Preface

The discipline of emergency medicine continues to grow, and the subspecialties continue to expand in breadth and number. Since the first edition of this book 20 years ago, there has been enormous change in the way emergency care is delivered. This has occurred both in countries where emergency medicine originally developed and in those where it was originally felt that it might not have a role because it was a 'first-world' specialty, limited in application because of cost. The World Health Organization is now completely changing this view and regards emergency medicine as the cornerstone of response to acute illness, even in countries with very limited resources.

An emergency medicine program provides essential structure to develop a response to disasters, epidemics and humanitarian crises. The importance of emergency medicine in ensuring an appropriate response to all acute medical problems is also becoming more obvious. This edition covers not only specific medical emergencies such as cardiac, neurological and respiratory emergencies, it also covers the complex organizational issues for disaster planning and response, humanitarian emergencies and refugee medicine.

A further feature of this book is that governance, training, research and organizational subjects are covered, to give the reader some frameworks to understand the complexity of managing major emergency systems of care.

The clinical subjects in this edition have all been extensively reviewed and updates provided. There have been major updates in some of the clinical chapters, such as airway, shock and sepsis, because guidelines have changed rapidly. The imaging chapters have also evolved with changing practice, improved technology and evidence for inclusion of emergency physician interpretation of imaging becomes more robust.

Despite the rapid escalation of topics and depth of potential content, we have tried to keep the book to a manageable length, to ensure accessibility for readers. As part of this process, we have moved many of the references online, so that readers who are interested can still access more detailed information. We have also moved many images and photos online to reduce printed matter. The additional material can be found in the free e-book that comes with the printed version—see inside front cover.

In a book of this size and complexity, there are many people to thank—more than 200 contributing authors from around the world, and their family and friends who were deprived of their company whilst writing the chapters! The production staff from Elsevier was extremely helpful, especially Fiona Conn for overall coordination. A special thanks to Angela Hodges, for assisting the editors and authors to complete the book in a reasonable timeframe.

Street (HIV/AIDS); Varadarajulu Suresh and Trevor Jackson (Osteomyelitis; Septic arthritis); Abel Wakai (Acute liver failure); Andrew Walby (Biliary tract disease); Richard Waller (Wound care and repair); Lee Wallis (Neurotrauma); Bryan G. Walpole (Death and dying); Allen Yuen (Privacy and confidentiality; Accreditation, specialist training and recognition); Salomon Zalstein (Urinary tract infection).

Introduction

It is hard to imagine an efficient, safe and accessible system of emergency care that is not underpinned by the specialty of emergency medicine. Although the systems of emergency care vary in maturity in different countries, there is consensus that having skilled and dedicated staff at the 'front door' of the hospital significantly improves outcomes and improves efficiency in the system.

Definition

Emergency medicine is defined by the International Federation for Emergency Medicine (IFEM) as 'a field of practice based on the knowledge and skills required for the prevention, diagnosis and management of acute and urgent aspects of illness and injury affecting patients of all age groups with a full spectrum of episodic undifferentiated physical and behavioural disorders; it further encompasses an understanding of the development of pre-hospital and in-hospital emergency medical systems and the skills necessary for this development'.

This definition is deliberately broad and encompasses both the pre-hospital and in-hospital domains of practice. It is important to note that, in many countries, elements of emergency medicine are practised under other specialties, such as anaesthesia, general practice and internal medicine. There is a strong belief among emergency physicians that, although there will always be a crossover between different specialty training, the emergency medical system will be optimized only by having a strong cadre of physicians trained specifically to provide emergency care available 24 hours every day.

The Franco-German model of emergency care has traditionally involved doctors in the prehospital sphere initiating resuscitation and assessment and then transporting the patient directly to inpatient services (without a formal emergency department). This model of care is becoming more difficult to sustain as inpatient services become more specialized and a greater emphasis is placed on early diagnosis, treatment and discharge. Many patients with potentially complex presentations can be fully 'packaged' within hours of arrival and discharged home. The idea of a consultant/professorial ward round the following day is difficult to justify. Equally, when patients arrive in hospital and are inadequately assessed and placed on the wrong clinical pathway, there are dangers for the patient and inefficiencies in the system.

Development of emergency medicine

In many ways, emergency medicine is the foundation of modern medicine. Going back to ancient times, patients were forced to seek the help of a physician for emergencies, such as wound management, and painful conditions, such as renal colic. Approaches to some of these conditions were quite sophisticated, even in ancient Egyptian and Chinese societies. However, there was little attention to systems of care and final outcomes were literally in the hands of the gods.

War—although a terrible thing—can have some positive influences. From Napoleonic times, it became evident that casualties could be better managed by triaging patients—identifying those most likely to live and identifying life-threatening injuries. In the last century, the First and Second World Wars saw huge improvements in the organization of the emergency response to injured soldiers. However, it was not until the Vietnam/American war that we saw a huge change in the way medical services responded to war casualties. With helicopter transport and well-organized paramedics, scene times were reduced to minutes and times to definitive surgery were shortened. Surgeons returning from duty on the war front realized that civilian practice in major urban centres was lagging behind services offered on the front line and set about improving response to civilian trauma.

At the same time, major improvements in medical practice meant that access to technology and skills, delivered quickly, could save lives. Examples included cardiac arrest, trauma, and sepsis. Prior to the 1950s, there were few time-dependent treatments that actually changed the final outcome for most patients.

A further influence on the development of medical systems was the transfer of industrial processes from the factory to the hospital. The lessons learnt in industry showed that if processes could be standardized with clear pathways and reduced variation, quality could be improved and costs reduced. The idea of the friendly doctor who knew his/her patients and everything that happened to them became a thing of the past. Hospitals changed from a 'cottage industry' to a 'factory' model. Emergency medicine, when it is performed well, ensures that patients are received, assessed and treated in a standardized fashion, 24 hours/day, 7 days/week. The necessity for emergency specialists to manage this system is clear. Putting patients on the wrong 'conveyor belt' of management because of poorly trained staff in the initial assessment period can have a devastating impact on outcome and lead to major inefficiencies in the hospital.

A final influence on the development of emergency medicine is the problem of worsening access to emergency care across the Western world. It is clear that demand for emergency care has risen at the same time that hospital bed numbers have been reduced. Governments have tried to make the best use of limited bedstock by reducing 'inappropriate' admissions and reducing length of stay. In good emergency medical systems, only those patients who are unable to be managed as outpatients will be admitted. In addition, patients will receive the right treatment from skilled practitioners at the earliest possible time. Realization of the importance of skilled practitioners to direct emergency patient management around the clock has led to a massive global investment in emergency medicine.

A functioning emergency medical care system helps to ensure a more robust response during natural and humanitarian disasters. The World Health Organization has recognized this more recently and promoted the development of basic emergency training and facilities in lower- and middle-income countries. Previously, the specialty of emergency medicine was viewed as an expensive addition to basic medical care—now it is seen as a fundamental structure to enable an adequate response to disasters.

Scope of practice

The fact that emergency physicians have general training which can act as a foundation for many subspecialties has led to a large variation in practice around the world—according to local needs and skills. There are core diagnostic and resuscitation skills that should be common to all emergency doctors. However, depending on practice location, some physicians may become more expert in specific skills because of need. For example, in many underdeveloped countries, expertise in obstetrics is essential, including the ability to perform a caesarean section. Drugs and alcohol will be very important in some inner-city emergency departments, whereas geriatrics may be more important in other locations. The basic skills of an emergency physician remain the same; identifying life/limb-threatening issues immediately, then prioritizing, diagnosing and treating other conditions before discharging home or admitting to an inpatient team. Finally, an emergency physician must coordinate the clinical team and the system to ensure optimal outcomes for the patient.

Emergency medicine now has a large number of subspecialties, including toxicology, paediatrics, trauma, critical care, prehospital/disaster medicine, sports medicine, hyperbaric medicine, academic emergency medicine and many more. There are now 1- to 2-year fellowships available in most of these disciplines. However, it is important that every emergency physician has a basic grounding in these subspecialties so that, when confronted with the unexpected, they feel comfortable managing the situation. Having subspecialist skills is important in large departments with many specialists, so that there are expert resource people to develop the clinical service as a whole.

The future

Emergency medicine is a specialty that has arisen from the evolution of medical care from cottage industry to a system of care based on industrial processes. This is not static and is likely to change even more dramatically into the future. It is certain that the work pattern of an emergency specialist going forward, will be very different. Changes to diagnostics, therapeutic modalities, patient demographics and the work pattern of our medical colleagues will all have an impact on what emergency medicine practice entails. Patient expectations regarding service delivery are also changing, with greater emphasis on shared decision making, timely access to care and physician accountability.

There are potential threats to the quality of emergency medical care delivered, such as overly burdensome time-based key performance indicators, used indiscriminately to meet government targets. Overcrowding has made life difficult to practice good care in many emergency departments and government changes to funding arrangements have served to deny poor people access to emergency care. These potential threats and others may also represent further opportunities to streamline care and improve interaction with colleagues in acute management and demand advocacy on the part of emergency physicians. Despite these threats, there is an underlying strength in our specialty—the ability to provide the best care to undifferentiated emergency patients 24 hours/day, 7 days/week. If we focus on our core business, the specialty will continue to grow and remain a central pillar of the overall medical system.

1.1 Basic life support

Sameer A. Pathan

ESSENTIALS

1 A patient with sudden out-of-hospital cardiac arrest (OHCA) requires activation of the Chain of Survival, which includes early high-quality cardiopulmonary resuscitation (CPR) and early defibrillation. The emergency medical dispatcher plays a crucial and central role in this process.

2 Over telephone, the dispatcher should provide instructions for external chest compressions only CPR to any adult caller wishing to aid a victim of OHCA. This approach has shown absolute survival benefit and improved rates of bystander CPR.

3 In the out-of-hospital setting, bystanders should deliver chest compressions to any unresponsive patient with abnormal or absent breathing. Bystanders who are trained, able, and willing to give rescue breaths should do so without compromising the main focus on high quality of chest compressions.

4 Early defibrillation should be regarded as part of Basic Life Support (BLS) training, as it is essential to terminate ventricular fibrillation.

5 There is strong emphasis on the implementation of public-access defibrillation programs, which include the use of automated external defibrillators by untrained or minimally trained lay rescuers in public areas.

Introduction

Basic Life Support (BLS) aims to maintain respirations and circulation in the cardiac arrest victim. BLS's major focus is on CPR with minimal use of ancillary equipment. It includes chest compressions with or without rescue breathing and defibrillation with a manual or automated external defibrillator (AED). BLS can be successfully performed immediately by any rescuer with little or no prior training or experience using dispatcher-assisted telephone instructions in the OHCA. BLS has proven value in aiding the survival of neurologically intact victims.[1–3]

This chapter outlines an approach to BLS that can be delivered by any rescuer while awaiting the arrival of emergency medical services (EMS) or medical expertise able to provide Advanced Life Support (ALS) (see Chapter 1.2).

Chain of Survival

The Chain of Survival is the series of linked actions taken in treating a victim of sudden cardiac arrest.[4] The first steps are early recognition of an individual at risk of or in active cardiac arrest and an immediate call to activate help from EMS. This is followed by early commencement of CPR with an emphasis on high-quality chest compressions and rapid defibrillation, which significantly improves the chances of survival from ventricular fibrillation (VF) in OHCA.[1–3] CPR plus defibrillation within 3 to 5 minutes of collapse following VF in OHCA can produce survival rates as high as 49% to 75%.[5–7] Each minute of delay before defibrillation reduces the probability of survival to hospital discharge by 10% to 12%.[2,3] The final links in the Chain of Survival are effective ALS and integrated post-resuscitation care targeted at optimizing and preserving cardiac and cerebral function.[8]

Development of protocols

Any guidelines for BLS must be evidence based and consistent across a wide range of providers. Many countries have established national committees to advise community groups, ambulance services and the medical profession of appropriate BLS guidelines. Box 1.1.1 lists the national associations that make up the International Liaison Committee on Resuscitation (ILCOR). The ILCOR group meets every 5 years to review the BLS and ALS guidelines and to evaluate the scientific evidence that may lead to changes.

