

Drugs of abuse are associated with psychotic presentations in several ways: psychosis as a manifestation of acute intoxication, psychosis during withdrawal reactions, chronic psychosis following prolonged use and the exacerbation of pre-existing psychotic illness due to drug abuse. Drugs of abuse that may contribute to psychosis are listed in Box 20.5.4.

The psychosis associated with intoxication may include auditory and visual hallucinations and persecutory or grandiose delusions. The patient is usually agitated, highly anxious and incoherent, and often shows autonomic signs, such as dilated pupils. Some drugs, such as phencyclidine, are particularly associated with disinhibited rage. Management is focused on ensuring safety and maintaining vital functions in the expectation that the psychosis will clear when the intoxication resolves.

Alcohol and benzodiazepines can lead to psychotic symptoms (most commonly visual hallucinations) in the context of withdrawal delirium. The psychotic symptoms resolve through management of the withdrawal with benzodiazepines.

Amphetamine (and amphetamine derivatives), phencyclidine and lysergic acid diethylamide (LSD) have all been associated with chronic psychosis, which can persist for weeks or months after cessation of drug use.[16–18] Whether or not the patients who develop these chronic psychoses may have been predisposed to psychotic illness is controversial but, nevertheless, the psychosis should not be regarded purely as an intoxication effect but treated in its own right. Amphetamine

Box 20.5.4 Drugs of abuse associated with psychosis

- Amphetamine and methamphetamine
- Methylenedioxymethamphetamine (MMDA, ecstasy)
- Cocaine
- Phencyclidine
- Ketamine
- Lysergic acid diethylamide
- Cannabis
- Alcohol
- Benzodiazepines

drugs are most frequently associated with this chronic psychosis, usually following prolonged heavy amphetamine abuse. The clinical picture can be quite distinctive, including beliefs that the patient is being watched or followed or that thoughts may be monitored with an implanted device. 'Running commentary' auditory hallucinations may occur as well as tactile hallucinations, which may lead the patient to excoriate the skin in pursuit of a supposed infestation with insects.

The role of cannabis as a cause of chronic schizophrenia-like psychosis is uncertain, although cannabis frequently exacerbates psychotic symptoms in patients with an existing illness.[19]

Alcoholic hallucinosis is a relatively uncommon condition found in some patients with long-term alcohol abuse histories. The patient experiences auditory hallucinations of a derogatory or 'running commentary' type in clear consciousness, without being in a withdrawal state. This disorder may persist for weeks or months and the symptoms may respond to antipsychotic medications.

Because alcohol and drug abuse can exacerbate psychosis in patients with an established schizophrenic or bipolar disorder, inquiry should be made into their use with every patient.

Psychotic-like reactive states

Patients with histories of severe personality disorder, post-traumatic stress disorder and dissociative disorder sometimes present with quasi-psychotic states.[20,21] These episodes usually follow acute stress, such as a relationship or other social crisis, or events that trigger recall of traumatic experiences. The patient is usually extremely anxious and may have impaired verbal communication, further complicating assessment. Psychotic-like experiences can include intense subjective experiences of a derogatory internal monologue, which can seem like auditory hallucinations or intense fears of being harmed, which mimic persecutory delusions. Some patients' recall of traumatic experiences is so persistent and vivid that it seems as if it is actually happening again.

When such patients are seen in emergency settings, they often need containment and assessment in a similar manner to patients with true psychoses. Benzodiazepines and sedative antipsychotic medications (see below) are often useful in reducing the high level of arousal.

Assessment

Objectives and sources of information

The assessment of the psychotic patient in ED has several objectives. The basic questions are:

- Is the altered mental state primarily due to a medical condition?
- To what extent are drugs or alcohol contributory?
- Can a primary psychiatric diagnosis be made?
- Can the patient be treated at home or is hospitalization necessary?
- Should the patient be detained involuntarily under the Mental Health Act?

These questions cannot be answered by considering only the clinical state of the patient. Decisions about risk assessment and disposition depend on a careful consideration of the social circumstances of the patient, recent events that have led to the emergency presentation and past and current engagement with community mental health treatment services. Diagnostic clarification is often greatly assisted by previous treatment records.

Information should be sought from family and community mental health teams about recent function, symptoms, dangerous behaviours, and alcohol and other drug use. The police who sometimes bring patients with psychosis to ED can often give important information about the circumstances that led to the presentation.

The assessment process is not a single one-off review of the patient's mental state, nor is it a linear process in which the various objectives of assessment can be serially addressed. It tends rather to be a back and forth process as multiple lines of inquiry are simultaneously pursued and the clinical data re-evaluated in the light of new information.

At the end of the assessment process, it should be possible to record a summary of the various parameters of assessment as outlined in Box 20.5.5, which can then form the basis for management planning.

Initial stabilization of the patient

In order that conditions can be created for an adequate assessment, there is an immediate need to stabilize the patient. The acutely psychotic patient has distorted understanding and may be an unwilling participant in the process. It is preferable to try to engage the patient in a calm manner with straightforward and clear explanation of the need for assessment. The patient's own concerns and perceptions of the problem should be listened to, without initially trying to seek answers to specific questions. This attention is reassuring to the patient and provides an opportunity for observation of the mental state, even if the patient's account lacks coherence.

Patients who are aroused and agitated, intoxicated, or have persecutory delusions may pose a risk of violent or aggressive behaviour. In these cases, it is important to monitor safety by having security staff present, by not assessing the patient in a confined space, and by remaining out of striking distance and not turning one's back on the patient. Sometimes the patient may have to be sedated before much assessment can be made. Sedating the aroused patient is discussed in Chapter 20.6.

Moderate use of benzodiazepines need not significantly complicate the mental state assessment, although these drugs may exacerbate delirium. High doses of benzodiazepines (especially diazepam, which has active metabolites with long half-lives) can produce a prolonged delirium, which will delay the assessment process.

Box 20.5.5 The psychotic patient—brief assessment schedule

1. Circumstances of referral
2. Presenting problem
3. Social circumstances
4. Previous treatment
5. Current mental health services
6. Current medication
7. Alcohol and other drug use
8. Mental state examination
9. Medical assessment and investigations
10. Provisional diagnosis
11. Risk assessment
12. Treatment and disposition plan

Mental state assessment

Especially in the aroused patient, it is often difficult to carry out a formal mental state examination. Nevertheless, it is possible to collect a lot of information by simple observation. The general appearance can give clues to the patient's level of self-care. The rate and mode of speech can suggest the presence of formal thought disorder. Hostile or euphoric affects may suggest a manic syndrome or intoxication. Patients may spontaneously reveal delusional ideas or auditory hallucinations, or may admit to these on specific questioning. Orientation to time and place and recent events should always be assessed because of the strong association of disorientation with delirium. Although detailed cognitive assessment is usually not possible, an attempt should be made to assess short-term memory function and attention and concentration.

As with all aspects of assessment, the assessment of mental state should not be based on a single evaluation but on serial assessments by medical staff and the observations of the nursing staff throughout the time the patient is in the ED.

Risk assessment

It is important to inquire directly about suicidal and homicidal ideation and to record the patient's statements. However, risk assessment depends on an evaluation of the whole situation. A patient with persistent persecutory beliefs may be at significant risk of behaving aggressively towards perceived persecutors, even though he or she may deny hostile intent. Conversely, a patient's expression of suicidal ideation may reflect long-standing frustration and dissatisfaction (which

may be alleviated by receiving help) rather than intent to act in a suicidal manner. The degree to which the patient can exercise judgement is also important. A floridly psychotic or grossly disorganized patient is at greater risk than a patient with chronic symptoms who presents with a social crisis. The home situation and the views of family should also be considered and taken very seriously. Inquiry also should be made into the provision of care for dependent children.

Decisions about hospital admission and involuntary detention usually focus appropriately on danger to self and others. Uncertainty may sometimes arise regarding the use of Mental Health Act detention powers in relation to patients who clearly deny any intent to harm themselves or others, but who are clearly in need of treatment, lack insight and are very unlikely to receive treatment unless compulsorily detained. However, most jurisdictions make some provision in their mental health legislation for such patients to be detained in the interests of their health or to prevent other 'harms', such as harm to reputation. The decision to detain involves balancing the patient's right to autonomy against the probable risks of not receiving treatment. In general, such a patient has only been brought to the ED because family, friends or other carers have been concerned about the behaviour or mental state of the patient; therefore it is wise to consult with these concerned others if there is doubt about the decision to detain.

Medical evaluation and investigation

Medical evaluation has three goals: excluding delirium (or dementia), considering other organic causes of psychosis and assessing for the presence of co-morbid medical illness.

The practice of 'medical clearance' prior to psychiatric evaluation may detract from a comprehensive evaluation of the patient. A more satisfactory process is to compile an adequate history of the presenting illness, assess the mental state, review the medications and alcohol and other drug use, consider previous medical history, check vital signs and carry out as comprehensive a physical examination as possible, with particular attention to signs of injury, poisoning or intoxication.[22] In services where both emergency physicians and psychiatrists are available, direct discussion about cases of uncertain diagnosis is useful.