Box 1.1.1 Membership of the International Liaison Committee on Resuscitation 2015

American Heart Association (AHA)
European Resuscitation Council (ERC)
Heart and Stroke Foundation of Canada (HSFC)
Resuscitation Council of Southern Africa (RCSA)

Resuscitation Council of Asia (RCA)

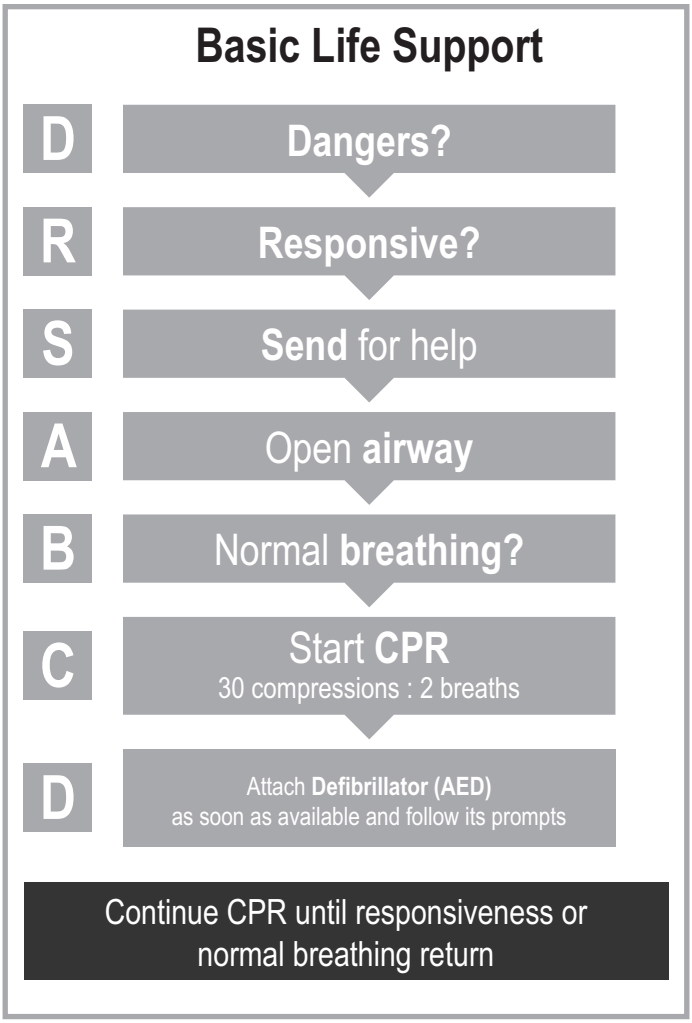

FIG. 1.1.1 Australian Resuscitation Council and New Zealand Resuscitation Council Basic Life Support flowchart. *AED*, Automated external defibrillator; *CPR*, cardiopulmonary resuscitation. (Reproduced from https://resus.org.au/guidelines/flowcharts-3/)

Revision of the Basic Life Support guidelines, 2015

The most recent revision of the BLS guidelines occurred in 2015 and followed a comprehensive evaluation of the scientific literature for each aspect of BLS. Evidence evaluation worksheets were developed and were then considered by ILCOR (available at http://circ.ahajournals.org/content/132/16_suppl_1/S40). The final recommendations were published in late 2015.[8]

Australian Resuscitation Council and New Zealand Resuscitation Council Basic Life Support guidelines

Each national committee endorsed the guidelines with minor regional variations to take into account local practices. The recommendations of the Australian Resuscitation Council (ARC) combined with those of the New Zealand Resuscitation Council (NZRC) on BLS were published jointly in 2016 and are available at http://www.resus.org.au/policy/guidelines/ and http://www.nzrc.org.nz/guidelines/ respectively.

DRSABCD approach to Basic Life Support

A flowchart for the initial evaluation and provision of BLS for the collapsed patient is shown in Fig. 1.1.1. This is based on a DRSABCD approach, the letters of which stand for *D*angers? *R*esponsive? *S*end for help; open *A*irway; normal *B*reathing? start *C*PR; and attach *D*efibrillator. This process therefore includes the recognition that a patient has collapsed and is unresponsive, a safe approach to checking for danger and immediately sending for help to activate the emergency medical response team. This is followed by opening the airway and briefly checking for abnormal or absent breathing, with rapid commencement of chest compressions and rescue breaths if the pulse is absent. A defibrillator is attached as soon as it is available, and prompts are followed if it is automatic or semiautomatic.

Change to the adult Basic Life Support in 2015

A significant change to the adult BLS in the ILCOR 2010 resuscitation guidelines was the recommendation for a Compressions, Airway, Breathing (CAB) sequence instead of an Airway, Breathing, Compressions (ABC) sequence. This was aimed at minimizing any delay in initiating chest compressions, particularly when the sudden collapse is witnessed and likely of cardiac origin. In the 2015 guidelines, the ILCOR task force differed from regional resuscitation councils in deciding to use the CAB or ABC sequence, as limited literature exists to make any single recommendation.

Regional variations

There are regional variations in the interpretation and incorporation of opening the airway within the BLS algorithm. In the European Resuscitation Council (ERC) and the ARC with the NZRC algorithm, opening the airway comes before assessment of breathing followed by compression if required. This effectively preserves the ABC sequence to avoid confusion, whereas the American Heart Association (AHA) Resuscitation Guidelines 2015 continue to advise a CAB sequence for CPR.

The ILCOR 2015 universal BLS algorithm with ARC and NZRC considerations is discussed in the remainder of this chapter.

Check for response and send for help

The patient who has collapsed is rapidly assessed to determine whether he or she is unresponsive and not breathing normally, indicating possible cardiorespiratory arrest. For an untrained rescuer, this can be sequentially assessed by a gentle 'shake and shout' and observation of the patient's response rather than by looking specifically for signs of life (which was deemed potentially confusing). The rescuer can then assess the unresponsive patient for absent or inadequate breathing.

If cardiac arrest is assumed, the rescuer should immediately telephone the EMS *(call first)* and initiate chest compressions as advised by the dispatcher to initiate BLS care. A trained rescuer or health care provider may check for unresponsiveness and abnormal breathing at the same time and then activate the EMS or cardiac arrest team.

The health care rescuers may commence CPR with ventilation for approximately 2 minutes before calling the EMS *(CPR first)* when the collapse is due to suspected airway obstruction (choking) or inadequate ventilation (drowning, hanging, etc.) or for infants and children up to 18 years of age.

Assessment of airway and breathing

Make an assessment of the airway if a patient has collapsed and is apparently unconscious. Place the patient supine if face down and look for any signs of obvious airway obstruction. A trained lay rescuer or health care rescuer may open the airway using the head tilt–chin lift manoeuvre when assessing breathing or giving ventilations. Care should be taken not to move the patient's neck in the case of suspected trauma; however, the airway takes precedence over any injury.

Adequate respiration is assessed by visually inspecting the movement of the chest wall, whether it rises and falls, and listening for upper airway sounds. In cases of cardiac arrest, occasional deep respirations (agonal gasps) may continue for a few minutes after the initial collapse; these are not considered to represent normal breathing. In suspected foreign body obstruction, one can assess the severity of obstruction by effective cough in a conscious patient. If the initial assessment of an unconscious patient reveals adequate respiration the victim should be turned to the semi-prone or lateral recovery position, followed by constant checks to ensure continued respiration and the maintenance of breathing while awaiting the arrival of the EMS.

The current recommendation for an untrained lay rescuer is that he or she should not attempt to palpate for a pulse, as a pulse check is inaccurate in this setting.[8] A health care provider should take no more than 10 seconds to check for a pulse. If the rescuer does not definitely feel a pulse within 10 seconds, chest compressions should be started immediately.

Cardiopulmonary resuscitation

In the past, the BLS sequence of rescuer opening the airway, positioning the patient, retrieving a barrier or giving mouth-to-mouth expired air resuscitation (EAR) breaths as two initial 'rescue breaths' often delayed the chest compressions. These are also difficult and challenging for an untrained lay rescuer to implement and have resulted in significant delays or, worse still, no attempt at CPR at all. Therefore the current recommendation is to initiate CPR with immediate chest compressions if the patient is assumed to be in cardiac arrest.

Management

Chest compressions

All lay rescuers (trained or untrained) and health care rescuers should begin CPR by performing chest compressions on the lower half of the sternum on any adult in apparent cardiac arrest. The patient should be placed supine on a firm surface—such as a backboard, hard mattress, or even the floor—to optimize the effectiveness of the chest compressions. There is strong emphasis on delivering high-quality chest compressions: rescuers should push hard to a depth of at least 5 cm (or 2 inches) at a rate of approximately 100 to 120 compressions per minute, allowing full chest recoil by avoiding leaning on the chest between the compressions and minimizing interruptions in the chest compressions.[8] Hence the maxim, '*Push hard, push fast, allow complete recoil and minimize interruptions*'. During BLS in the OHCA setting, there is insufficient evidence to support a pulse check while performing CPR. Therefore all attention should be paid to delivering high-quality CPR and noting any obvious change in the patient's response until the EMS arrives.

Cardiac or thoracic pump mechanism

There is ongoing debate as to whether external chest compressions generate blood flow via a 'cardiac' or a 'thoracic pump' mechanism. Whatever the predominant mechanism of blood flow, owing to the relative rigidity of the chest wall, chest compressions result in around 20% of normal cardiac output in the adult.

Chest compressions with ventilation

Rescuers willing, trained, and able to provide ventilation should give two rescue breaths after each 30 compressions, for a compression/ventilation ratio of 30/2. However, time to deliver two rescue breaths should be kept to 10 seconds or less, followed by immediate resumption of the chest compressions.

'Chest compression only' cardiopulmonary resuscitation

In the case of untrained rescuers, where rescuers are unable or unwilling to perform mouth-to-mouth breaths ('standard' CPR), 'compression only' CPR is recommended. This technique is also recommended for EMS dispatchers providing telephone advice to callers seeking to aid adults with suspected OHCA.

Health care professionals as well as lay rescuers are often uncomfortable giving mouth-to-mouth ventilation to an unknown victim of cardiac arrest. This should not, however, prevent them from carrying out at least 'hands-only' or 'chest compression–only' CPR, as bystander CPR has been shown to improve survival over no CPR at all.[9] The consensus on compression-only CPR compared with conventional CPR suggests no difference between the two methods in survival and favourable neurological or functional outcome in the short or long term.[10] Therefore to improve the likelihood of bystander CPR, compression-only CPR remains the recommended technique for the untrained rescuer or OHCA responder who is unable or unwilling to deliver rescue breaths.

Passive ventilation with chest recoil

The rationale for hands-only or chest compression–only CPR is that if the airway is open, passive ventilation may provide some gas exchange during the recoil phase of the chest compressions. However, the passive ventilation technique should not be considered an alternative to conventional CPR. The EMS responders may adopt the passive ventilation technique as part of a bundled intervention of care with free-flowing oxygen supply during a continuous high-quality chest compression phase.

Emergency medical services bundled intervention cardiopulmonary resuscitation care

In a broad definition, most EMS bundled interventions include 200 initial chest compressions followed by single shock and immediate resumption of next 200 chest compressions before a rhythm or pulse check. The rate of compressions remains 100 to 120 per minute and ventilation is achieved with bag-mask device at the rate of 8 per minute so as to minimize interruptions during compressions. Few EMS systems also use passive oxygen insufflation with basic airway adjunct and rely solely on passive ventilations during chest recoil. There is a growing literature in support of EMS bundled intervention as an alternative to conventional CPR for witnessed shockable OHCA.

Airway and breathing

The airway is opened using the head tilt–chin lift manoeuvre when assessing breathing or giving ventilations in an unresponsive adult or child. Solid material in the oropharynx should be removed with a careful sweep of a finger if inspection of the airway reveals visible foreign material or vomitus in the upper airway.

Foreign body airway obstruction

If a victim suspected of a foreign body airway obstruction (FBAO) can cough, he or she should be encouraged to cough and expel it out. If the cough is ineffective and the patient is conscious, he or she may be given up to five back blows with the heel of a hand and then up to five chest thrusts at the same compression point as in CPR, but sharper and slower. These techniques may be alternated, but it is also important to call for the EMS. If the victim becomes unresponsive, CPR may be started as described in Fig. 1.1.1.

Airway obstruction manoeuvres A number of manoeuvres have been proposed to clear the airway if it is completely obstructed by a foreign body. In many countries, abdominal thrusts are still endorsed as the technique of choice (i.e. the Heimlich manoeuvre). However, as this technique is associated with life-threatening complications, such as intra-abdominal injury, it

is no longer recommended by the ARC or NZRC. Instead, the preferred technique for clearing an obstructed airway is by alternating back blows and/or chest thrusts.

Airway equipment

When cardiac arrest occurs in a medical facility, simple airway equipment may be used as an adjunct to EAR. This would include the use of a simple face mask or bag-valve-mask ventilation with or without an oropharyngeal Guedel airway. This equipment has the advantage of familiarity, it decreases the risk of cross-infection, is aesthetically more appealing and may deliver additional oxygen, but it does require prior training.[8]

Whichever technique of assisted ventilation is used, the adequacy of the tidal volume delivered over 1 second is assessed by a rise of the victim's chest. Current guidelines during adult cardiac arrest support the use of the highest possible percentage of inspired oxygen during CPR. However, any concentration of oxygen during CPR is acceptable, the aim being to use the maximum available concentration to correct tissue hypoxia.[8]

Defibrillation

As soon as a defibrillator is available, the electrode pads should be attached to the victim and the device switched on. Self-adhesive defibrillation pads have the practical advantages of being safe, convenient and effective; they are increasingly preferred over handheld paddles. In all cases, the safety of the rescuers and other team members remains paramount during the handling of defibrillators and shock delivery.

Shock delivery

When using an automated external defibrillator, the rescuer follows the voice instructions, such as 'stand clear' and 'press the button' to deliver the shock if indicated. When using a manual defibrillator, the health care rescuer must personally select the desired energy level and deliver a shock after recognizing a shockable rhythm (VF or pulseless ventricular tachycardia [VT]).

Minimizing interruptions to chest compressions Irrespective of the resultant rhythm, chest compressions must be resumed immediately after each shock to minimize the 'no-flow' time. The interruption during chest compressions, including the preshock interval (for rhythm analysis and shock delivery) and postshock interval (from shock delivery to resumption of compressions), should be no more than 10 seconds.

All modern defibrillators are now biphasic rather than monophasic and are more effective in terminating ventricular arrhythmias at lower energy levels. However, there is still no randomized study showing superiority in terms of neurological survival or survival to hospital discharge.

If a shock is not indicated, the rescuer should immediately resume CPR at a 30/2 compression/ventilation ratio and wait for EMS to arrive or for the victim to start responding.

Automated external defibrillator

The automated external defibrillator is now considered a part of BLS. AED devices are extremely accurate in diagnosing VF or VT. AEDs are simple, safe and effective when used by either lay rescuers or health care professionals (in or out of hospital).

Lay rescuer/nonmedical personnel and public-access automated external defibrillator

AEDs have been shown to be an effective part of the BLS program. Both ILCOR and ANZCOR strongly recommend implementation of public-access AED programs for patients with OHCA. AED use in public places such as airports, schools, sport facilities and recreation facilities by minimally trained rescuers, untrained rescuers, police officers or fire and disaster management first responders has achieved improved survival rates. Data from multiple observational, nationwide studies have shown improved rates of successful defibrillator use and chances of survival through public-access AED programs.

Home-access automated external defibrillator

Finally, an AED may be placed in the home of a patient who is at increased risk of sudden cardiac arrest (who does not have an implantable cardioverter-defibrillator [ICD]) for use by a relative who might witness the event. However, home-access AEDs are not associated with any improvement in survival rates. Therefore the use of such a device may be considered on an individual basis rather than as routine recommendation.

Implantable cardioverter defibrillator and cardiopulmonary resuscitation

Patients at highest immediate risk of unexpected cardiac arrest may have an ICD inserted which, on sensing a shockable rhythm, will discharge approximately 40 J through an internal pacing wire embedded in the right ventricle. Although most patients with an implanted defibrillator remain conscious during defibrillation, CPR should be commenced if the patient fails to respond to the ICD counter shocks and becomes unconscious. Intermittent firing of the implanted defibrillator presents no additional risk to bystanders or medical personnel. However, it is prudent to wear gloves and to minimize contact with the patient while the device is discharging.

Basic life support summary

The five links in the Chain of Survival for a patient with sudden cardiac arrest include the following:

- Immediate *recognition* of the emergency and *activation* of help from the EMS system
- Early *CPR* with an emphasis on chest compressions
- Earliest use of *defibrillation*
- Effective *ALS*
- Integrated *post-resuscitation care*

Cardiac arrest may be presumed if the adult victim is unresponsive and not breathing normally (ignoring occasional gasps) without assessing for a pulse. A trained rescuer may open the airway using the head tilt–chin lift manoeuvre as part of the breathing assessment, but the lay/untrained rescuer should waste no time in initiating chest compressions. Rescuers should activate the EMS system and start chest compressions immediately. If a lone health care rescuer responds to suspected asphyxia or respiratory-related cardiac arrest (e.g. immersion or drowning), it is still reasonable for the health care rescuer to provide 2 minutes of CPR before leaving the victim alone to activate EMS.

All rescuers, whether trained or not, should at least provide chest compressions to a victim of cardiac arrest, with a strong emphasis on delivering high-quality chest compressions. Trained rescuers should also provide two rescue breaths after each 30 chest compressions at a ratio of 30/2 and deliver five cycles of 2 minutes each. The compression rate should be approximately 100 to 120 per minute and a depth of at least 5 cm (or 2 inches). All BLS guidelines encourage the use of an AED by lay rescuers in cases of cardiac arrest, maintaining chest compressions while charging the defibrillator to minimize any pre-shock pause.

BLS care should be continued until advanced help arrives and takes over CPR, the victim starts to respond or begins breathing normally, it is impossible for the rescuer to continue CPR (e.g. exhaustion or safety compromise to rescuer) or a health care professional calls for the cessation of CPR.

CONTROVERSIES AND KNOWLEDGE GAPS

- CPR to follow ABC or CAB sequence initially
- Role of passive oxygenation and ventilation in compression only CPR
- EMS bundled intervention care in OHCA presenting in non-shockable rhythm
- Timing of CPR cycle and optimal interval for rhythm check
- Value of pulse check while performing CPR in BLS
- Role of real-time audiovisual feedback and prompt devices during CPR

1.2 Advanced life support

Sameer A. Pathan

ESSENTIALS

1 **Follow the Advanced Life Support (ALS) resuscitation guidelines developed by, or based on, those of the International Liaison Committee on Resuscitation (ILCOR).**

2 **Perform chest compressions without interruption for patients with no pulse, except when performing essential ALS interventions.**

3 **Deliver a shock to attempt defibrillation (150–200 joules [J] biphasic or 360 J monophasic) if the rhythm is either ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT).**

4 **Institute other ALS interventions as indicated.**

5 **Correct reversible causes of cardiac arrest—the '4 Hs and 4 Ts'.**

6 **Implement a comprehensive, structured post-resuscitation treatment protocol.**

Introduction

A patient in cardiac arrest represents the most time-critical medical crisis an emergency physician manages. The interventions of Basic Life Support (BLS) and Advanced Life Support (ALS) have the highest probability of success when applied immediately; they become less effective with the passage of time and, after only a short interval without treatment, are ineffectual.[1]

Larsen et al., in 1993, calculated the time intervals from collapse to the initiation of BLS, defibrillation, and other ALS treatments and analysed their effect on survival after out-of-hospital cardiac arrest. When all three interventions were immediately available, the survival rate was 67%. This figure declined by 2.3%/min of delay to BLS, by a further 1.1%/min of delay to defibrillation, and by 2.1%/min to other ALS interventions. Without treatment, the decline in survival rate is the sum of the three, or 5.5%/min.

Chain of Survival

The importance of rapid treatment for cardiac arrest led to the development of a systems management approach, represented by the concept of a 'Chain of Survival', which has become the accepted model for emergency medical services (EMS).[2] This concept implies that more people survive sudden cardiac arrest when a cluster or sequence of events is activated as rapidly as possible. The Chain of Survival includes the following:

- Early access to EMS and cardiac arrest prevention
- Early high-quality cardiopulmonary resuscitation (CPR)
- Early defibrillation
- Early advanced care and post-resuscitation care

All the links in the chain must connect, as weakness in any one reduces the probability of patient survival. ALS involves the continuation of BLS as necessary, but with the additional use basic or advanced airway devices, vascular access techniques, and the administration of pharmacological agents.

Aetiology and incidence of cardiac arrest

The commonest cause of sudden cardiac arrest in adults is ischaemic heart disease.[3] Other causes include respiratory failure, drug overdose, metabolic derangements, trauma, hypovolaemia, immersion and hypothermia.

The incidence of out-of-hospital cardiac arrest (OHCA) recorded in Aus-ROC Epistry was 102.5 cases per 100,000 population.[4] The crude incidence of OHCA in New Zealand was noted as 124 cases per 100,000 person-year. In both studies, 12% to 15% of cases with attempted resuscitation survived to hospital discharge or 30 days.

Advanced Life Support guidelines and algorithms

The most clinically relevant advance in ALS, over the last two decades has been the substantial simplification of the management of cardiac arrest by the development of widely accepted universal guidelines and algorithms that include evidence-based recommendations.

International Liaison Committee on Resuscitation

In Chapter 1.1, Box 1.1.1 shows the national associations that formed the International Liaison Committee on Resuscitation (ILCOR) in 1993. The ILCOR group used to meet every 5 years to review the best available scientific literature and to publish the Consensus on Cardiopulmonary

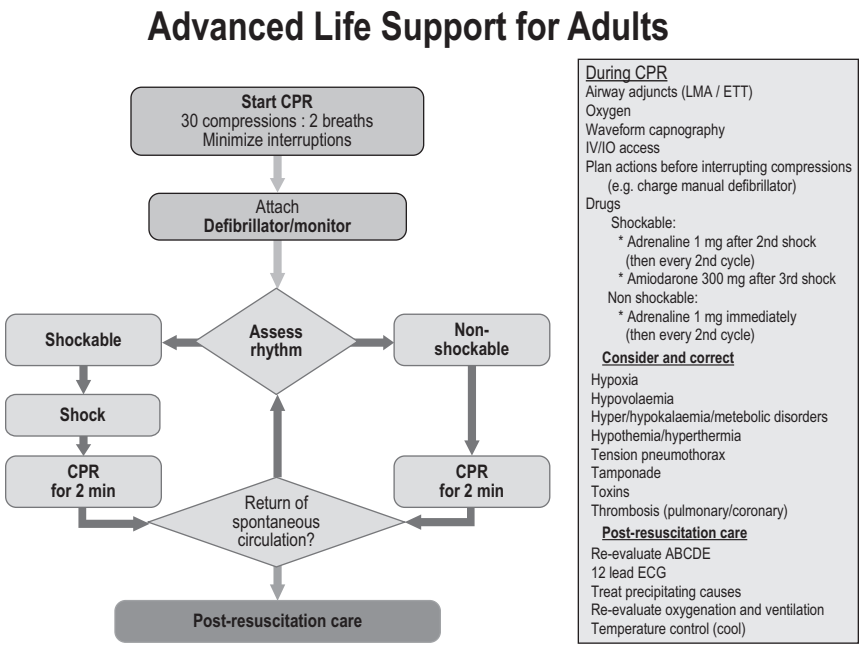

FIG. 1.2.1 Algorithm for the management of adult cardiorespiratory arrest. (Reproduced from https://resus.org.au/guidelines/flowcharts-3/)

Resuscitation and Emergency Cardiovascular Care Science with Treatment Recommendations (CoSTR). However, ILCOR realized the potential drawbacks of this approach in terms of delays in the implementation of new effective treatments. Since 2016, therefore, ILCOR has adopted the new procedure of publishing annual ILCOR CoSTR summary articles so as to provide a nearly continuous review of resuscitation science. The conference held in Dallas in February 2015 gave rise to the CoSTR documents published later that year.

Australasian guidelines and algorithms

Each ILCOR member body is expected to use the CoSTR documents to develop its own guidelines for local use. The Australian Resuscitation Council (ARC) and the New Zealand Resuscitation Council (NZRC) released joint Australasian guidelines in 2016; these are available at http://www.resus.org.au/policy/guidelines/ and http://www.nzrc.org.nz/guidelines/ respectively. The Australasian guidelines include an Adult Cardiorespiratory Arrest algorithm (Fig. 1.2.1) that is clear, concise and easy to memorize and adapt into poster format. It is also readily applied clinically. This algorithm provides the framework used throughout this chapter to discuss ALS interventions.

However, resuscitation knowledge is still incomplete and many ALS techniques currently in use are not supported by the highest levels of scientific evidence. Thus strict adherence to any guideline should be informed by common sense. Individuals with specialist knowledge may modify practice according to the level of their expertise and the specific clinical situation or environment in which they practice.

Initiation of Advanced Life Support

The purpose of BLS is to support the patient's cardiorespiratory status as effectively as possible until equipment—particularly a defibrillator—and advanced treatment support become available. High-quality CPR remains the cornerstone of both BLS and ALS. The vast majority of cardiac arrest survivors have ventricular fibrillation (VF) as the primary rhythm, and electrical defibrillation is fundamental to the successful treatment for VF and pulseless ventricular tachycardia (VT). Therefore the likelihood of defibrillation restoring a sustained, perfusing cardiac rhythm and of a favourable long-term outcome greatly depends on good CPR and decreasing the time to defibrillation. The chances of survival to hospital discharge decline rapidly after as little as 90 seconds of cardiac arrest.

The point of entry into the ALS algorithm depends on the circumstances of the cardiac arrest. In situations where there are multiple rescuers, BLS should be initiated or continued while the defibrillator-monitor is being prepared. For a single rescuer who witnesses cardiac arrest in a setting where a defibrillator-monitor is readily available, it is a reasonable approach to obtain and attach the defibrillator immediately without commencing BLS. In all other cases, there is low-quality evidence suggesting that a brief period (1.5–3 minutes) of CPR before defibrillation may improve survival in patients where the cardiac arrest is unwitnessed or time to get a defibrillator is more than 4 to 5 minutes from arrest time.

Automated Chest Compression Devices

Load-distributing band and piston devices as well as the Lund University Cardiac Arrest System (LUCAS) are commonly used automated chest compression devices (ACCDs). Moderate-quality evidence has shown uncertainties regarding the benefits or harms of ACCDs over manual compressions.[5] Therefore ILCORs suggest against the routine use of ACCDs to replace manual chest compressions. An ACCD can be used as an alternative where manual compressions are impractical or may compromise a provider's safety, as in a moving ambulance, CPR in limited space or fewer personnel available for CPR.

Attachment of the defibrillator-monitor and rhythm recognition

Automated external defibrillator

Apply the self-adhesive pads in the standard anteroapical positions for defibrillation (see further on) when using an automated external defibrillator (AED). An internal microprocessor analyses the electrocardiographic (ECG) signal and, if VF/VT is detected, the AED displays a warning and then either delivers a shock (automatic) or advises the operator to do so (semiautomatic).

Manual external defibrillator

In manual defibrillation, after applying the self-adhesive pads or handheld paddles of an external

defibrillator, the rescuer must determine whether or not the cardiac rhythm is VF/VT.

Rhythm recognition

Ventricular fibrillation

VF is a pulseless, chaotic, disorganized rhythm characterized by an undulating, irregular pattern that varies in amplitude and morphology, with a ventricular waveform of more than 150/min.

Pulseless ventricular tachycardia

Pulseless VT is characterized by broad, bizarrely shaped ventricular complexes associated with no detectable cardiac output. The rate is more than 100/min by definition and is usually in excess of 150.