Medical causes for an altered mental state will usually be suggested by the history, mental state assessment, abnormal vital signs and physical examination. As noted above, particular consideration should be given to medical causes in a first presentation of psychosis, especially in an older patient.

Investigations should be driven by history and examination findings, such as neurological signs or signs of infection. Nevertheless, because of the difficulties in compiling comprehensive medical histories, it is often appropriate to do a number of 'screening' investigations as indicators of unsuspected medical illness. The range of suggested tests varies, but usually includes urea and electrolytes, full blood count, liver function tests, random blood sugar, blood alcohol level, thyroid function tests and B12 and folate levels.[23]

The availability of computed tomography (CT) scanning in more centres has facilitated the use of neuroimaging as an aid to diagnosis. This investigation is likely to be indicated in patients where stroke, neoplasm, haemorrhage or central nervous system infection may be suspected. It is also appropriate to consider a CT scan of the brain in first episode psychosis cases to assess further the possibility of neurological disease presenting with only psychotic or affective symptoms. However, the yield of positive results with this investigation is low,[24] especially in the younger patient[25]; therefore neuroimaging is generally not required as an emergency investigation if the patient is otherwise medically well.

It is well established that patients with chronic psychotic illness tend to have poorer physical health than the general population.[26] Common conditions include obesity, late onset diabetes, hypertension, arteriosclerotic disorders, smoking-related disorders and alcohol and other drug-related disorders. The prevalence of these problems can be related to lifestyle factors, the side effects of medication and the difficulties in making effective use of primary medical care. It is worth considering the possible presence of these common conditions as they sometimes need acute treatment or contribute to an exacerbation of the mental state.

Treatment

Management in the emergency department

Once medical causes have been excluded, the primary psychiatric diagnosis is likely to fall into one of the following groups:

- drug-induced psychosis
- acute schizophrenia
- mania
- chronic schizophrenia
- psychosis-like reactive state
- depressive psychosis.

Patients with psychotic illness often stay in the ED for prolonged periods. Sometimes this is due to delays in the assessment process, but it is also significantly a result of access block; that is, the lack of ready availability of beds in psychiatric wards. In some hospitals, these circumstances have resulted in the establishment of specific psychiatric 'holding beds', within or closely related to the ED, where patients may be observed and treated for up to 48 hours while further management and disposition plans are being made.[27,28] The availability of such specialized psychiatric observation units is likely to reduce the need for reliance on sedative medications to manage behavioural disturbance. The patient can move around more freely, preferably with access to an outside secure area, and specialized mental health staff can provide assessment, supervision, explanation and reality orientation.

In the more conventional ED setting, behavioural management is more difficult as a balance must be achieved between imposing restrictions on the patient and maintaining the safety of all patients and staff. Psychotic patients should be in areas that can be easily observed, and often one-to-one supervision will be necessary, preferably with trained mental health nurses. If possible, this should be in a quiet area without too much coming and going. Engagement of the patient in reality-based conversations (explanation of what is happening, attention to personal concerns) is often useful. It may be possible to enlist the help of family members in providing reassurance and comfort.

The use of specific medications will depend in part on the diagnostic picture. Patients with drug-induced psychosis are usually quite aroused and require significant levels of sedation. Benzodiazepines, such as midazolam and diazepam, are usually preferred as they are less likely to lead to medical complications (especially arrhythmias) in a person who has already taken other drugs and has a high sympathetic drive. The period of sedation may become prolonged for several hours (or even days if high doses of diazepam are used). The mental state needs to be reassessed for the presence of persistent psychosis when the sedation abates.

Patients with acute schizophrenia, mania or persistent psychosis following drug use all have similar management in the short term. These patients tend to be aroused and agitated and to have considerable difficulty in coping with the restrictions and the stimulation of the ED environment. If the patient will take oral medications, sedative antipsychotics (e.g. olanzapine) or benzodiazepines (e.g. lorazepam) can be used. These are better prescribed as regular doses (e.g. olanzapine 5 mg tds or lorazepam 1 mg qid) than on a pro re nata (PRN) basis to ensure consistency in dosing. Repeated divided doses to maintain a more constant level of sedation are preferable to infrequent large doses. Estimates of the probable appropriate dose can be made on the basis of the size of the patient and the degree of arousal, and then titrated upward or downward on the basis of response in the first 24 hours.

If the patient refuses oral medication, lorazepam (if available) or clonazepam can be used

intramuscularly or intravenously. Olanzapine also can be used effectively intramuscularly. Patients who are likely to stay in the ED or short-stay unit for more than 24 hours can be given zuclopenthixol acetate 50 to 150 mg IM (dose dependent on the size of the patient). This is a medium-acting depot antipsychotic preparation that will last for 3 to 4 days. However, the onset of action is delayed for 6 to 8 hours, and this medication should be avoided in neuroleptic-naïve patients because of the risk of prolonged dystonia.

The patient who presents with acute schizophrenia who is not aroused may benefit from explanation and only small doses of medication, such as olanzapine 5 mg at night. Similarly, the patient with chronic schizophrenia should be maintained on usual medications, possibly with the addition of a PRN benzodiazepine if very anxious.

Patients with psychotic depression can be quite agitated, but also may be quiet and withdrawn. They should be considered at high risk of suicidal behaviour and need close supervision. Their mental anguish may be helped in the short term with the use of benzodiazepines or sedative antipsychotics (olanzapine or quetiapine). Regular doses are better than PRN, although smaller doses are needed than in the treatment of the acutely schizophrenic or manic patient. It is not essential to commence an antidepressant medication during the time the patient is in the ED.

The patient with severe personality disorder or a history of severe trauma who presents with a psychosis-like reactive state often requires similar treatment to a patient with acute schizophrenia. The patient may require containment in a place of safety and will benefit from explanation and reassurance. Benzodiazepines and sedative antipsychotics can be very useful in lowering arousal.

Admission to inpatient care

The decision to admit the patient for inpatient psychiatric care depends on the acuity of the presentation, the supports available at home, the degree of risk and the availability of community mental health services.

Patients with an acute episode of schizophrenia, especially a first episode, often require admission because they are often very disorganized, lack insight and are likely to be non-compliant with medication; they also may be at risk of suicide or aggressive behaviour. However, the increasing availability of mobile crisis teams (community mental health teams with the capacity for rapid and intensive follow-up in the home) has made it more possible to treat even these acutely unwell patients at home. This is usually preferred by the patient and sometimes by the family, especially where the patient is an adolescent or young adult still living with their family. In these cases, careful assessment of potential risks to the patient or others and a frank discussion of these issues with the family is advisable.

The acutely manic patient who has been brought to the ED almost certainly requires admission. Once established, the manic syndrome is likely to persist for several weeks if untreated. In some cases, especially those involving recurrence of a previous bipolar disorder, the patient presents relatively early in the relapse and with sufficient insight to accept advice about increasing or changing medications. If such a patient is discharged to outpatient care, specific arrangements should be made with the family and the community mental health services for monitoring and follow-up.

The patient with an acute psychotic depression almost always requires admission because of the high risk of suicidal behaviour.

On the other hand, patients with chronic schizophrenia who present with a mild exacerbation of symptoms or family or social crisis should generally be managed in the community if possible. These are chronic conditions analogous to diabetes or asthma and quality of life can be enhanced if the patient can be helped to engage with community treatment services, achieve stability of accommodation and daytime activity, and learn to self-manage the condition.[29]

For patients with reactive psychoses in the context of personality disorder or trauma history, the individual circumstances vary widely and the decision to admit depends on careful assessment of the risk factors. Every effort should be made to return the patient as quickly as possible to reality-based perceptions of the world and to restore a sense of autonomy and personal responsibility. It is sometimes not possible to achieve this during the course of an ED stay and a brief crisis admission to a psychiatric unit may be necessary.

Criteria for involuntary treatment

When inpatient admission is considered desirable but refused by the patient, consideration should be given to the use of Mental Health Act powers for referral and detention. Contemporary mental health legislation requires the person considering this option (which may be a doctor or other authorized mental health practitioner) to review options for less restrictive treatment before making this decision.

Mental health acts generally stipulate that persons can only be referred under the act if they suffer from a 'mental disorder' and are also at some 'risk'. Risks involving danger to self through suicidal intent or behaviour, and danger to others as a result of aggression or persecutory delusions, are usually straightforward grounds for referral and detention. The decision may be more difficult in relation to the patient with partial insight. The need for detention involves weighing up the potential consequences of not receiving treatment, the possibility of access to community services and the availability of family or other social supports.

Where mental health specialists are not readily available to the ED, ED doctors may appropriately refer a patient under the Mental Health Act so that assessment by a psychiatrist can take place at another location. Especially in cases where the need for involuntary treatment is uncertain, it is good practice for the ED doctor to make this referral to ensure that the decision to detain or release can be made by a psychiatrist, who is in a clearer position to take medico-legal responsibility.