Asystole

Asystole is identified by the absence of any electrical cardiac activity on the monitor. Occasionally it is incorrectly diagnosed ('apparent asystole') on the ECG monitor because

- The ECG lead may be disconnected or broken. Look for the presence of electrical artefact waves on the monitor during external chest compression, indicating that the ECG leads are connected and intact. A perfectly straight line suggests lead disconnection or breakage.
- Lead sensitivity may be inappropriate. Increase the sensitivity setting to maximum. The resulting increase in the size of electrical artefact will confirm that the sensitivity selection is functioning.
- VF has a predominant axis. Even coarse VF may cause minimal undulation in the baseline if the axis is at right angles to the selected monitor lead and thus resembles asystole. Select at least two leads in succession before asystole is diagnosed, preferably leads at right angles, such as II and aVL.

Pulseless electrical activity/ electromechanical dissociation

The absence of a detectable cardiac output in the presence of a coordinated electrical rhythm is called pulseless electrical activity (PEA), also known as electromechanical dissociation (EMD). Use of an arterial line in place, monitoring of end-tidal carbon dioxide ($ETCO_2$) or point-of-care cardiac ultrasound can help to differentiate between a true PEA and a pseudo-PEA. In general PEA has a poor outcome compared with shockable rhythms and there is some evidence regarding true PEA having a worse outcome than pseudo-PEA.[6] In an observational study of OHCA and patients with PEA, an electrical frequency of greater than 60/min compared with the frequency of less than 60/min showed better 30-day survival rate (22%) and good neurological outcome (in 15%) – comparable to with shockable cardiac arrest.

Defibrillation

The only proven effective treatment for VF and pulseless VT is early electrical defibrillation. The defibrillator must immediately be brought to the person in cardiac arrest and, if the rhythm is VF/VT, a shock must be delivered without delay.

Anteroapical pad or paddle position

There are two accepted positions for the defibrillation pads or paddles to optimize the delivery of current to the heart. The most common is the anteroapical position: one pad/paddle is placed to the right of the sternum just below the clavicle and the other is centred lateral to the normal cardiac apex in the anterior or midaxillary line (V5–6 position).

Anteroposterior pad or paddle position

An alternative is the anteroposterior position: the anterior pad/paddle is placed over the precordium or apex and the posterior pad/paddle is placed on the patient's back to the left or right of the spine at the level of the lower scapula or even in the interscapular region.

Do *not* attempt defibrillation over ECG electrodes or medicated patches and avoid placing pads/paddles over significant breast tissue in females. Also, the pads/paddles should be placed at least 8 cm away from the module and pulse generator, if the patient has an implanted pacemaker or a cardioverter-defibrillator. Arrange to check the function of any pacemaker or cardioverter-defibrillator as soon as practicable after successful defibrillation.

Waveform and energy of shocks

Two main types of waveform are available from cardiac defibrillators.

Biphasic waveforms

All modern defibrillators use biphasic waveforms with impedance compensation; this is now considered the 'gold standard'. Biphasic (bidirectional) truncated transthoracic shock defibrillators are effective at lower energies and result in fewer ECG abnormalities after defibrillation.

Set the energy level at 150 to 200 J or follow the manufacturer's advice if using a biphasic defibrillator in an adult with VF/pulseless VT cardiac arrest. For subsequent shocks, if the defibrillator is capable of increasing energy, it is reasonable to do so.

Monophasic sinusoidal waveform

Old defibrillators use a damped monophasic sinusoidal waveform, which is a single pulse lasting for 3 to 4 ms. Set the energy level at the maximum when using a monophasic defibrillator in adults, which is usually 360 J for all shockable rhythms in cardiac arrest.

Optimizing transthoracic impedance

A critical myocardial mass must be depolarized synchronously for defibrillation to be successful. This interrupts the fibrillation and allows recapture by a single pacemaker. The transthoracic impedance must be minimized for the greatest probability of success.

Reduction of transthoracic impedance

- Use pads/paddles 10 to 13 cm in diameter for adults. Smaller paddles/pads allow too concentrated a discharge of energy, which may cause focal myocardial damage. Larger pads/paddles do not make good chest contact over their entire area and/or may allow current to be conducted through non-myocardial tissue.
- Use conductive pads or electrode paste/gel. This reduces impedance by 30%. Take care to ensure that there is no electrical contact between the pads or paddles, either directly or through electrode paste, as this will result in current arcing across the chest wall.
- Apply a pressure of 5 to 8 kg to the paddle when adhesive pads are not being used.
- Perform defibrillation when the chest is deflated (i.e. in expiration).
- However, routine use of impedance thoracic device in addition to conventional CPR is discouraged.

Current-based defibrillation

Conventional defibrillators are designed to deliver a specified amount of energy measured in joules. Depolarization of myocardial tissue is accomplished by the passage of electrical current through the heart; clinical studies have determined that the optimal current is 30 to 40 amps (A). The current delivered at a fixed energy is inversely related to the transthoracic impedance, so a standard energy dose of 200 J delivers about 30 A to the average patient.

Some newer current-based defibrillators automatically measure transthoracic impedance and then predict and adjust the energy delivered to avoid an inappropriately high or low transmyocardial current. These devices have defibrillation success rates comparable to those of conventional defibrillators while cumulatively delivering less energy. The reduced energy should result in less myocardial damage and may reduce post-defibrillation complications.

Automated external defibrillators

Automated external defibrillators (AEDs) were first introduced in 1979 and have become standard equipment in EMS systems for use outside

hospital, as well as in many areas within hospital. EMS systems equipped with AEDs are able to deliver the first shock up to 1 minute faster than when a conventional defibrillator is used. Rates of survival to hospital discharge are equivalent to those achieved when more highly trained first responders use manual defibrillators.[2]

The major advantage of AEDs over manual defibrillators is their simplicity, which reduces the time and expense of initial training and continuing education and increases the number of persons who can operate the device.[2] Members of the public have been trained to use AEDs in a variety of community settings and have demonstrated that they can retain these skills for up to a year.[2] Encouraging results have been produced when AEDs have been placed with community responders, such as firefighters, police officers, casino staff, security guards at large public assemblies, and public transport vehicle crews.[2]

The Australasian College for Emergency Medicine recommends that all clinical staff in health care settings should have rapid access to an AED or a defibrillator with AED capability.

Delivering a shock

If the rhythm is assessed as shockable (VF or pulseless VT), the defibrillator should be charged while CPR continues. Then, after health care personnel are clear of the patient, a single shock is delivered. Following this shock, CPR should be recommenced *immediately* without any delay to assess or analyse either the pulse or the rhythm.

If the resuscitation team leader is uncertain whether the rhythm is shockable or non-shockable, no shock should be given.

Three stacked shocks

In 2010, the ILCOR recommended single-shock delivery for cardiac arrest patients with a shockable rhythm. Since 2010 no study has shown that any specific shock strategy is of benefit for survival, return of spontaneous circulation (ROSC) or recurrence of VF outcomes. However, keeping in mind the significance of minimal interruptions to chest compressions in improving survival outcomes, the 2015 CoSTR by ILCOR recommends single-shock delivery for all cases of cardiac arrest with shockable rhythm.

In a witnessed and monitored cardiac arrest with VF/VT, if the time to deliver shock is less than 20 seconds and time to rhythm check and recharge the defibrillator is less than 10 seconds, a sequence of up to three stacked shocks can be considered. This may be applicable to a patient who develops witnessed cardiac arrest while connected to a defibrillator with monitoring capability in a prehospital, emergency department (ED), critical care unit, coronary care unit or operation theatres.

Technical problems

Whenever attempted defibrillation is not accompanied by skeletal muscle contraction, take care to ensure good contact and that the defibrillator is turned on, charged up, develops sufficient power and is not in synchronized mode. The operational status of defibrillators should be checked regularly, and a standby machine should be available at all times. The majority of defibrillator problems are due to operator error or faulty care and maintenance.

Complications of defibrillation

- Skin burns may occur; these are usually superficial and can be minimized by ensuring optimal contact between the defibrillator pad/paddle and the patient.
- Myocardial injury and post-defibrillation dysrhythmias may occur with cumulative high-energy shocks.
- Skeletal muscle injury or thoracic vertebral fractures are possible, albeit rare.
- Electrical injury to the health care provider may occur as a result of contact with the patient during defibrillation. These range from paraesthesia to deep partial-thickness burns and cardiac arrest. The defibrillator operator must ensure that all rescue personnel are clear of the patient before delivering a shock.
- Also ensure that the patient, rescuers, and equipment are dry before defibrillation is attempted in wet conditions, such as outdoors or around a swimming pool area.

CPR 'code Blue' process

Shockable rhythms

Immediate defibrillation is essential for VF/pulseless VT, although periods of well-performed CPR help maintain myocardial and cerebral viability and may improve the likelihood of success with subsequent shocks. After delivering a single shock, CPR should be resumed immediately and continued for 2 minutes unless the patient becomes responsive and resumes normal breathing.

The rationale for continuing the CPR cycle immediately after shock is that there is typically a delay of several seconds before a diagnostic-quality ECG trace is obtained. Additionally, even when defibrillation is successful, there is temporary impairment of cardiac function from seconds to minutes, associated with a weak or impalpable pulse. Thus waiting for a recognizable ECG rhythm or palpating for a pulse that may not be present—even after successful defibrillation—unnecessarily delays the recommencement of CPR. This is detrimental to the patient who does not yet have ROSC.

At the conclusion of this period of CPR, reassess the ECG rhythm and, when appropriate, the pulse. Give a single shock without delay if VF/pulseless VT persists. Chest compressions should continue while the defibrillator is charging, and the scene is assessed for safe conditions to deliver the shock. This strategy is recommended to minimize 'no flow' time.

Non-shockable rhythms

When PEA or asystole is present on ECG rhythm and/or pulse assessment, do not defibrillate, as this may be deleterious. The prognosis for these conditions is much worse than for VF/VT and, unless there is potentially a reversible cause, the application of other ALS interventions (see further on) is indicated but seldom of value.

Cardiac pacing does *not* improve survival from asystole, either pre-hospital or in the ED setting.

Algorithm loops

Either continuously or during each 2-minute CPR cycle of the algorithm, give attention to the following:

- Minimize interruption to chest compressions during ALS interventions by planning and confirm their utility before attempting them.
- Administer 100% oxygen when available.
- Attempt to secure an advanced airway/ventilation technique but do not interrupt CPR for more than 20 seconds.
- Use waveform capnography to confirm airway placement and monitor the adequacy of CPR.
- Obtain vascular access.
- Administer adrenaline every second loop (i.e. every 4–5 minutes).
- Administer other drugs or electrolytes as indicated for individual circumstances.
- Correct potentially reversible conditions that may have precipitated the cardiac arrest and/or reduced the chances of successful resuscitation. These are listed in Fig. 1.2.1 and are conveniently remembered with the 4 Hs and 4 Ts.

The 4 Hs

Hypoxaemia
Hypovolaemia
Hyper-/hypokalaemia/other electrolyte or Hydrogen ion disorders
Hypo-/hyperthermia

The 4Ts

Tension pneumothorax
Tamponade (Cardiac)
Toxins, poisons, drugs
Thrombosis: pulmonary or coronary

Even the best-trained team will be unable to complete all of these management aspects within a single loop of the algorithm, but further opportunity will present itself if subsequent cycles are necessary.

Advanced airway management

Endotracheal intubation is considered the optimal method of airway management during cardiac arrest, with accompanied risk of complications such as oesophageal intubation if performed without adequate training and experience. Other alternative airway devices commonly used during CPR include the laryngeal mask airway (LMA), i-gel supraglottic airway, laryngeal tubes and the oesophageal-tracheal Combitube. There is insufficient evidence to support the preference of any single advance airway device over others or over basic airway management with a bag-mask device. Therefore choice of airway should be based on the equipment available, the circumstances of the cardiac arrest and the training and experience of the health care provider. Either an advance airway device or bag-mask device is an acceptable choice during cardiac arrest in any setting.

Endotracheal intubation

When a sufficiently experienced person is available, tracheal intubation should be performed provided that it does not interfere with or impede the CPR process. Laryngoscopy should be carried out during chest compressions with a strong recommendation that only a short interruption in chest compressions, not exceeding 20 seconds, should be permitted for insertion of tracheal tube between the cords.

Once the tube has been inserted, correct placement must be verified by seeing the tube pass between the cords, clinical observation of chest rise/fall and auscultation as well as, importantly, an exhaled carbon dioxide detector, such as a waveform capnograph.

The main benefit of an advanced airway, such as endotracheal intubation, is that no interruption to chest compressions is then necessary for ventilations during CPR. Also, an endotracheal tube isolates and protects the airway, allows suction and facilitates ventilation.

Ventilation and oxygenation

Cardiac arrest and CPR cause an increase in dead space and a reduction in lung compliance, thus compromising gas exchange. Therefore a fractional inspired oxygen concentration (FIO_2) of 1.0 (100% oxygen delivery system) is essential in cardiac arrest to maximize oxygen delivery.

Minute volume

Carbon dioxide (CO_2) production and delivery to the pulmonary circulation are limited by the markedly reduced cardiac output achieved during CPR. As a consequence, a relatively low minute volume of 3.5 to 5.0 L is sufficient to achieve adequate CO_2 excretion and prevent hypercapnia. This situation will be altered if a CO_2-producing buffer, such as sodium bicarbonate, is administered. A small increase in minute ventilation is then required to prevent the development of a respiratory acidosis.[1]

Ventilation rate and tidal volume

A ventilation rate of 8 to 10/min without pausing during chest compressions and a tidal volume of 400 to 500 mL (5–6 mL/kg) are sufficient to clear CO_2 during most cardiac arrest situations when an advanced airway is in place. This should cause a visible rise and fall of the patient's chest.

Vascular access and drug delivery

Intravenous route

The ideal route of drug delivery should combine rapid and easy vascular access with quick delivery to the central circulation. The intravenous route is preferred. This is most easily performed by inserting a cannula into a large vein in the upper limb or into the external jugular vein. Avoid lower limb veins because of their poor venous return from below the diaphragm during CPR as well as immediate or inexperienced central line insertion, which can have fatal consequences, such as pneumothorax or arterial laceration.

Drug delivery

Give a 20 to 30 mL IV fluid flush following any drug administered and/or raise the limb to facilitate delivery to the central circulation. A central venous cannula delivers drugs rapidly to the central circulation and should be used when already in place. Otherwise, insertion of a cannula during CPR requires time and technical proficiency and interferes with defibrillation and the CPR process; this, of course, is unacceptable.

Intraosseous route

The intraosseous route is also acceptable for drug delivery in adults as well as children. Suitable sites of insertion include above the medial malleolus or the proximal tibia. Practice is needed to perfect the technique, usually with a semiautomatic, handheld drill device.

Intratracheal route

The intratracheal instillation of drugs is an alternative during CPR, especially when tracheal intubation precedes venous access. Adrenaline, lignocaine and atropine may be safely administered through the endotracheal tube if there is a delay in achieving vascular access, although their efficacy is unproven (as it is for all ALS drugs by any route).

The ideal dose and dilution of drugs given by this route are unknown, but using 3 to 10 times the standard intravenous drug dose diluted in 10 mL of water or normal saline is recommended. The drug should be delivered via a catheter or quill placed beyond the tip of the endotracheal tube and followed by ventilations to aid dispersion.

Fluid therapy

Crystalloid solutions are used for the intravenous delivery of drugs during CPR. Glucose-containing solutions are avoided during CPR as they may contribute to post-arrest hyperglycaemia, which reduces or impairs cerebral recovery.

Drug therapy in Advanced Life Support

Not one drug used in resuscitation has been shown to improve long-term survival in humans after cardiac arrest. Despite this, a number of agents are employed based on theoretical, retrospective, or low-quality evidence of their efficacy.[1]

Adrenaline (epinephrine)

The putative beneficial actions of adrenaline in cardiac arrest relate to its alpha-adrenergic effects, which result in an increased aortic blood pressure as well as increased perfusion of the cerebral and coronary vascular beds and reduced blood flow to splanchnic and limb vessels. Adrenaline is considered the 'standard' vasopressor in cardiac arrest.[1] In observational studies, adrenaline was shown to improve short-term outcomes such as ROSC and admission to hospital; however, in clinical trials it had no effect on survival to discharge and was associated with poor neurological outcome, questioning its routine use in cardiac arrest.

Indications

- VF/pulseless VT when there is no ROSC after initial attempts at defibrillation.
- Asystole and PEA as initial treatment and then during every second loop thereafter.

Adverse effects

- Tachyarrhythmias
- Severe hypertension after ROSC
- Tissue necrosis after extravasation
- Poor neurological outcomes in longterm

Dosage

The standard adult dose is 1 mg IV q 4 to 5 minutes. Higher doses have not been shown to improve long-term outcome.

Amiodarone

Amiodarone has some benefit in survival to hospital admission refractory VF/VT in the setting of out-of-hospital cardiac arrest.[1] However, none of the anti-arrhythmics have shown to consistently result in improved survival to hospital discharge or favourable neurologic outcomes when compared to placebo.[9] The CoSTR 2015 recommendations suggest the use of amiodarone in adults with refractory VF/pVT to improve rates of ROSC.[1]

Indications
- Persistent VF/pulseless VT during the third loop following failed defibrillation and adrenaline administration
- Prophylaxis of recurrent VF/VT

Adverse effects
- Hypotension, bradycardia, heart block, QTc prolongation with proarrhythmic effects

Dosage
The initial bolus of amiodarone is 300 mg or 5 mg/kg, followed by a further 150 mg if necessary.

Atropine
Atropine has no consistent benefits in cardiac arrest and is no longer recommended for routine use in asystole/PEA.

Calcium
Calcium is indicated only when the cardiac arrest is caused or exacerbated by the conditions listed here:

Indications
- Hyperkalaemia
- Hypocalcaemia
- Poisoning by calcium-channel blocking drugs

Adverse effects
- Increase in myocardial and cerebral injury mediated by cell death
- Tissue necrosis with extravasation

Dosage
The initial dose is 5 to 10 mL of 10% calcium chloride or 15 to 30 mL of 10% calcium gluconate (three times the volume of calcium chloride for the equivalent cation dose).

Lignocaine (lidocaine)
The antiarrhythmic properties of lignocaine in cardiac arrest are known. In the Bayesian network meta-analysis published after CoSTR 2015 recommendations, lignocaine was found to be more effective than amiodarone as an effective anti-arrhythmic agent for survival to hospital discharge in patients with VF.[10]

Indications
- VF/pulseless VT refractory to defibrillation and adrenaline when amiodarone cannot be used.
- Prophylaxis of recurrent VF or VT.

Adverse effects
- Hypotension, bradycardia, heart block, asystole
- Central nervous system (CNS) excitation with anxiety, tremor and convulsions, followed by CNS depression with coma

Dosage
The initial dose is 1 to 1.5 mg/kg with an additional bolus of 0.5 mg/kg after 5 to 10 minutes if indicated.

Magnesium
Magnesium is indicated when the cardiac arrest is caused or exacerbated by the conditions listed here. There is no support for its routine use at present.

Indications
- Torsades de pointes (polymorphic VT). This is often associated with a prolonged QT interval due to ischaemia, electrolyte disturbances and drugs.
- Hypokalaemia.
- Hypomagnesaemia.
- Digoxin toxicity.
- Cardiac arrest due to VF/VT refractory to defibrillation and adrenaline.

Adverse effects
- Muscle weakness and paralysis if excessive quantities are administered

Dosage
The initial dose is a 5-mmol bolus (1.25 g or 2.5 mL of a 49.3% solution), repeated if indicated, and followed by an infusion of 20 mmol (5 g or 10 mL of a 49.3% solution) over 4 hours.

Potassium
Potassium is indicated only when the cardiac arrest is caused or exacerbated by the conditions listed here. There is no support for its routine use in cardiac arrest.

Indication
- Hypokalaemia

Adverse effects
- Hyperkalaemia with attendant dysrhythmias
- Extravasation may cause tissue necrosis

Dosage
A bolus of 5 mmol of potassium is given intravenously.

Sodium bicarbonate
Sodium bicarbonate is indicated only when the cardiac arrest is caused or exacerbated by the conditions listed here. There is no support for its routine use in cardiac arrest.

Indications
- Hyperkalaemia
- Poisoning by tricyclic antidepressants
- Severe metabolic acidosis
- Protracted cardiac arrest beyond 15 minutes

Adverse effects
- Metabolic alkalosis, hypernatraemia, hyperosmolality
- Production of CO_2 causing paradoxical intracellular acidosis, which may in part be ameliorated by adequate ventilation in CPR

Dosage
The initial dose is 1 mmol/kg (1 mL/kg of 8.4% sodium bicarbonate) over 2 to 3 minutes, then as guided by the arterial blood gases.

Vasopressin
Vasopressin is an alternative vasopressor to adrenaline. There is currently insufficient evidence to support its routine use either alone or in combination with adrenaline in any cardiac arrest rhythm.

Consider administration for:
- Vasopressor effect as an alternative to adrenaline

Adverse effects
- Cerebral oedema or haemorrhage after ROSC
- Persistent vasoconstriction following ROSC, which may exacerbate myocardial ischaemia and interfere with left ventricular function
- Procoagulant effect on platelets

Dosage
The dose is a single bolus of 40 U IV administered once during the episode of cardiac arrest.

Hemodynamic monitoring during CPR

End-tidal carbon dioxide
Animal and clinical studies indicate that measuring $ETCO_2$ is effective and informative for determining progress during CPR, particularly if there is ROSC.

$ETCO_2$ typically falls to less than 10 mmHg at the onset of cardiac arrest. It can rise to between one-quarter and one-third of the normal level with effective CPR and rises to normal or supranormal levels over the next minute following ROSC. A value of 10 mmHg or greater after tracheal intubation or 20 mmHg or greater after 20 minutes of CPR may be a predictor of survival to discharge. However, the $ETCO_2$ cut-off value alone should not be used to predict mortality or to stop CPR.

Arterial blood gases
Arterial blood gas (ABG) monitoring during cardiac arrest is used as an indicator of oxygenation and the adequacy of ventilation but is not an accurate measure of tissue acidosis. An increase in $PaCO_2$ may indicate improved tissue

perfusion during CPR or with ROSC, if ventilation is constant. The measurement of ABGs should never interfere with the overall performance of good CPR.

Post-resuscitation care

This is covered in detail elsewhere but is mentioned here too as successful ROSC is only the first step in recovery from cardiac arrest. The post-cardiac arrest syndrome—comprising brain injury, myocardial dysfunction, a systemic ischaemia/reperfusion response and persistence of the causative pathology—often complicates the post-resuscitation phase. Among patients surviving to intensive care unit (ICU) admission but subsequently dying in hospital, brain injury is the cause of death in 68% after out-of-hospital cardiac arrest and in 23% after in-hospital cardiac arrest.

Implementation of a comprehensive, structured post-resuscitation treatment protocol may improve survival in cardiac arrest victims after ROSC. The most important elements of such a protocol are summarized in the following algorithm for adult ALS management (see Fig 1.2.1):

- Targeted temperature management (TTM; select and maintain between 32°C and 36°C), and treatment of hyperpyrexia
- Optimized airway management including advanced airway techniques in patients requiring continued ventilation
- Maintenance of normocapnoea and an arterial oxygen saturation of 94% to 98%
- Circulatory support to maintain tissue perfusion
- Control of seizures
- Control of blood glucose at 10 mmol/L or less but avoiding hypoglycaemia
- Treatment of any underlying cause of the cardiac arrest, in particular coronary reperfusion for myocardial ischaemia

Extracorporeal CPR

Limited data exist related to the use of ECPR in cardiac arrest. Observational studies have shown that the use of ECPR improved survival with good functional outcomes at 30 and 180 days, both in IHCA and OHCA. However, these observations were subject to selection bias. Therefore ANZCOR suggests that in patients with cardiac arrest not responding to standard CPR, it is reasonable to use ECPR as a rescue therapy for selected patients in settings capable of implementing it. ECPR can be used as bridging therapy for patients in cardiac arrest requiring percutaneous coronary intervention.

Futile resuscitation with prolonged CPR

The vast majority of patients who survive out-of-hospital cardiac arrest have ROSC before arrival at the ED. Only 33 of 5444 patients (0.6%) in 18 studies between 1981 and 1995 who were transported to an ED still in cardiac arrest after unsuccessful prehospital resuscitation survived to hospital discharge. Twenty-four of the surviving patients arrived in the ED in VF and 11 of these had their initial cardiac arrest in the ambulance en route to the hospital or had temporary ROSC before arrival.

Terminating resuscitative efforts before hospitalization

A range of recommendations with varying degrees of evidence are available to guide the decision to terminate CPR.[11] However, the termination of resuscitative efforts may be considered if *all* of the following criteria apply to a normothermic adult with OHCA:

1. Unwitnessed out-of-hospital cardiac arrest
2. No AED shocks delivered
3. No bystander CPR delivered
4. Primary arrest condition does not achieve ROSC within 25 minutes following standard ALS

In-hospital cardiac arrest with a poor outcome

A poor outcome is linked to pre-existing conditions, such as cardiogenic shock, metastatic cancer, renal failure, sepsis and an acute cerebrovascular accident. Age alone is not an independent predictor of outcome for either in-hospital or out-of-hospital cardiac arrest.

Outcome of prolonged Advanced Life Support

ALS resuscitation efforts lasting more than 30 minutes without ROSC at any stage are so uniformly unsuccessful that resuscitation should be abandoned, except in certain special circumstances, such as hypothermia, possibly some drug overdoses and following thrombolysis in suspected massive pulmonary embolism (PE). The return of spontaneous circulation at any time during the resuscitation process resets the clock time to zero.

Prognosis for survival after cardiac arrest

The best prospect of neurologically intact long-term survival after a cardiac arrest exists when

- The victim's collapse is witnessed.
- CPR is commenced immediately.
- Cardiac rhythm is VF or pulseless VT.
- Defibrillation is performed as soon as possible, ideally within 2 to 3 minutes of collapse.

CONTROVERSIES

- Acceptance of a universal algorithm
- Lack of a demonstrated role for any drug used in ALS
- Timing and dose for initial epinephrine in shockable rhythm
- Use of automated chest compression devices
- Role of ECPR in cardiac arrest management
- Amiodarone versus lidocaine in persistent VF arrest
- Criteria for the termination of CPR

CRITICAL CARE

Edited by *Conor Deasy*

2.1 Airway and ventilation management

Christopher Groombridge • Amit Maini • Peter Fritz

ESSENTIALS

1 **Respiratory failure is a common presentation to the emergency department and ventilatory support may be required.**

2 **Non-invasive ventilation is appropriate for many patients with respiratory failure; endotracheal intubation and mechanical ventilation is used for cases where non-invasive ventilation is unsuccessful or contraindicated.**

3 **Rapid sequence intubation, using a sedative plus muscle relaxant drugs to facilitate endotracheal tube placement, is the default technique in the emergency department.**

4 **If visualization of the vocal cords at laryngoscopy is difficult, a 'plan B', previously agreed to, should be initiated to avoid patient hypoxaemia.**

5 **Clinical checks to confirm correct endotracheal tube position are unreliable. Waveform capnography must be used to confirm tracheal placement.**

6 **In patients with acute lung injury and decreased pulmonary compliance, a protective lung ventilation strategy using low tidal volumes should be used to avoid barotrauma.**

Introduction

Assessment and management of the airway is a core skill in emergency medicine. Contemporary practice focuses on optimal preparation to mitigate the risks inherent in airway management, particularly rapid sequence intubation (RSI).