Community referral

The range of potential community treatment options is now wide. Patients may receive outpatient treatment through general practitioners, private psychiatrists and psychologists, community mental health clinics, public and private drug and alcohol services, relationship counselling agencies and various other specialized services (e.g. non-government community support services, services for indigenous persons and services for victims of trauma). In planning outpatient care, a good approach is to determine initially which service providers may be already involved in helping the patient and the strength of the patient's relationship with those services. Direct communication between the ED staff and the community service providers is very desirable, especially if the patient is a new referral to those services.

Some of the more effective psychiatric emergency services work in close liaison with mobile crisis teams or acute care teams, who actively and intensively follow up discharged patients in their own homes or in crisis accommodation.[28,30]

CONTROVERSIES AND FUTURE DIRECTIONS

- As a result of the contemporary mental health community focus, EDs will continue to have a major role in the assessment and stabilization of patients with psychosis.
- Should this assessment occur within traditional EDs or should EDs facilitate the development of co-located psychiatric emergency services?
- The models of care that will achieve the best integration of emergency mental health assessments with community services require better definition.

20.6 Pharmacological management of the aroused patient

John C. Spencer

ESSENTIALS

1 **Benzodiazepines and antipsychotics, often used most effectively in combination, are the first-line drugs for sedation of the aroused patient.**

2 **As much information as possible should be collected before the patient is sedated.**

3 **The risks involved in administering sedative drugs need to be considered, particularly at higher doses.**

4 **Dose adjustments are necessary in the older or medically compromised patient.**

Introduction

Aroused patients who present to the emergency department (ED) of their own accord can generally be best assisted by verbal reassurance and prompt mental health evaluation. Reducing the waiting time and arriving quickly at an action plan will provide the best response to the patient's anxiety and agitation.

For highly aroused patients who have been brought to the hospital reluctantly, the immediate need is to gain control of the situation to permit further evaluation, while ensuring the safety of the patient, the staff and the public.

Where possible, it is desirable to collect some information about the patient before sedation. The patient should be approached in a calm manner in a safe, observed area of the ED, with security staff in the background if necessary. The patient should be asked about his or her understanding of the problems and listened to attentively, even if the account is incoherent. This attention will be reassuring to the patient and helps in building rapport. During this process observations can be made about the mental state. If possible, vital signs should be recorded and a brief physical examination carried out, with particular attention to signs of injury, intoxication or overdose.

In the hostile or frightened uncooperative patient, it will often be necessary to proceed to rapid tranquilization. This is a familiar procedure to the emergency physician and the practice can be enhanced by attention to the basic principles of care, an awareness of the risks and knowledge of the characteristics of the available drugs.

Pharmacological management should always be tailored to the particular patient. The medically compromised patient will be at greater risk of the complications of sedation. In elderly patients, decreased and delayed metabolism and elimination can result in prolonged therapeutic and adverse effects. Dose adjustments and agents with shorter half-lives and more favourable side-effect profiles must be considered for these patients.

General principles of rapid tranquillization

The general principles of care are:

- Use sedative benzodiazepines and/or antipsychotics as the first-line agents.
- Should the situation allow, oral dosing is the least distressing approach for patients and staff.
- Treating physicians should use agents with which they are familiar. In particular, they should be aware of maximal safe dosing and expected adverse effects.
- The endpoint should be a calm cooperative patient. Sedation to the point of loss of airway protection is dangerous.
- The patient should be nursed in a quiet, calm and gently lit environment if possible.
- Sedated patients should be monitored with basic observations; a 12-lead electrocardiogram (ECG) should be performed on any patient being administered repeat doses of antipsychotics.
- Supportive care, such as hydration, indwelling catheterization, pressure care and deep vein thrombosis prophylaxis, are essential for patients requiring ongoing sedation. This is particularly relevant in overcrowded EDs and if patients are detained in the ED for prolonged periods.
- Maintenance of patient dignity by using single rooms and limiting visual exposure of the patient to the public is often forgotten but should be a basic standard of care.

Risks of rapid tranquillization

There are inherent risks in attempting to gain control of the aroused patient, including risks of injury to the staff and patient. If physical restraint is necessary to administer parenteral medication, adequate staff, trained in restraint procedures should be on hand. Sometimes mechanical (padded strap) restraint may be necessary in the early stages or to limit the dose of medication if the patient is developing toxic effects. Mechanical restraint should not be maintained in the absence of chemical sedation due to the risks of physical injury and rhabdomyolysis, as well as for ethical reasons.

The risks of adverse events from medication administration are well recognized.

Over-sedation and resultant respiratory depression and pulmonary aspiration are relatively common and for the most part avoidable with proper care.

Sudden cardiac death, particularly with agents that prolong the QT interval and precipitate torsade des pointes and ventricular tachycardia (VT), is a rare but catastrophic complication of rapid tranquilization. This risk is heightened in the aroused patient with increased circulating catecholamines and in patients with pre-existing heart disease or conduction disturbance. Antipsychotics combined with other medications that prolong the QT interval pose an increased risk. The agents most associated with risk of sudden death are thioridazine and clozapine. Droperidol and haloperidol are associated with QT prolongation but rarely with the risk of torsade des pointes. Quetiapine and chlorpromazine are associated with QT prolongation but this is probably less clinically significant than with the above agents. The atypical agent olanzapine appears to be relatively safe from this perspective.

Hypotension can occur with administration of any agent with alpha blockade effects, but is especially associated with chlorpromazine (particularly when given intravenously). Dystonic reactions are seen with all antipsychotics, most frequently with the butyrophenones, such as haloperidol, and less commonly with atypical agents, such as olanzapine. Neuroleptic

malignant syndrome is a risk with any antipsychotic agent, even following a single dose.

Anticholinergic effects, such as delirium and urinary retention, are risks with virtually all antipsychotics and are generally seen at high doses. Delirium is also caused by high doses of benzodiazepines, particularly diazepam, which accumulates with recurrent dosing. All antipsychotics have the potential to lower the seizure threshold.

Elderly patients are at significantly greater risk of drug accumulation and adverse effects. They are also at far greater risk of delirium, particularly with the combination of possible underlying cognitive impairment and environment change. Age-related reductions in hepatic metabolism and renal function make it reasonable to assume that all agents will have prolonged elimination half-lives in these patients. Even small doses of benzodiazepines can produce significant and prolonged respiratory depression in the elderly. Standard doses of antipsychotics, such as haloperidol, may result in prolonged extrapyramidal effects that impair mobility for days to weeks post-administration.

Specific agents

Benzodiazepines

Midazolam This water-soluble benzodiazepine has major benefits over diazepam in that it produces fewer site reactions and can be given intramuscularly. It has a rapid effect by intramuscular (IM) or IV injection (2 to 5 minutes), with a half-life of 1 to 3 hours. The active metabolite has a similar half-life. The elimination half-life is significantly prolonged in the elderly. The major adverse effect is respiratory depression. It is available in ampoules (5 mg/mL, 15 mg/3 mL, 5 mg/5 mL and 50 mg/10 mL).

Diazepam Diazepam can be used orally or intravenously. It is not recommended for IM use due to unpredictable absorption. Diazepam demonstrates biphasic elimination with rapid redistribution of 1 to 3 hours, followed by a prolonged terminal elimination phase of up to 20 hours. Hepatic metabolism produces active metabolites and excretion is renal. Elimination is significantly prolonged in the elderly. Major adverse effects are respiratory depression and accumulation causing delirium. It is available in ampoules (10 mg/2 mL), tablets (2 mg and 5 mg) and elixir (10 mg/10 mL).

Clonazepam Clonazepam can be used by oral, IV or IM routes. Clonazepam has a prolonged elimination half-life (20 to 50 hours) with hepatic metabolism and renal excretion. The major adverse effects are excessive sedation and risk of accumulation. It is available in ampoules (1 mg/mL), tablets (0.5 mg and 2 mg) and oral liquid (2.5 mg/mL).

Lorazepam In Australia, lorazepam is readily available in oral preparation in in 0.5/1/2mg tablets tablets. However, in other countries, it is widely used intramuscularly in the sedation of psychotically aroused patients. It is available in a parental 2 mg ampoule in Australia but only on a hospital's application under the Special Access Scheme. Thus it is only used in a small number of hospitals due to the prohibitive nature of this application. It is well absorbed orally and intramuscularly with an elimination half-life of 12 to 15 hours. The hepatic metabolites are non-active. The major adverse effect is excessive sedation, but it is less likely to accumulate than diazepam or clonazepam.

Antipsychotics

Droperidol Droperidol can be administered intramuscularly or intravenously. Clinical effects are seen within 3 to 10 minutes, maximum at 30 minutes and the elimination half-life is approximately 2 hours. It is significantly more sedating than haloperidol, which makes it an attractive choice for the aroused patient. It is also a potent antiemetic. The black box labelling of droperidol is highly controversial as there appears to be little evidence that there is greater cardiovascular risk with this agent than with haloperidol. QT prolongation is seen with greater frequency at higher dose, but deterioration to torsade de pointes is rare. The risk is greater when combined with agents that prolong the QT interval or in patients with pre-existent QT prolongation. As with haloperidol, there is a risk of dystonic reactions and neuroleptic malignant syndrome (ampoules 2.5 mg/mL).

Haloperidol Haloperidol can be given by oral, IM or IV routes. Peak plasma levels occur 20 minutes after IM injection and 2 to 6 hours post-oral dose. Mean elimination half-life is 20 hours, but this includes initial rapid elimination followed by a prolonged elimination over days. Hepatic metabolites are renally excreted. Major adverse effects are extrapyramidal effects that may persist for days (particularly in the elderly), prolongation of QT interval with risk of torsade and neurolept malignant syndrome (NMS). It is available in tablets (0.5 mg, 1.5 mg and 5 mg), liquid (2 mg/mL) and ampoules (5 mg/mL).

Olanzapine Olanzapine is licensed for oral, sublingual (SL) and IM use. Also, there are common reports in the literature of IV use. It is an atypical antipsychotic that is well absorbed orally with peak plasma levels 2 to 5 hours post-oral dose and 30 minutes post-IM injection. It has a half-life of approximately 33 hours and is hepatically metabolized to inactive metabolites that are renally and faecally excreted. There is also now a long-acting preparation with a half-life of 30 days. Major adverse effects include excessive sedation, mild anticholinergic effects and NMS. Extrapyramidal side effects (EPSEs), including dystonias, are rare. Cardiotoxicity is also rare. It is available in tablets (2.5 mg, 5 mg, 7.5 mg and 10 mg), dissolvable tablets, wafers (5 mg and 10 mg) and ampoules (10 mg).

Risperidone Risperidone is for oral and SL use. It is an atypical antipsychotic that is well absorbed orally with a peak effect in 1 to 2 hours. It is hepatically metabolized to an active metabolite that is renally excreted. The half-life of the parent compound is 3 hours in extensive metabolizers and 17 hours in poor metabolizers; the active metabolite elimination half-life is 24 hours. Risperidone's adverse effect profile is benefited by the absence of anticholinergic effects, but includes postural hypotension with initial dosing, extrapyramidal effects and NMS. Extrapyramidal reactions, including dystonias, are less frequent with risperidone than with haloperidol. There has been an increased mortality associated with risperidone and elderly patients on frusemide, so caution should be taken to ensure adequate hydration in these patients. It is available in tablets and SL 'quicklets' (0.5 mg, 1 mg, 2 mg, 3 mg and 4 mg) and solution (1 mg/mL).

Chlorpromazine Chlorpromazine is for oral, IM or IV use. It has variable and incomplete absorption and a large first-pass metabolism, with peak plasma levels 1 to 4 hours after oral and 30 minutes after IM administration. Metabolism is hepatic with many metabolites that are renally excreted. Elimination is complicated with early (2 to 3 hours), intermediate (15 hours) and late (60 days) elimination phases. Major adverse effects are postural hypotension, strong anticholinergic effects, excessive sedation and the risk of NMS. Extrapyramidal effects are relatively uncommon. It is available in tablets (10 mg, 25 mg and 100 mg), syrup (5 mg/mL) and ampoules (50 mg/2 mL).

Zuclopenthixol acetate ('Acuphase')

This is given intramuscularly. Zuclopenthixol acetate is a medium-acting depot preparation of a typical thioxanthene antipsychotic. Maximal plasma levels are achieved 24 to 36 hours post-IM injection, declining to 30% of maximum levels by day 3. It is hepatically metabolized to inactive metabolites and is faecally excreted. Zuclopenthixol acetate should be avoided in neurolept-naïve patients and those with organic brain disorders, cardiac disease and lowered seizure threshold. This is because any adverse effects, including NMS, will be prolonged because of the slow absorption and elimination. The usual dose is 50 to 100 mg.

Dexmedetomidine and clonidine

These central α-agonists have a significant sedative effect. Dexmedetomidine is used as

an infusion, primarily in the intensive care unit setting. Clonidine has a recognized role in opiate and, to a lesser extent, alcohol withdrawal. It may be administered by the oral, subcutaneous, IM or IV route. It has a rapid onset of action when given parenterally and a half-life of greater than 12 hours. There is the potential for both these agents to have an increasing role in the ED for the management of hyperaroused patients. Both have a risk of bradycardia and hypotension and should be avoided in patients with pre-existent cardiac conduction abnormalities and be used with caution in patients on rate-lowering agents.

Anaesthetic agents

Ketamine Ketamine is an N-methyl-D-aspartate (NMDA) receptor antagonist that has widespread anaesthetic, sedative and pain-relieving properties with the usual maintenance of airway and breathing in correct dosages. There are increasing reports of its safe usage both in the prehospital and ED environments, and it has been written into ambulance protocols.[1,2] It is given parentally usually IM to dose up to 4 mg/kg with rapid onset of sedation. It is presented in a 200 mg/2 mL ampoule.

A rapid tranquillization algorithm

There are a variety of published algorithms for rapid tranquillization.[3–15] The following is a reasonable approach in terms of effectiveness, the risk of adverse effects and availability. This algorithm applies to the management of a previously well adult patient. It must be remembered that, in general, the risk of adverse events is increased the greater the doses used. Elderly patients as a general rule should have lower initial doses and smaller daily doses.

First-line treatment

Try to develop rapport with the patient, use verbal de-escalation techniques and oral/sublingual medications if possible. Oral agents of choice include:

- benzodiazepines: diazepam 10 mg, clonazepam 2 mg or lorazepam 2.5 mg (elderly: lorazepam 0.5 to 1 mg)

and/or:

- antipsychotic: olanzapine 5 to 10 mg oral/SL (elderly: olanzapine 2.5 mg oral/SL or risperidone 0.25 to 0.5 mg oral/SL).

Second-line treatment

If oral therapy is not achievable or is not effective, parenteral medications must be given. Agents of choice include:

- Droperidol or haloperidol IM 5 to 10 mg, every 1 to 2 hours up to maximum 20 mg/24 hours (ensure that an ECG is done within 15 minutes of administration where possible) **OR**
- Olanzapine IM 5 to 10 mg, repeated 2 to 4 hourly up to a maximum of 30 mg/24 hours **and/or**
- Lorazepam IM 1 to 2 mg, every 60 minutes up to a maximum of 8 mg in 24 hours.
- The use of IM olanzapine within 60 minutes of an IM/IV benzodiazepine has been associated with additive respiratory depression and hypotension. The combination should only be used where adequate resuscitation facilities are present and the benefits outweigh the risks.
- The side effects include hypotension, arrhythmia and EPSEs. Treatment of EPSE can be initiated with benztropine oral/IM/IV 1 to 2 mg as a single dose, but prophylactic use is not indicated.

There is evidence of more rapid onset of sedation and less adverse events when a combination of midazolam and antipsychotics is used rather than midazolam alone.[12]

Or

- ketamine 2 to 4 mg IM 1 mg/kg IV. Risks include hallucinations and imagery—especially care in the already psychotic patient. Other side effects include hypertension and raised intracranial and intraocular pressure.

IV sedation may be considered if it is safe to insert an IV canula, when IM medications ARE not effective, AND there is serious risk of harm to PATIENT AND STAFF and for immediate treatment of extreme agitation. Antipsychotics (droperidol or haloperidol IV 5 to 10 mg every 60 minutes until sedated) with a maximum dose of 20 mg in 24 hours, or lorazepam IV 1 to 2 mg every 60 minutes up to 8 mg in 24 hours may be used. Short-acting anaesthetic agents may be considered in the presence of adequate facilities and expertise, and include midazolam IV 5 to 10 mg stat and then titrated at 3- to 5-minute intervals until sedated; propofol IV 50 to 100 mg stat, then titrated at 3- to 5-minute intervals until sedated; and/or ketamine 1 mg/kg as a single dose.

Third-line treatment

If the maximal doses of the above agents have been reached with the first- or second-line drugs without adequate effect, it is necessary to try other options. Sometimes the first- or second-line drugs may have to be avoided because of previous adverse effects. The maximum doses described here are based on the likelihood of very limited greater benefit (and the probability of greater adverse effects) of exceeding these doses.

Third-line agents include:

- diazepam 2.5 to 5 mg IV, up to a maximum of around 100 to 150 mg (risks include accumulation, delirium and respiratory depression; should not be given intramuscularly)
- clonazepam 1 to 2 mg IM/IV up to a maximum of 8 mg/day. Clonazepam can also be given as an infusion at a rate of 4 to 6 mg/24 hours; the rate of the infusion can be varied according to the arousal level of the patient (risks include accumulation, delirium and respiratory depression)
- haloperidol 2.5 to 5 mg IM/IV, up to a maximum of around 30 to 50 mg/24 hours (risks are similar to droperidol)
- chlorpromazine can also be given as an IV infusion, with an initial rate of 6.25 to 12.5 mg/h to gain initial control and then reduced to a maximum of around 200 mg/24 hours (risks include anticholinergic effects, hypotension, delirium, accumulation, QT prolongation and NMS.)