Initial approach

Evaluation of the airway

Evaluation of the airway commences with a '*look, listen, feel*' approach to detect partial or complete airway obstruction. If airway compromise is suspected, initial basic airway manoeuvres include the jaw thrust, chin lift and head tilt, and placement of an oropharyngeal airway (OPA) (see Chapter 1.1, 'Basic Life Support').

Gentle direct inspection of the upper airway using a laryngoscope may be necessary to detect a foreign body, which can be removed using a Yankauer suction catheter for liquids/secretions and/or Magill's forceps for solid material. Once the airway is cleared, supplemental oxygen by face mask is commenced as consideration is given to the breathing status.

Evaluation of breathing

Evaluation of breathing also uses a '*look, listen, feel*' approach. A pulse oximeter gives initial information about the adequacy of oxygenation and the breathing may be further assessed with an arterial or venous blood gas analysis to measure the PCO_2.

Conscious patients with a patent airway but who have hypoxia and/or hypercapnia should then be considered for non-invasive ventilation (NIV) or endotracheal intubation (ETI) and mechanical ventilation.

Non-invasive ventilation

Patients in respiratory failure with hypoxaemia and/or hypercapnia may benefit from a trial of NIV.[1] The use of NIV involves administration of a controlled mixture of oxygen and air delivered at a set positive pressure via a tightly sealed face mask. The pressure is generally maintained between 5 and 10 cm H_2O during both inspiration and expiration. This continuous positive airway pressure (CPAP) recruits lung alveoli that were previously collapsed, improving the ventilation/perfusion (VQ) ratio and thus helping to correct hypoxaemia. There may also be a reduction in the work of breathing as a result of improved pulmonary compliance.

Inspiratory support (i.e. 5 to 20 cm H_2O above the baseline pressure) during NIV is known as bi-level NIV or BiPAP. This additional inspiratory support is thought to further reduce the work of breathing when there is poor lung compliance or increased airway resistance.

Contraindications to NIV include comatose or combative patients, poor tolerance of a tight-fitting face mask, poor seal of the face mask due to facial hair, and/or the lack of trained medical or nursing staff to institute and monitor the NIV.

Advanced airway management

Rapid sequence intubation

Indications

1. **Actual or impending airway compromise (threat to airway patency or protection):** Attempts to improve airway patency should occur automatically and include positioning manoeuvres such as a jaw thrust, suctioning of the oropharynx and the use of airway adjuncts including oropharyngeal and nasopharyngeal airways. Unconscious patients may maintain airway patency but be unable to protect their airway and are at risk of aspiration.
2. **Ventilatory failure: Patients may require ventilatory support for myriad reasons** including trauma (e.g. flail chest), weakness (e.g. Guillain-Barre syndrome) or for fatigue (poor lung compliance, e.g. acute respiratory distress syndrome [ARDS]).
3. **Unmanageable or severely agitated patients requiring assessment and management:** To facilitate safe assessment and care of the patient and to enable the clinical team to progress resuscitation efforts without risk to their own safety.
4. **Anticipated Clinical Course:** Patients who are likely to deteriorate, for example patients with an altered conscious state with a head injury, or with airway burns, should have their airway definitively managed early. This may also be appropriate for patients who will need operative intervention during their resuscitation and are likely to undergo a series of painful procedures prior to the anaesthetic they will receive in theatre.

The decision to intubate a patient should be made collaboratively by the resuscitation team leader and the doctor responsible for airway management. In every case consider whether the benefits of RSI outweigh the potential risks of the procedure.

Preparation of patient

Assessment Careful preparation is essential prior to RSI. A history of current medications, allergies and time of the last meal should be sought and the airway examined looking for anatomical features that may predict difficult intubation.

Pre-oxygenation The administration of a fast-acting muscle relaxant is a critical component of RSI allowing prompt laryngoscopy and passage of a cuffed endotracheal tube (ETT). Apnoea is a necessary part of this process and desaturation will occur without efforts to prevent it. Effective pre-oxygenation may allow several minutes of apnoea without desaturation and should be utilized in the management of any patient who requires intubation. Pre-oxygenation involves the provision of a high concentration of oxygen for a sufficient period to wash out the nitrogen in the lungs. This 'denitrogenation' establishes an oxygen reservoir in the lung volume which prolongs the safe apnoea time. Fig. 2.1.1 compares the efficacy of denitrogenation of pre-oxygenation techniques available in the emergency department compared with the anaesthetic circuit.[2]

Apnoeic oxygenation The continuous provision of oxygen through a patent airway in the form of high flow nasal oxygen is called 'apnoeic oxygenation' and will also increase the safe apnoea time.[3] Other factors can reduce the safe apnoea time however, for example children and pregnant women consume oxygen at a faster rate and their safe apnoea times are shorter as a result. The same is true of unwell patients whose metabolic rate is increased due to sepsis or drugs. Fig. 2.1.2 illustrates the different safe apnoea time duration for these patient groups despite effective denitrogenation preoxygenation.[4]

Traditional RSI teaching prohibited face mask ventilation (FMV) during the apnoeic period to reduce the risk of gastric insufflation and aspiration but this must be balanced against the risk of hypoxia. For patients who are already hypoxic, those with profound acidaemia, and paediatric patients, it is safer to provide ongoing ventilation during apnoea using a two-person FMV technique focusing on airway patency and generating the minimum airway pressure to achieve chest rise and fall.

For some patients requiring emergent intubation, pre-oxygenation is difficult or impossible due to agitation and poor tolerance of a face mask. Administration of a muscle relaxant to facilitate control of the patient in the hope that

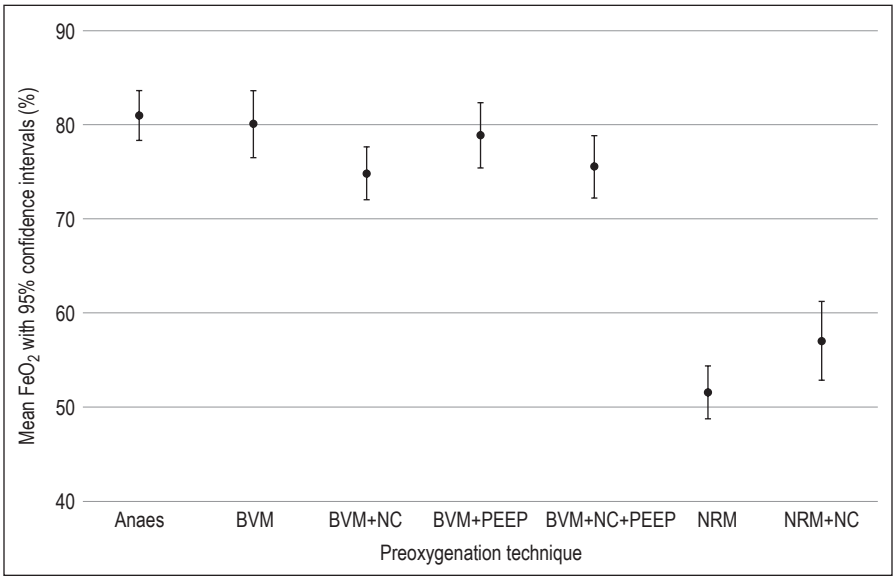

FIG. 2.1.1 Comparison of mean FeO_2 achieved with each preoxygenation technique. Data are shown as mean with a 95% confidence interval. *BVM*, Bag-valve-mask; *NC*, nasal cannula; *NRM*, nonrebreather mask; *PEEP*, positive end-expiratory pressure valve. (From Groombridge C, Chin CW, Hanrahan B, Holdgate A. Assessment of common preoxygenation strategies outside of the operating room environment. *Acad Emerg Med*. 2016;23(3):342–346 with permission.)

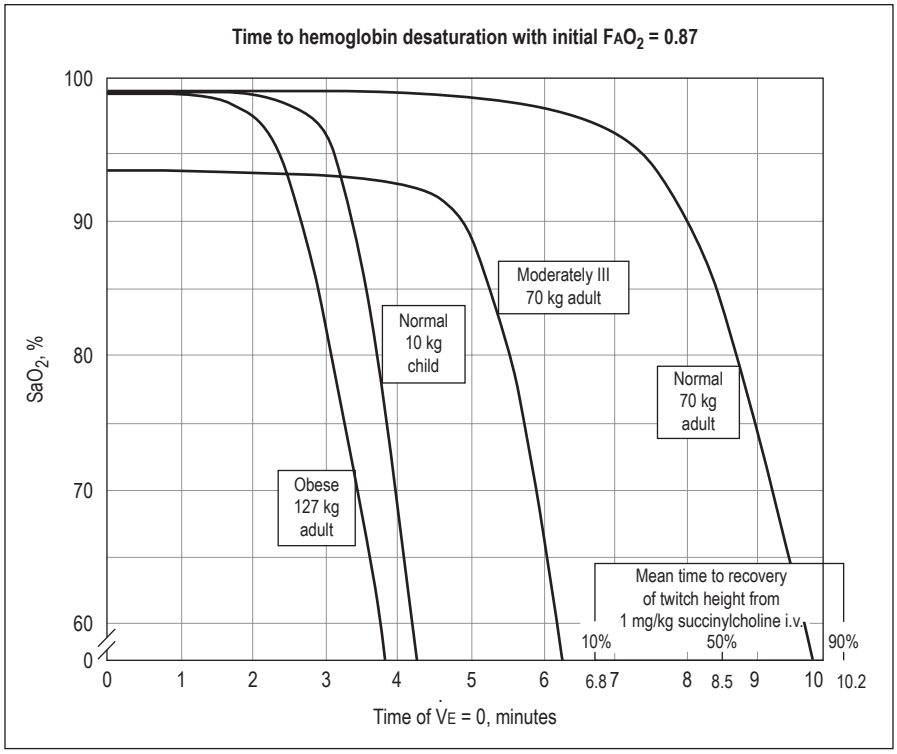

FIG. 2.1.2 SaO2 versus time of apnoea for various types of patients. (From Benumof JL, Dagg R, Benumof R. Critical hemoglobin desaturation will occur before return to an unparalyzed state following 1 mg/kg intravenous succinylcholine. *Anesthesiology.* 1997;87(4):979–982 with permission.)

a rapidly passed ETT will allow oxygenation is a risky approach and is often associated with desaturation even in the anatomically normal airway, let alone unexpectedly difficult airways. A safe approach is the judicious use of sedation to facilitate pre-oxygenation prior to RSI. This is sometimes referred to as delayed sequence intubation (DSI) which is essentially procedural sedation for pre-oxygenation.[5] Ketamine (intramuscular (IM) or intravenous (IV)) may be the ideal agent as the patient should continue to maintain airway patency and ventilation whilst sedated.

Positioning For trauma patients with spinal precautions the use of the reverse Trendelenburg position will improve VQ matching.[6] Raising the head with a folded towel placed under the occiput brings the cervical spine to a more anatomical position and also improves the position of the airway for laryngoscopy, as well as FMV.[7] Manual in-line stabilization of the spine should be maintained during laryngoscopy by a dedicated team member.

Where cervical spine injury is not a concern positioning the patient in the ear-to-sternal-notch position, with the face parallel to the ceiling, is preferred.[8]

Preparation of team and equipment

An RSI checklist should be used as a guide to preparation of the team, equipment and patient, prior to the final challenge-response run through of the checklist (Fig. 2.1.3).

In addition, the use of a standardized RSI equipment template, or 'kit-dump' may facilitate rapid preparation of the essential equipment (Fig. 2.1.4).

All drugs must be drawn up and checked in advance and the syringes clearly labelled. A spare laryngoscope must be available in case of failure of the first and the appropriate size of ETT opened, lubricated and the cuff checked. Another ETT (one size smaller) should also be available. Finally, a bougie must be immediately available. An ETT introducer (stylet) is preferred by some practitioners to provide a 'hockey-stick' or 'straight to cuff' shape to the end of the ETT.

The administration of drugs for RSI should not occur until the airway team (laryngoscopist and airway assistant) indicates to the team leader that they are ready to undertake the RSI, having optimized the patient, and completed the airway checklist.

The use of cricoid pressure is controversial. Historically it has been used to prevent aspiration but the evidence base for this is not strong and more recent evidence suggests it may worsen the view at laryngoscopy.[9]

Monitoring

Monitoring required during RSI must include a continuous electrocardiography (ECG) trace and pulse oximetry. The blood pressure should be measured either non-invasively using an automated monitoring device or invasively using an intra-arterial catheter for the haemodynamically unstable patient. Waveform capnography for end-tidal carbon dioxide ($ETCO_2$) measurement following RSI must be calibrated and ready to use.

Airway pharmacology

Sedative agents

The ideal sedative agent would rapidly render a patient unconscious and amnesic on administration, whilst also providing effective analgesia, and maintaining cerebral perfusion, without negative haemodynamic compromise or other major adverse side effects. Unfortunately, there is currently no such drug available, and the main agents all have potential advantages and disadvantages associated with their use.