Aroused patients with amphetamine intoxication should be managed with benzodiazepines and supportive care, sometimes requiring large doses for initial control. Both IV midazolam and oral/IV diazepam are reasonable first choices. Severe intoxication with hyperthermia and rigidity requires paralysis and intubation. In patients who present with paranoid psychosis associated with amphetamine abuse, the addition of an antipsychotic, such as olanzapine (oral or IM), is appropriate.

Maintenance therapy

Following initial rapid tranquillization, the patient will remain sedated for several hours, during which collateral history may be obtained. When the patient awakes, a further psychiatric assessment should be made, especially with a view to deciding whether the patient needs to be admitted to a psychiatric unit.

If the patient does need to remain in hospital, consideration must be given to further appropriate medication. A general approach is to use lorazepam (1 or 2 mg three times a day) or sedative antipsychotics (olanzapine 5 or 10 mg three times a day). It is better to prescribe regular medication (rather than 'pro re nata' [PRN]) to ensure consistency of dosing. The appropriateness of the prescribed medication and the side effects should be reviewed at least daily.

If the patient remains uncooperative, IV benzodiazepines or IM olanzapine can be used on a PRN basis. If adequate facilities are available for monitoring respiratory function, the use of an infusion of clonazepam or chlorpromazine can help to achieve control. Alternatively, some patients who are likely to remain in the ED for more than 24 hours may benefit from a one-off dose of zuclopenthixol acetate.

CONTROVERSIES AND FUTURE DIRECTIONS

- The role of butyrophenones versus atypical antipsychotics is controversial from a drug safety perspective.
- There is debate about the appropriateness of prolonged restraint and sedation of patients 'stranded' in emergency departments.
- The role of the central alpha-2 agonists in the management of hyperaroused patients in the emergency department is yet to be determined.
- Increased experience and usage of ketamine.

SECTION 21

CHALLENGING SITUATIONS

Edited by *Biswadev Mitra*

21.1 Death and dying

William Lukin • Carol Douglas

ESSENTIALS

1 **Death and management of the dying process is core business for emergency medicine.**

2 **Death in the emergency department can be either sudden and unexpected or the natural and expected evolution of a disease process.**

3 **Emergency physicians have a responsibility to understand the principles of a 'good death' and to manage departmental deaths in alignment with these principles.**

4 **Communication skills for discussing death and dying are part of the skill set of an emergency physician.**

5 **Persons undertake advance care planning to support best care at the end of life. Personal wishes and values supporting such decisions may be available for viewing at the time of admission to the emergency department. Such considerations may support a 'good death' or may complicate clinical decision making and resuscitation.**

6 **How a death is managed in the emergency department has a profound impact on the next of kin and their grieving process. Emergency physicians should understand and be able to manage their role in establishing a normal grieving process for bereaved families.**

7 **Organ donation should be considered for all patients where death is expected. Suitability for donation should be discussed with an organ donation specialist.**

8 **Local statutory obligations for coronial reporting must be well understood and observed.**

9 **The emotional health of emergency medicine practitioners should be monitored and external assistance sought when appropriate.**

Introduction

For most people, the normal expectations are that they will live a full life, that parents will predecease their children and that the dying person will be able to deal with any unfinished business and die surrounded by loved ones, as portrayed in the media. There is an expectation that death will be natural, peaceful and, for the majority, free of pain. In marked contrast to such expectations is the unexpected death of a loved one at an emergency department (ED), where sudden unexpected and violent death is not uncommon.

Death and dying patients are an inevitable part of emergency medicine practice. In 2014 to 2015 a total of 4916 people died in Australian EDs before they could be admitted.[1] These deaths can be either sudden and unexpected or the natural evolution of a dying process. Sudden unexpected death from trauma or rapid, overwhelming disease processes is somewhat unique to emergency medicine; the management of patients and families in this situation is something with which all emergency physicians must be familiar. The management of the patient dying from a life-limiting illness in the ED calls for a skill set different from that needed to deal with an unexpected death, but it is just as important. For some, facing a surviving family or counselling a dying patient may symbolize failure in the battle against disease; however, it is a privilege and, done correctly, can be an extremely fulfilling part of emergency medicine practice. In such situations, one does not have the benefit of a long-standing doctor-patient relationship. The support and mutual understanding that are the cornerstones of family practice are missing; therefore rapport must be forged in the heat of the moment. Families need space and time to come to grips with a death, but both are limited in the ED. Access block and overcrowding should not preclude sensitive, empathetic grief management.

To follow the strain and pace of a difficult resuscitation with the grace and emotional energy required to care for a family requires considerable effort. Emergency physicians also have a duty of

care to the survivors, who deserve compassion as much as the recently deceased.

Similarly, management of the patient dying at the end of a life-limiting illness can be a complex and challenging task. Patients and their families in this setting attend the ED for many reasons, including fear, unrelieved symptoms and the inability to access appropriate services. This does not always represent a failure of the health system but is determined by clinical complexity, as an ED is sometimes the only place that can deliver the level of care required. An understanding of the concepts of advance care planning is required. Clinicians must be familiar with local processes, as these may vary from state to state (see Chapter 21.6). ED clinicians should have sufficient knowledge of local palliative resources to enable advocacy roles for patients with special needs and foster partnerships with local care providers to facilitate transition into other services.

The concept of a good death is recognized widely and based on key themes (Box 21.1.1).[2] These apply equally to unexpected and expected deaths. Death in an ED may violate some or all of these principles. Emergency physicians should apply these concepts to practice as best they can within the constraints of a busy, crowded ED.

The better the memory of the death, the more likely the bereavement will be normal. The quality of care provided may prevent significant morbidity, as pathological or unresolved grief can lead to later problems with physical and mental health.[3]

The process of dying

Diagnosing dying

Death does not occur at a finite moment. Cardiac death, cerebral death, brain-stem death and cellular death form a continuum over minutes or hours. Considerable effort has been directed to the core recognition of diagnosing death. Legal definitions for diagnosing brain death, circulatory death and the staff involved are outlined in the relevant transplantation and organ donation acts in various jurisdictions. This has been done largely to facilitate organ transplantation.

There has been little research in the area of diagnosis of the dying process and the part that emergency physicians may play in this. The diagnosis of dying is a skill best exemplified by palliative medicine specialists. The timing of the death can be hard to estimate and comes with experience. A diagnosis of the likelihood of dying sets appropriate goals of care and so enables the emergency physician to engage families in preparation and allows patients to be supported with appropriate systems of care. Where possible, the patient should be enabled to maintain some control and may be able to plan for the time he or she has remaining (see Chapter 21.6).

Managing the dying process

When the point of dying is reached, the practitioner must be acutely aware of the dying person's needs. Although physical needs, such as analgesia, are relatively easily met, other domains can easily be ignored.

For patients whose death is inevitable or not unexpected, guidance documents published by the International Collaborative for Best Care of the Dying Person can be tailored to local conditions and can help to support clinicians.[4] These care documents can be instituted in the ED. This tool focuses team care on the optimal relief of the dying patient's symptoms and the avoidance of unnecessary interventions. The intent is to provide hospice-level care in other clinical settings. At this point, the principles of a good death previously described can act as an aspirational target as emergency clinicians attempt to rationalize the care they provide.

A large family may need significant space, which can interfere with the routine work of the ED; ideally a private room should be available. The clinicians' role then includes focusing on physical comfort, symptom management, and the privacy of the patient and family.

Death

Family members should be encouraged to be present during resuscitation efforts. A senior support person should be available for the family if at all possible during this time. As survival becomes increasingly unlikely, family members can be encouraged to be involved in decision making around resuscitative efforts and whether or not they should continue. After death, families should be encouraged to view, touch and talk to the deceased. It is well recognized that this facilitates the grieving process. They will remember these moments for the rest of their lives. Participation in the resuscitation process and in the decision to end it can be helpful.

Box 21.1.1 Ten key elements of best care for the dying

1. The fact that the patient is in the last hours or days of life should be acknowledged by the multidisciplinary team and documented by the senior doctor responsible for the patient's care.
2. Where possible and deemed appropriate by the relative, carer or advocate, recognition of the imminence of death should be shared with the patient.
3. The patient and relative, carer or advocate should have the opportunity to discuss the patient's wishes, feelings, faith, beliefs and values.
4. Anticipatory prescribing for symptoms of pain, excessive respiratory secretions, agitation, nausea and vomiting and/or dyspnoea should be in place.
5. All clinical interventions should be reviewed in the best interest of the patient.
6. There should be a review of hydration needs, including the commencement, continuation or cessation of clinically assisted (artificial) hydration.
7. There should be a review of nutritional needs, including the continuation or cessation of clinically assisted (artificial) nutrition.
8. There should be a full discussion of the plan of care with the patient where possible and deemed appropriate and with the relative, carer or advocate.
9. There should be regular reassessments of the patient at least every 4 h.
10. Care of the patient and relative, carer or advocate immediately after death should be dignified and respectful.

(From Ellershaw J, Lakhani M. Best care for the dying patient. *BMJ* 2013;347:f4428, with permission.)

Initiation of the grieving process

Quality management of grief states can prevent significant morbidity, as pathological or unresolved grief can lead to later problems with physical and mental health. Emergency physicians have a duty of care to the survivors and to playing their part in the initiation of family grief.

Grief is not like an illness, to be fought and cured, as so often is the case in Western medicine. Generalizations can be made about human behavioural tendencies and time lines can be drawn for predicted recovery, but each person's grieving process is unique. Some people never get better and nobody survives grief unchanged.

All relatives need time to receive the clear message of death, which they may have to be given again and again. Some need to make meaning of the event, and the clinical art of managing perceptions is paramount. For the families of the deceased, this time will be recalled with unrivalled clarity. It is a great privilege to be part of those memories and it carries the responsibility to assist the family in keeping with best-practice principles for the initiation of grieving.

Breaking bad news

The interview with the family of the recently deceased can be more difficult than the resuscitation. Handled with sensitivity, however, it can be a positive start to successful grieving and recovery.

The room in which such information is given should be private and comfortable and contain a telephone. Tea, coffee, iced water and simple food should be readily available. If refreshments arrive soon after the news has been broken, this can help to diffuse tension. The offering of food is a time-honoured expression of warmth and comfort and facilitates communication and the grieving process.

The emergency physician should greet the family by name, confirm the relationship with the patient of each and shake hands or touch them gently. All parties should be seated, and a helpful way to start is to ask the family members what they know. A simple unambiguous summary of events should be given. This must often be repeated and the family members given time to ask questions.

It is important to use the word 'dead' or 'died'; euphemisms such as 'passed away', 'she's gone' and 'departed this life' are unclear messages that can mislead. The grieving process cannot start until there is acknowledgement of death. A truthful explanation can be comforting. There is no curriculum for teaching this type of interaction. Junior staff should be able to be present when a more senior staff member is conducting these discussions, thus facilitating role modelling. Over time, junior staff should be encouraged to facilitate these discussions in the presence of more senior mentors.

Sedatives

Requests for sedatives can come from survivors or a third party, who may ask that the bereaved be given medication. It is now recognized that the use of anxiolytic medication is contraindicated in early grieving. This must be carefully explained to families making such a request. Anxiety, sadness and insomnia can be a natural part of early grief.

Reactions

There is a range of responses to the information that a close relative has died. The mode of death can be a guide. Homicide can lead to great distress, along with suicide and unintended injury. Some common reactions are as follows:

- Disbelief: Some will immediately deny the event, claiming that it must be somebody else or that they are dreaming. Reinforcement is required.
- Numbness: Some sit mute, appearing not to take in the information. They need time to absorb it.
- Expressive: A sudden flood of tears or loud cries with upsetting or disturbing noises should be allowed to run its course. Such acknowledgement can be a positive response.
- Guilt: Particularly with homicide and suicide, such news is often followed by 'if only' or 'why couldn't I have?' Here, gentle repeated reassurance and discussion can be important. These people are at risk of pathological grief reactions and can be helped by seeing the body and talking to it.
- Displacement activity: An immediate call to inform relatives, organize the funeral and discuss family matters is a poor prognostic sign. These people are often seen as mature, rational and born organizers, but they are at risk of pathological grief reactions months later.

Offers of follow-up can be made at this time. If the family members have unresolved questions, they need to have a contact in the ED to arrange further meetings if required.

Viewing the body

Relatives and their invited friends should be encouraged to view the body. By seeing the body, by feeling and touching it, the grieving process, separation and rebuilding can start. People should be encouraged to speak, touch, kiss, stroke, caress—even to argue, negotiate and cajole in private for as long as they wish. This facilitates natural grieving. The presence of a bereavement or viewing room can make this process much easier as, particularly with children, visiting can go on for several hours. A hospital morgue may be used; some have a purpose-built facility and appropriate staff support.

Cultural issues

Various ethnic and religious groups have differing practices for the handling and disposal of bodies. Emergency physicians should be able to manage different family requests in a sensitive manner while bearing in mind local statutory obligations.

In the case of Australians of aboriginal or Torres Strait Island descent, cultural practices and beliefs vary from region to region and families will guide practitioners. Aboriginal and Torres Strait Islander liaison services should be accessed.

Death certificates

Doctors managing deaths in the ED must understand and have a sound knowledge of reporting requirements for the coroner's court (see Chapter 28.2, The coroner).

Organ donation

A thorough knowledge of local definitions is crucial for the emergency physician expected to participate in efforts to improve the rates of organ transplantation (see Chapter 21.7).

Bereavement counselling

Most hospitals have qualified practitioners to support the recently bereaved. Referral should be arranged prior to the family's departure if counsellors have not already made contact. Ministers of religion are trained in grief counselling and are usually available after hours. The general practitioner should always be promptly informed of the death of a patient. Social workers are expert in grief counselling and many funeral companies and coroner's offices now provide counselling services.

Subsequent issues

Permission to leave

Recently bereaved people are sometimes confused, frightened, stunned and at a loss as to what to do next. When forensic issues (identification and statements) and viewing have been completed, they can be given the dead person's possessions and politely given permission to leave the hospital. 'There is nothing more you can do' or 'Can I phone someone or get a taxi to take you home?' may be usefully offered.

Information about contacting a funeral office to arrange for collection of the death certificate and the body and to discuss burial rites should be given in a readily available explanatory leaflet.

Professional issues

One of the important aspects of looking after survivors is caring for the carers, who are often overlooked. That is, patient death has been reported to lead to physical and emotional symptoms in emergency medicine practitioners.[5] Often, after an unsuccessful resuscitation, the professional may choose to talk about the events within the team environment. It is uncertain whether this improves psychological outcome. There is, however, a distinct propensity for those who spend their lives among the dying and their suffering to become cynical and full of black humour. The cultural norms of emergency medicine can become so integrated into personal values that the physician may not even recognize their presence. We should regularly assess our own emotional fatigue and, if there is a significant divergence between our personal values and career activities, we may want to seek support from a trusted source.

CONTROVERSIES AND FUTURE DIRECTIONS

- Partnering with palliative care colleagues will improve the skill mix of emergency clinicians. Local documentation to support the dying patient may be tailored for use in the ED or short-stay unit.
- Increasingly, attention will be paid to ensuring the well-being of staff who are constantly exposed to death and dying in the course of their duties.

21.2 Sexual assault

Jeremy Stevens

ESSENTIALS

1 **Sexual assault is defined as an act of a sexual nature carried out against a person's will.**

2 **There is widespread under-reporting of this criminal offence.**

3 **The complex medical, legal and psychological sequelae mandate a team-based approach for victims involving doctors, police and counsellors in a collaborative effort.**

4 **Management by a sympathetic non-judgemental physician can help the victim to regain control.**

5 **Medical evaluation is specifically directed at the issues of injury assessment and management, infection risk and emergency contraception.**

6 **The forensic aspects of the examination require vigilant examination and documentation by the physician to assist the court in legal proceedings.**

Introduction

Sexual assault is defined as an act of a sexual nature carried out against a person's will. Following sexual assault, a patient presenting should first be evaluated for acute traumatic physical injuries and drug or alcohol exposure. The victim should be offered prophylaxis for sexually transmitted infections (STIs) and pregnancy as appropriate. If the clinician is required to collect forensic evidence to assist in any police investigation, consent must be obtained for recording the victim's account of the assault, the findings on physical examination and the collection of forensic material. Follow-up medical care and psychological support should be arranged prior to safe discharge.

Definitions

Every jurisdiction has its own legislation and definitions used to describe all types of sexual offences with a lack of consent being the crucial issue. Sexual assault is an act of a sexual nature where the victim does not give consent and includes attempts to force the victim into sexual activity. Types of sexual assault include rape (sexual penetration), sexual assault (intentional touching of a sexual nature) and attempted or threatened rape or sexual assault (assault with intent to commit a sexual offence). Penetration is not an essential element to sexual assault.

The absence of physical resistance by the victim is not regarded as consent. Consent means free agreement of a persons' free will. Consent is not given when a person is physically forced or intimidated or if he or she is incapable of giving consent due to being asleep or so affected by drugs or alcohol that free agreement is not possible.

Sexual assault by a carer upon a child or dependent person (such as a disabled person) is termed sexual abuse. In this case consent is not at issue as it involves the child in sexual activity that is either beyond the child's understanding or contrary to accepted community standards. Legal definitions regarding age vary depending on the jurisdiction.

Epidemiology

It is estimated that 0.4% of Australians aged 18 years and over experience sexual assault.[1] Crime statistics are limited; it is estimated, for example, in the Australian Bureau of Statistics Personal Safety Survey 2005, that only 19% of women who were sexually assaulted reported the incident to police.[2] Victims hesitate to report because of humiliation, fear of retribution, fear that they will not be believed, self-blame and lack of understanding of the criminal justice system.

Males experience sexual assault less frequently; for females, it is estimated that less than a quarter were assaulted by a stranger. Stranger assaults are more common among males.