Commonly used sedative drugs (and doses) include:

- Ketamine (1–2 mg/kg [IV], 5 mg/kg [IM])
- Propofol (0.5–2.5 mg/kg)
- Thiopentone (2–5 mg/kg)
- Midazolam (0.05–0.3 mg/kg)

Ketamine

Ketamine is a dissociative anaesthetic agent with hypnotic, analgesic and local anaesthetic properties. It is unique in that unlike the other sedative agents listed, it may lead to tachycardia, increased blood pressure and cardiac output. This may be advantageous in the shocked patient. Ketamine's other beneficial effects include relative preservation of respiratory drive and airway reflexes as well as acting as a bronchial smooth

ED intubation checklist

Team

- ❑ Is this a potentially **difficult airway**?
- ❑ Do **anaesthetics or ENT** need to be contacted?
- ❑ Senior ED doctor and resource nurse **notified**?
- ❑ **Roles** allocated?
  - Team leader
  - Airway doctor
  - Airway nurse
  - Drug administrator
  - Scribe
  - CICO rescuer
  - +/– Cricoid pressure
  - +/– Manual in-line stabilisation

Patient

- ❑ **Position** optimised?
  - Manual in-line stabilisation with collar open
  - Reverse trendelenburg
  - Occipital raise
  - Ramp (unless trauma)
- ❑ **Physiology** optimised?
  - Fluid bolus
  - IV access x2
  - Ino- / vasopressor considered (unless trauma)
- ❑ **Preoxygenation** optimised?
  - 3 minute timer
  - Rigorous mask seal
  - BVM
  - Nasal cannula
  - Consider NIV / PEEP valve
  - Consider gentle ventilation during apnoea
- ❑ **Monitoring** applied?
  - $EtCO_2$ waveform seen
  - BP (cycled q3min NIBP)
  - SpO_2
  - ECG

Equipment

- ❑ Is equipment checked and **ready** (template)?
  - BVM with O_2 flowing
  - Nasal cannula O_2
  - Airway adjuncts
  - Supraglottic airway device
  - ETT x 2 (+ 1 size down)
  - Laryngoscopes x 2 (direct/video)
  - Bougie
  - CICO rescue equipment
  - Suction
- ❑ Are **drugs and lines** ready?
  - IV checked and flushed
  - Fluids on pumpset
  - Post-intubation sedation and analgesia chosen
  - Ino- / vasopressors discussed

Plan

- ❑ **Plan** verbalised?
  - A:
  - B:
  - C:
  - D:
- ❑ What is the reoxygenation **desaturation** stop-point?
- ❑ What **drugs / doses** are to be given?
  - Induction
  - Muscle relaxant
- ❑ Does anyone have **questions or concerns**?
- ❑ Do we need additional **help** or equipment?

FIG. 2.1.3 Example of an emergency department *(ED)* intubation checklist. *Bp*, blood pressure; *BVM*, Bag-valve-mask; *CICO*, can't intubate can't oxygenate; *ENT*, ear nose & throat; *$EtCO_2$*, end-tidal carbon dioxide; *ETT*, endotracheal tube; *NIBP*, non-invasive blood pressure; *NIV*, non-invasive ventilation; *O_2*, oxygen; *PEEP*, positive end-expiratory pressure; *SpO_2*, oxygen saturation.

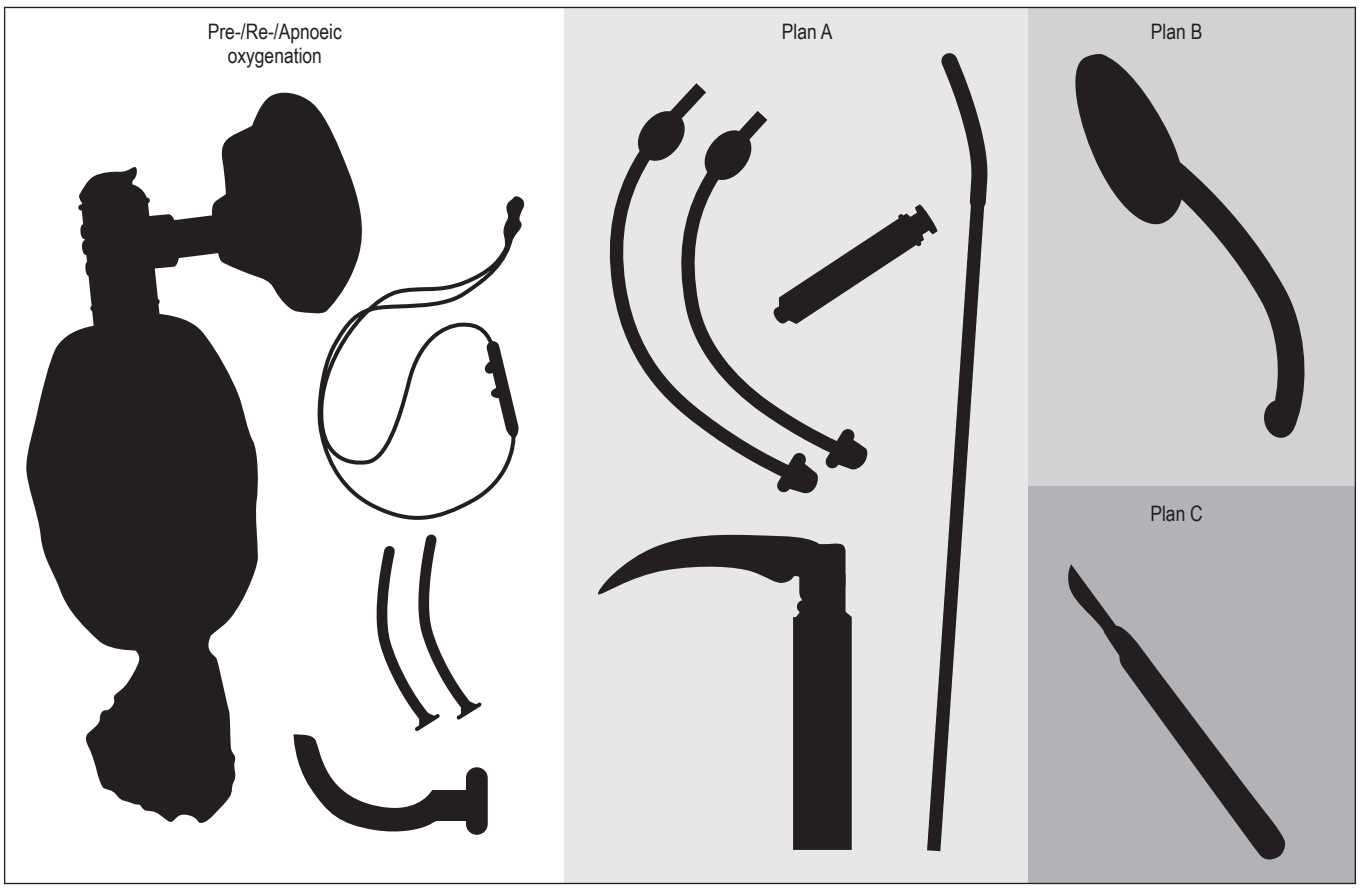

FIG. 2.1.4 Emergency department Rapid Sequence Intubation kit dump.

muscle relaxant. These properties combined may make ketamine the ideal choice in a wide range of clinical settings, including:

- shocked patients—e.g. haemorrhagic shock
- traumatic brain injury
- severe asthma
- procedural sedation

Ketamine should be used cautiously in patients with known coronary artery disease and poorly controlled hypertension.

Propofol

Propofol is a short-acting general anaesthetic drug, with a rapid onset time less than 30 seconds. It is delivered as a lipophilic emulsion and is preferred by many anaesthetic practitioners especially in the setting of elective surgery. It can produce profound hypotension through reductions in systemic vascular resistance, cardiac contractility and pre-load. It should therefore be used with extreme caution in haemodynamically unstable patients, especially those with concurrent traumatic brain injury, or reduced left ventricular function.

Thiopentone

Thiopentone is the most commonly used barbiturate sedative, producing rapid onset of deep sedation within 30 seconds. It may potentially reduce intracranial pressure through its effects in reducing cerebral blood flow and metabolism and is also a potent anti-convulsant agent, making it useful in patients presenting in refractory status epilepticus. Thiopentone may cause myocardial depression and reduced mean arterial pressure (MAP) due to reduced sympathetic outflow. This may be more pronounced in shocked patients, as well as patients on beta-blocker medications, and should be used cautiously (including appropriate dose reduction).

Midazolam

Midazolam is a commonly used benzodiazepine within the emergency department, though its onset of action is relatively slow (60–120 seconds), limiting its use as an effective sedative agent for emergency department RSI.

Paralytic agents

Suxamethonium

Suxamethonium is considered by many as the agent of choice for emergency department (ED) RSI, producing adequate intubating conditions rapidly within 30–45 seconds. The duration of paralysis is variable, lasting around 9 minutes, with effective respirations resuming at about 12 minutes. Disadvantages of suxamethonium use in ED RSI include:

- Bradycardia (especially after repeated dosing)
- Severe hyperkalaemia in patients with recent burns, crush injury as well as those with prior upper motor neurone lesions e.g. stroke, spinal cord lesions
- Masseter muscle spasm leading to severe trismus. This rare complication can be overcome using a non-depolarizing muscle relaxant such as Rocuronium
- Malignant hyperthermia

Rocuronium

Rocuronium produces optimal intubation conditions by 45–60 seconds, while the duration of paralysis ranges from 20 to 60 minutes. Both the onset of paralysis and duration of action are dose-dependent; a higher dose produces a quicker onset but longer duration of action. While the 'standard' paralytic dose of rocuronium is 0.6 mg/kg, a dose of 1.5 mg/kg of ideal body weight is more suitable for emergency RSI. Rocuronium has few or no cardiovascular effects and is safe in chronic renal failure patients and children.

All non-depolarizing agents should be used with care in patients suspected to be suffering with myasthenia gravis, as it may lead to prolonged paralysis.

Details of the indications, dosages and side effects of all the commonly used drugs for emergency RSI are shown in Table 2.1.1.

Endotracheal tube delivery

Human factors

'Human Factors' refers to situational and individual factors that can impact performance. A consistent team approach is essential, with a focus on optimal preparation, including role allocation and pre-briefing the airway plan. Running through an airway checklist prior to RSI may reduce the cognitive load of the laryngoscopist and reassure the team that a thorough preparation has been undertaken prior to administering induction medications.

Airway plan

Verbalization of a plan for a failed intubation is vital. Difficult airway algorithms[10] attempt to standardize this process but it is wise to assess the most appropriate rescue manoeuvre for each and every patient; for example, a supraglottic airway (SGA) device may be effective in most intubations but may be inappropriate in cases of airway obstruction where a surgical airway should be undertaken.

Table 2.1.1 Common Intravenous Drugs for Rapid Sequence Intubation

Drug	*Dose*	*Onset Time (s)*	*Haemodynamic Effects*	*Side Effects*	*Notes*
Sedative					
Ketamine	1–2 mg/kg	30–45	Increases blood pressure (BP) and heart rate (HR)	Increased salivation, bronchorrhoea	Potential use in traumatic brain injury, asthma, shocked patients
Propofol	0.5–2.5 mg/kg	30–45	Decreases BP	Hypotension in shocked patients	Potential use in severe asthma, dose reduce in shock, avoid in suspected traumatic brain injury
Thiopentone	2–5 mg/kg	15–30	Decreases BP	Hypotension, can cause bronchospasm	Potential use in status epilepticus, dose reduce in shock, avoid in hypotensive suspected traumatic brain injury
Midazolam	0.05–0.3 mg/kg	60–120	Decreases BP	Hypotension	Onset time too long for most emergency indications
Muscle Relaxant					
Suxamethonium	1.5 mg/kg	30–45	Bradycardia (esp in children)	Transient increase in serum potassium, anaphylaxis	Avoid in recent burns, crush injury and patients with neuromuscular disorders, history of malignant hyperthermia
Rocuronium	1.5 mg/kg	45–60	Neutral	Nil significant	Use cautiously in patients with myasthenia gravis

Technique

Performing ETI in a stepwise manner will improve visualization of the larynx and passage of the ETT. Identification of laryngeal structures starts after suctioning the pharynx, the laryngoscopist then gently applies the tip of the laryngoscope blade to the base of the tongue to expose the uvula, followed by progressive insertion until the epiglottis is visualized. The laryngoscope is subsequently advanced into the vallecula with the tip of the blade engaging the hyoepiglottic ligament; the glottis is exposed by lifting the laryngoscope along the direction of its handle, moving the soft tissues out of the 'line of sight' to the vocal cords. At this point the view of the glottis may be improved by external laryngeal manipulation where the laryngoscopist moves the thyroid cartilage with their right hand to alter the interaction between the laryngoscope and larynx. Lastly, elevation of the patient's head may be attempted as this will improve the view in the majority of cases.[7,8]

Manoeuvres to improve view

- External laryngeal manipulation (and remove cricoid pressure if applied)
- Head elevation
- Change operator position
- Change patient position
- Change laryngoscope
- Suction
- Insertion of laryngoscope blade deep in the midline and withdraw slowly until recognized anatomy is identified

The best view obtained at laryngoscopy should be documented along with any manoeuvres required to achieve that view. Cormack and Lehane classified the view at laryngoscopy into grades 1–4.[11] A Cormack and Lehane grade 1 describes a clear view of the entire glottis. A grade 2 laryngoscopy is a view of only the posterior part of the vocal cords or arytenoids. In a grade 3 view, only the epiglottis is visualized and in grade 4 only the soft palate is seen.