Sexual assault is more common in vulnerable populations. Individuals in psychiatric facilities may be targeted and their reports may not be believed, as may occur with intellectually or physically disabled persons with diminished ability to detect or escape from such danger. Homeless women with serious mental illness have a very high lifetime risk for this violent victimization. Young adult male prisoners are also at risk.[3]

Barriers to care

The ABS study[4] found that once an incident of sexual assault has been reported to the police, one in four cases results in the perpetrator being charged, but the conviction rate is low, with less than 50% of defendants found guilty. The study showed that 12.5% of women also did not report the assault to the police because of shame and embarrassment. Emergency physicians and nurses must be aware of these attitudes that the victim and they themselves may have when approaching the sexual assault victim. A non-judgmental, accepting stance by care providers is essential. It is not the health professional's role to make a judgement as to whether a criminal

offence occurred; the courts will decide this. False allegations of rape are made, but such a person is likely to be in need of help in any event.

The role of the doctor in attending to victims of sexual assault who have consented to forensic examination and evidence collection is not the usual model of a therapeutic relationship. There is a dual obligation, as it is recognized that the physician has both a therapeutic role and a duty to the court to provide completely objective expertise in collecting evidence and interpreting the findings on examination to a court of law, where the impartiality of experts is key to their duty.

Consent

Victims who experience sexual assault frequently experience a loss of control and may feel in danger. For the person to regain control, every step of the process must be explained and consent gained. Consent must be obtained for the forensic examination and evidence collection and for the release of the information to the police. Consent must be informed, specific and freely given. The consent must be witnessed. The capacity of the victim to give consent has to be carefully assessed. The mental competence to understand the information can be impaired, for example, by the ingestion of drugs or alcohol, and the victim's mental state should be first tested. Certain patients are bound by formal legal requirements, which vary in each jurisdiction, for consent or responsibility for medical treatment. These include intellectually disabled persons, psychiatric patients under involuntary admission and children under custody orders or under the care of the state.

The evidence collected under this consent must be accurately labelled and secured.

Chain of evidence

Once a forensic specimen has been collected from its origin, all aspects of its existence must be recorded. All persons coming into custody of the specimen must be identified and the details of all transfers of custody and maintained security of the material must be recorded. A forensic register must be maintained for all items in a dedicated and secure storage facility.

Medical evaluation of the victim (MCQ 1)

The medical, forensic and psychological needs of a complainant depend on the nature and timing of the assault. The immediate medical needs are paramount. Medical care for victims of sexual assault includes consideration of physical injury, toxicological issues and the risks of acquiring an infection or becoming pregnant.

Evaluation of acute traumatic injuries is the first priority. The literature typically reports that about half the victims have some sort of physical injury,[5] although less than 5% of victims require admission to hospital for treatment. An analysis of over 1000 cases in the United States[6] revealed that physical examination showed evidence of general body trauma in 64% of victims. Genital trauma was noted in 52%, whereas 20% had no injuries documented. An Australian study confirmed non-genital injuries in 46% of women and genital injuries in only 22%.[7] These findings indicate that many sexual assault victims may not have either general or genital trauma on examination, and this absence does not mean that an assault did not occur.

A study from Florida found that 1 in 1500 sexual assaults resulted in the death of the victim, with asphyxiation being the most common cause of death. Although there has been no comparable Australian study, the Australian Institute of Criminology reports that 288 homicides were committed in Australia in 2003 and that a sexual assault was the precipitating factor in 9.[8]

Survivors of strangulation may have no visible markings in up to 50% of cases.[9] Although external injury may appear trivial, it may indicate potentially significant sequelae, both acute and delayed. Airway compromise from laryngeal injury, mucosal oedema or soft tissue swelling may occur, as may aspiration. Hypoxic brain damage depends on the duration of hypoxia and, if present, is usually obvious. Vascular injury, such as carotid artery dissection, has been reported and may present as a delayed focal deficit from subsequent stroke up to 2 weeks after the incident.[10] Attempted strangulation warrants a high index of suspicion to rule out injuries, and a period of observation may be required.

Examination findings, where present, can include ligature abrasions, fingertip bruising from the assailant's grasp and curvilinear abrasions caused by fingernail markings, occurring singly or in sets, caused by the victim's struggle to pry the assailant's fingers from her neck. In addition subconjunctival haemorrhage and petechial haemorrhages of the skin may be present.

Penetration with foreign bodies can cause overt or occult pelvic injury. Further investigation or operative intervention may be necessary.

Forensic history, examination and evidence collection (MCQ 3)

The forensic history and examination is carried out for the purpose of obtaining evidence of the rape or assault that could be used in a prosecution. The aim is to record the victim's report of the assault and collect and record evidence related to this report as well as to collect DNA. Specific consent should be sought before this examination is undertaken, as therapeutic benefit is not intended. Specific consent must be additionally obtained to turn over the specimens to the police. Police services produce kits that give a comprehensive guide to the history and examination, including body charts required for various aspects of the prosecution. Each emergency department (ED) should have access to a multidisciplinary team including a clinician trained in such collection. In many jurisdictions there may be a specified forensic medical service.

Physical examination recorded for the forensic record must include every wound detected on meticulous forensic examination. Injury could have been inflicted by the assailant or in the victim's attempted defence or escape; in the interpretation of the injury, even minor wounds that may not require treatment take on key forensic significance. Physical examination requires a sympathetic but professional and methodical approach of every body surface, as with the collection of relevant forensic samples. Every injury must be carefully recorded on a body chart. Height and weight are required for the interpretation of toxicological results.

Standard nomenclature including lacerations, abrasions and bruises should be used in wound description (Table 21.2.1). Correct anatomical sites must be recorded and labelled, including in genital examination.

A wound is a disruption in the continuity of tissues produced by physical injury. Description of the physical characteristics of a wound includes the site, size, shape and depth of the wound as well as the appearance of the wound edges and adjacent tissue, the contents of the wound and whether there is evidence of healing. Bruises may not occur at the site of the trauma and their size does not always correlate with the applied force; they may be altered by coincident conditions, such as anticoagulant therapy. The term *laceration* is often misused to describe an incised wound. The correct classification of injuries can assist in determining the mechanism of injury or the object or weapon that caused the injury.

Patterns of injury may be observed. Blows to the head, face and neck may cause bruising, lacerations and fractures and include hyphaemas, dental trauma and tympanic membrane perforation. Fingertip bruising and imprint bruising may be evident. Attempts at self-defence may result in injuries to the hands—for example, incised wounds to the palm or bruising on extensor surfaces of the arms. Fingertip bruising can be present on the medial thighs. Bite marks may be seen on breast or buttocks. Abrasions from contact with unshaven skin may be detected. Postmenopausal women are significantly more likely to need surgical management and repair of genital injuries than are younger women.[12]

Table 21.2.1 Standard wound nomenclature and specific considerations

Wound type	*Definition*	*Important descriptors*	*Considerations*
Bruise	An area of haemorrhage within or beneath skin due to blunt trauma Also called haematoma, contusion or haemorrhage	Colour and pattern of multiple bruises	The age of a bruise cannot be determined by colour Yellow discolouration indicates bruise is at least 18 hours old[11]
Abrasion	Superficial injury of skin caused by pressure and movement applied simultaneously	Shape and depth	May indicate direction May contain trace materials
Laceration	Ragged or irregular tear in skin, subcutaneous tissues or organs from blunt force	Size and depth	Irregular or crushed margins, bridges of intact tissue Intact structures within wound (e.g. tendons)
Incised wound	Injury produced by a sharp-edged object	Length, depth	Sharply defined edges

Examination of the genitalia includes the inner thighs, buttocks and anus. Common locations for genital injuries include tears or abrasions of the posterior fourchette (where the two labia meet posteriorly), abrasion or bruising of the labia minora and fossa navicularis (directly anterior to the fourchette) and bruising or tears of the hymen. After relevant forensic specimens have been collected, it may be necessary to use a Foley catheter to tease out any folds in hymenal tissue to facilitate the inspection of hymenal injury. An examination of the vagina and cervix can then be completed using a speculum. In the course of this any evidence of injury is recorded, as is any bleeding or discharge, with the source identified. Perianal injury may need a moistened swab to tease out folds for inspection and proctoscopy may be required for inspection as appropriate.

Despite the relatively low frequency of obvious injury, the documentation of such injuries increases the chance of successful prosecution.[13] Photography must have the specific consent of the victim and is best performed by an experienced practitioner, and the secure storage of images must be ensured.

Collection of forensic specimens

The perpetrator may have left evidence on the victim. Sampling from sites of contact between the victim and assailant is the basis of evidence collection. Specimens collected are guided by the circumstances. Standardized evidence collection kits used in each jurisdiction contain both forms of swabs and slides appropriate to obtain trace evidence of saliva, semen, blood and skin-to-skin contact. Samples should be collected, allowed to dry, sealed and packaged with all contents carefully labelled and the chain of evidence maintained. Slides should be made where the presence of semen is suspected.

Any sample collected from the victim that contains cellular material from the victim's assailant can be used for DNA testing. This includes spermatozoa, semen if it contains cells or blood or tissue from under fingernails, which should be clipped. DNA evidence left on or in the body of a victim, particularly in moist areas, degrades quickly over 2 to 10 days. The forensic assessment should thus be made as soon as possible. Underpants and panty liners worn during or after the assault may be contaminated with forensic material and should be retained. DNA, if moist, degrades quickly; therefore underclothes with overgrowth of organisms should be stored in paper and not plastic bags.

Proof of sexual contact is established by the detection of spermatozoa or semen either on or within the victim or on the victim's clothes. The likelihood of detecting spermatozoa or semen from the vagina is generally very low by 72 hours. However, under some circumstances, spermatozoa may persist for days longer and can be obtained from the endocervical os or cervix. The detection of sperm or semen from the rectum or mouth is possible but very dependent on the actions of the victim after the assault, which should be recorded. The presence of DNA in deposited saliva may give a positive result for up to 2 days. Skin swabs for epithelial cells are generally unhelpful after 12 hours.

Care must be taken when the victim undresses for the examination. Hair or clothing fibres from the offender or other traces from the crime scene may have adhered to the body or clothes of the victim. The victim should undress standing over a drop sheet, which should then be included in a bag into which the clothes are placed. This becomes part of the physical evidence.

The most accurate laboratory method currently available to identify the assailant is DNA testing. The chance of incorrectly identifying an alleged assailant as the source of DNA material is very small. However, the risk of contamination of the evidence samples with that of DNA belonging to other individuals is significant and has resulted in wrongful incarceration.[14] Accordingly, forensic collection and analysis techniques are under increasing scrutiny by the legal system and sources of contamination must be excluded. All measures to minimize DNA cross-contamination in the clinical setting—including the consistent use of gloves, gowns, mask and drapes—and in the techniques of collection must be taken and recorded.

Toxicological issues

Drugs may be administered to the victim in order to facilitate sexual assault. The commonest drug is alcohol, but large numbers of drugs, including flunitrazepam and gamma hydroxybutyrate (GHB), have been implicated and the victim may be unaware or have no memory of events surrounding the assault. Self-reported alcohol consumption immediately prior to assaults is very common, including up to 77% of those reporting drug-facilitated sexual assault, and alcohol is the most commonly detected substance on toxicological testing.[15] This is likely to have had a significant impact on conscious state and the ability to consent at the time of assault and may impair the victim's subsequent recall of events. The victim is at additional risk, particularly where there is a combination with prescription or recreational drugs. The interpretation of drug levels and their possible effects is difficult. In general, urine is the preferred specimen, although blood samples should be collected within 24 hours of the assault, and these must be refrigerated prior to laboratory analysis.

Medical aftercare

The risk of genital infection after sexual assault (MCQ 4)

The risk of acquiring a STI following rape is reported to be 4% to 56%, with infection reflecting those organisms that are locally prevalent. One study showed that with baseline testing, 43% of victims had evidence of pre-existing infection.[16] The finding of pre-existing infection is not admissible in court under Australian law. Most experts discourage testing for STIs in the ED unless the victim is symptomatic.

Baseline screening for the following infections is recommended in follow up:

- HIV: HIV antibody
- Hepatitis B: Hepatitis B surface antigen (HbsAg), hepatitis B core antibody (anti-HBc) and hepatitis B surface antibody (anti-HBs)
- Syphilis: Rapid plasma reagin (RPR) and *Treponema pallidum* haemagglutination assay (TPHA)
- Chlamydia: Polymerase chain reaction (PCR) endocervical swab, first void urine

- Gonorrhoea: Endocervical swab, PCR and microscopy culture and sensitivity
- *Trichomonas*: High vaginal swab, microscopy culture and sensitivity

Although the risk of acquiring an infection is difficult to define, antibiotic prophylaxis is not generally recommended for the victim unless the person committing the assault is known to be suffering from an STI, is at high risk for having an STI or is thought unlikely to return for follow-up. Poor follow-up rates are the norm and all patients should be offered prophylaxis in the ED if urgent follow-up cannot be ensured. If antibiotic prophylaxis is considered necessary, the regimens recommended for the treatment of gonococcal infection (which will also treat chlamydial infection) and trichomoniasis should be used. Prophylaxis for syphilis should also be considered (use the regimen for early syphilis).

Hepatitis B virus (HBV) can be transmitted by sexual intercourse but the risk of transmission is undefined. HBV vaccination and hepatitis B immune globulin (HBIG), 400 IU IM, should be available where the assailant is either known to be HBV-positive or the victim is considered to be particularly at risk of infection (refer to Chapter 9.6).

It is likely that the victim will be concerned about HIV or will become concerned at a later date. The offer of HIV testing should be made, accompanied by the usual full explanation. Written consent must be obtained before the test is done. HIV seroconversion has occurred in persons whose only known risk factor was sexual assault, although the frequency of this occurrence is thought to be low.[17] In consensual sex, the risk for HIV transmission from vaginal intercourse is 0.1% to 0.2% and for receptive anal intercourse 0.5% to 3.0%. The risk of transmission from oral intercourse is much lower. Specific circumstances of an assault that might increase the risk for HIV transmission include the site of penetration, site of exposure to ejaculate and the presence of mucosal trauma, genital lesions or another STI.

Other factors that should be considered in the recommendation for post-exposure prophylaxis (PEP) include multiple assailants, the likelihood of an assailant having HIV (given the local epidemiology for HIV) and whether the assailant is from a high-risk group, including men who have sex with men or who use drugs by injection.

HIV PEP should be offered as soon as possible after the assault up to 72 hours post-exposure. Local and regional guidelines should be consulted (refer to Chapter 9.7)

Tetanus prophylaxis must be considered as part of the management of any injury.

Pregnancy prophylaxis

The risk of pregnancy following a single unprotected episode of coitus has proven difficult to define. However, a large prospective study from North America rated the risk of pregnancy from rape as 5%.[18] Emergency contraception is readily available in Australian pharmacies and it is the responsibility of the medical practitioner to make sure that the patient knows of its availability and has immediate access to the medication.

Progestagen levonorgestrel is used alone for emergency contraception in a dose of 1.5 mg and can be given up to 5 days from the time of unprotected intercourse. If this single dose is given within 72 hours, the proportion of pregnancies prevented was 85% in the World Health Organisation's multicentre study.[19] The earlier it is given, the more effective it will be.

The literature demonstrates that there is poor compliance with follow-up instructions in this setting. Arrangements for follow-up testing for pregnancy, STIs, HIV and hepatitis B vaccination should be supplied as written instructions, as victims may subsequently remember little of their interview.

Crisis intervention

Acute reactions to rape range from emotional numbing to shame, self-blame and severe emotional distress. The predominant reaction is a devastating sense of loss based on the fear for survival and the gross invasion of bodily boundaries, thus removing the victim's control over that which she finds most personal to her. Longitudinal data suggest that sexual assault survivors are at increased lifetime risk of post-traumatic stress disorder (30%) and major depression (30%). The input of sexual assault counsellors in evaluating the patient's immediate and ongoing emotional and safety needs must be in place prior to discharge. The role of various psychological therapies in decreasing long-term sequelae is not yet clear.

It has been found that the greater support the doctor provides the victim, the better the outcome. However, this study found doctors were the least supportive health professionals in this setting.

Children

Child sexual assault is ideally managed by a team with specific paediatric expertise. The circumstances regarding children who are the victims of sexual assault differ from those relating to adults. First, the child is likely to have been the victim of chronic abuse rather than an attack by a stranger. Second, almost always the offender will be a man known to the child, often in a position of authority and trust. This introduces the issue of protecting the child from further molestation. The injury pattern is highly variable. Chronic sexual abuse tends to develop as a pattern of behaviour between the victim and the offender, beginning with touching and possibly leading to penetrative intercourse. This escalation of activity may evolve over a lengthy period and physical trauma may not be a feature. If the child has been the victim of a stranger assault, the risk of physical injury is greater than that for an adult victim.

Conclusion

A patient presenting for care after sexual assault should first be evaluated for acute traumatic injury and any intoxication issues. The victim should be assessed in order to offer appropriate PEP to pregnancy and sexually transmitted diseases including gonorrhoea, chlamydia, trichomoniasis, hepatitis B and HIV, plus routine tetanus prophylaxis. Specific informed consent must be obtained prior to forensic evaluation. The involvement of a multidisciplinary team with an experienced forensic examiner and sexual assault counsellor is of value. Discharge must not occur until the immediate safety of the victim has been ensured. Follow-up for medical issues and ongoing psychological support should be arranged prior to discharge A sympathetic, non-judgemental approach on the part of the physician can help to improve the victim's outcome.

CONTROVERSIES AND FUTURE DIRECTIONS

- The incidence of sexual assault has previously been under-recognized among the disabled, mental health inpatients, military and police recruits in academies and a range of other institutional and educational settings.
- One of the most challenging areas is the endemic problem of violence, including sexual violence inflicted on indigenous women. Some groups of Aboriginal girls and women report that half of them have been the victims of incest or sexual assault.
- Every precaution must be taken to reduce possible cross-contamination of DNA during the collection and storage of forensic specimens.[20]