A bougie, or 'straight to cuff' shaped stylet, is recommended for all ED RSIs as these patients should be considered potentially difficult. When using a bougie, hold-up of the tip of the ETT on the aryepiglottic fold can be overcome by rotating the tube anti-clockwise or by inserting a smaller ETT. Advancing an ETT off a stylet can be facilitated by rotating the tube clockwise as the tip can catch on the tracheal rings. With both of these methods maintaining a view of the glottis, by keeping the laryngoscope in position, aids tube passage as well as maintaining airway patency for apnoeic oxygenation.

Confirmation of endotracheal tube placement

Successful intubation of the trachea is confirmed by the detection of CO_2, either with waveform capnography, or using a colorimetric CO_2 detector. The absence of a recognizable waveform indicates a failure of intubation; even during cardiac arrest, effective CPR leads to an attenuated but recognizable capnography trace.[12] Other indicators of correct ETT placement include misting of the tube, maintenance of oxygen saturations, and equal air entry audible in both lung fields, although the latter is less reliable. A chest x-ray (CXR) confirms the depth of placement of the ETT and the tip should lie approximately 5 cm above the carina.

Complications of rapid sequence intubation

Hypotension following ETI is common and must be addressed promptly. The causes include the vasodilator and/or negative inotropic effects of the sedative drug(s) given and the reduction in preload from positive-pressure ventilation decreasing venous return and cardiac output. Treatment consists of administration of a fluid bolus of crystalloid, such as saline or Hartmann's and/or infusion of a vasopressor/inotrope, depending on the clinical setting.

Alternatively, in the setting of bronchospasm, hypotension may be due to gas trapping which may be improved by immediate temporary detachment from the circuit and thereafter allowing increased time for expiration. Importantly, hypotension can be due to the development of a tension pneumothorax occurring after the commencement of positive-pressure ventilation. Conversely, hypertension usually indicates inadequate sedation and analgesia.

Face mask ventilation

Important for both pre-oxygenation and re-oxygenation, effective FMV is an essential and sometimes challenging skill. The practitioner's focus should be on maintaining a rigorous face mask seal and ensuring airway patency, by applying a jaw thrust and using adjuncts, such as oro- or nasopharyngeal airways. Suctioning the pharynx and releasing cricoid pressure may also improve airway patency. A two-person technique is recommended, with the practitioner using two hands to hold the mask with thumbs atop the mask, or thenar eminence grip, with their fingers performing a jaw thrust and achieving a good mask seal[13]; the second person squeezes the bag using small tidal volumes at a slow rate of 6 to 8 breaths/min aiming to minimize gastric insufflation and air leak from the mask. Positioning the patient for optimal laryngoscopy as described above also improves airway patency for FMV. The reverse Trendelenburg position may also assist FMV by unloading the weight of the abdomen from the diaphragm.

Supraglottic airway

SGA devices are generally used as a rescue device in the emergency department. Whilst not a definitive airway they do afford some protection against aspiration and they achieve greater airway pressures and are associated with less gastric insufflation when compared to FMV.

Video-laryngoscopy

The use of video-laryngoscopy for ETI is becoming increasingly common and allows real time guidance of supervised laryngoscopists as well as facilitating directed external laryngeal manipulation. The technique is similar to direct laryngoscopy with progressive laryngeal exposure as described above. Airway secretions can soil the camera view and careful suction prior to insertion of the video laryngoscope is recommended.

Hyper-angulated blades usually achieve excellent visualization of the larynx but difficulties may be encountered with ETT passage. Paradoxically, obtaining a full view of the larynx may result in difficulty guiding the ETT between the cords and a partial view, with the posterior vocal cords and arytenoids pictured in the top half of the screen, is preferred. In addition, a stylet, shaped to match the blade, should always be used.

Front of neck access

Surgical cricothyroidotomy is superior to needle cricothyroidotomy techniques as it allows ventilation as well as airway protection.[12,14] Percutaneous techniques using proprietary kits are generally slower to insert and front of neck access (FONA) may be most rapidly achieved by the scalpel, finger, bougie technique. Whilst efforts to oxygenate the patient by FMV or SGA device continue, the neck is extended facilitating access to the larynx. The larynx is stabilized using the non-dominant hand and a vertical incision made in the midline, centred on the cricothyroid membrane. The membrane can now be confidently palpated through the incision and then incised horizontally. Once the scalpel is withdrawn the index finger of the non-dominant hand can be placed into the cricothyroid space, this maintains the tract and ensures that a bougie, passed over the pad of the index finger, enters the trachea. Lastly, a size 6.5 ETT is passed over the bougie into the airway. In obese patients it may be necessary to make a longer skin incision, from the level of the thyroid cartilage to the upper manubrium, followed by blunt dissection in the midline to identify the cricothyroid membrane. Local bleeding, which should be expected, may prevent visualization of the anatomy and the practitioner should rely on palpation of the laryngeal structures.

Difficult airway approach

An airway may be considered difficult for anatomical or physiological reasons, or because 'human factors' impair the performance of the airway team. An assessment of potential difficulty is part of the preparation phase for any airway procedure and an airway should be considered difficult if any of the standard airway techniques are predicted to be challenging, including FMV, SGA insertion, laryngoscopy, or surgical access to the neck. In general, airway procedures in the ED should all be considered potentially difficult as this cohort of patients are usually un-fasted, and have anatomical or physiological derangements which necessitate airway interventions, often in an urgent time frame. To mitigate these challenges it is essential that the airway team attempt to optimize the patient's positioning and physiology, to ensure that all equipment that may be needed is available, and that a tailored plan is chosen and verbalized to the team. Difficult airway algorithms aim to provide a step-by-step approach for when unanticipated difficulty is encountered but as discussed it is prudent to anticipate difficulty for every airway case and to plan for that eventuality.

An example of an unanticipated difficult airway algorithm is shown in Fig. 2.1.5.

Being familiar with an airway algorithm such as that produced by the Difficult Airway Society[10] or a visual cognitive tool like the Vortex Approach[15] may help the airway team remain effective during an airway crisis. Central to most algorithms is the requirement to have optimal attempts at ETI, SGA and FMV prior to proceeding to surgical airway if these fail. Oxygenation of the patient is the primary goal and it is important to avoid repeated attempts at an individual airway technique without changing something. Progression to a surgical airway should occur rapidly if less invasive techniques fail to achieve oxygenation as cardiac arrest due to hypoxia will otherwise ensue.

Clear effective communication between the airway operator and team is essential: declare the difficulty, call for help and ensure leadership continues throughout the crisis.

Expected anatomic difficulty

Distorted anatomy

Examples such as radiation to neck, tumours, expanding haematomas or collections in the floor of mouth or neck all increase the likelihood of difficulty. A fibreoptic approach or awake intubation may be the most appropriate method with an operator assigned to perform a surgical airway if necessary.

Burns

Deciding when to secure a burned airway will depend on a number of factors such as the skill of the operators involved, the necessity for retrieval of the patient and the age of the burn. Indications for intubation may include hoarseness, stridor, coughing, and burns and oedema of the mouth, face and oropharynx. Development of these major signs necessitates ETI, which should be performed by the most experienced operator. A second operator should be ready to perform a surgical airway without delay, as SGA and FMV are likely to be difficult.

Airway trauma

Dyspnoea, stridor, subcutaneous emphysema and the inability to lie flat are major signs of laryngeal trauma with swelling, hoarseness, dysphagia and haemoptysis being minor signs. Issues with securing the airway include the risk of making the injury worse during airway

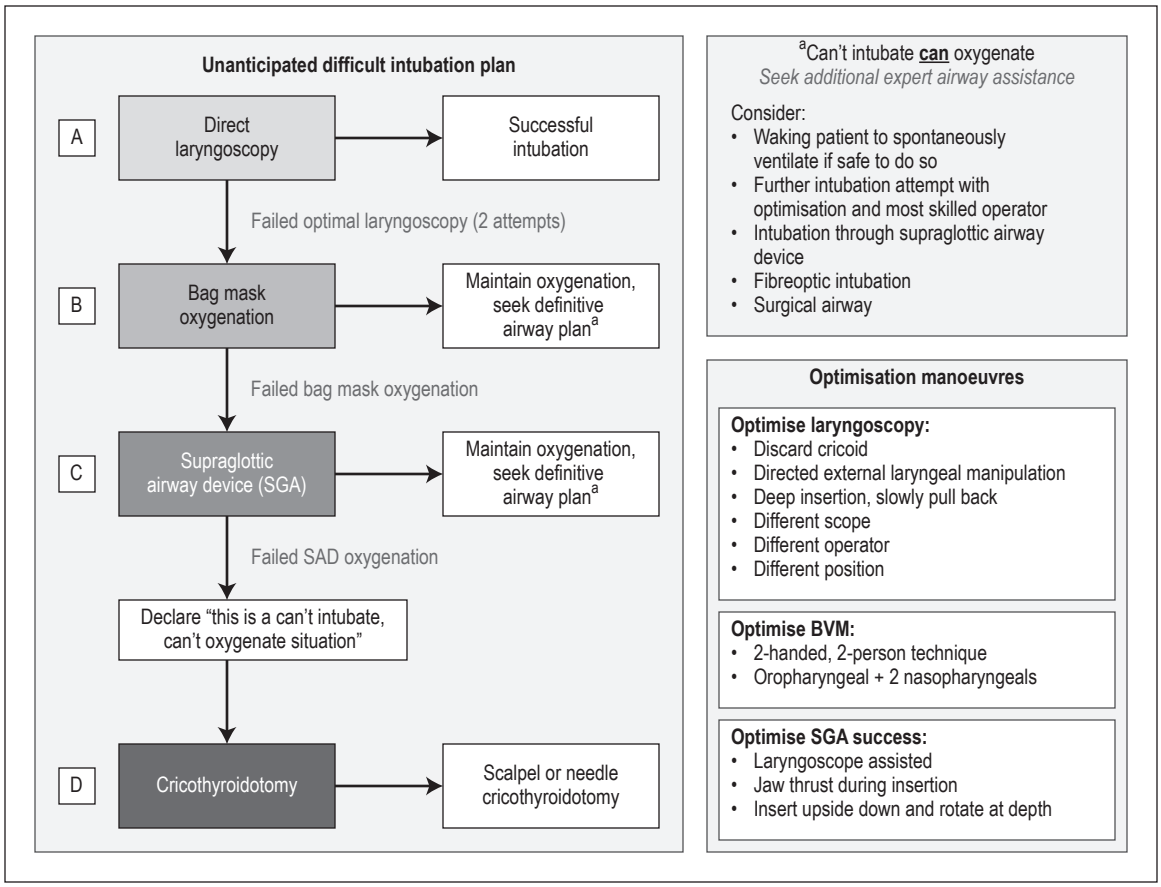

FIG. 2.1.5 Airway plan flowchart with optimization manoeuvres.

instrumentation, inability to intubate due to the distorted anatomy, and difficult surgical airway access due to haematoma, distorted anatomy, and subcutaneous emphysema. A collaborative approach with an experienced airway operator and a dedicated surgical team is recommended in these situations.

History of difficulty

As much information as possible should be obtained as to the details of the previous attempt, what the difficulty was and what successful techniques were employed. The most experienced operator should be present, and a detailed airway plan and contingencies should be agreed upon prior to further interventions.

Expected physiological difficulty

Shock

A modified RSI approach is preferred in shocked patients with reductions in dose of sedative agents, and the use of agents which are less likely to cause further hypotension.

In shocked patients the combined effects of sedative induced sympatholysis, application of positive pressure ventilation and muscle relaxation can result in cardiovascular collapse. Efforts to optimize patient haemodynamics should occur prior to RSI drugs being administered, with titrated fluid boluses, commencement of vasopressor if appropriate to the cause of shock (e.g. noradrenaline in sepsis), and consideration of invasive blood pressure monitoring to guide ongoing resuscitation.

Profound hypoxia

Patients with profound hypoxaemia or respiratory failure should be aggressively pre-oxygenated prior to administering RSI drugs (this is described above under pre-oxygenation), as they are at risk of rapid desaturation during the apnoea period.

A delayed sequence approach may be employed, utilizing ketamine as a dissociative agent to allow adequate pre-oxygenation with BVM device, or NIV, aiming for SaO_2 greater than 95% or highest achievable prior to intubation. These patients may also need gentle FMV during the apnoeic period in addition to 'apnoeic oxygenation' with nasal cannula.

Acidosis

In patients with a severe acidaemia the additional respiratory acidosis caused by apnoea may precipitate malignant cardiac arrhythmias. Continued ventilation during the apnoeic period is necessary in these patients to mitigate any further worsening of acidaemia, along with appropriate adjustment of ventilator settings in the immediate post intubation phase.

Post intubation package

Sedation and analgesia

Post intubation sedation and analgesia must be drawn up prior to commencement of RSI. Delays in commencement of post intubation sedation and analgesia can cause hypertension and tachycardia, and ventilatory difficulties due to ventilator dyssynchrony and patients biting on the ETT.

Recommended regimens:

- Propofol and Fentanyl: if expected course of ventilation is to be brief
- Fentanyl and Midazolam: initial boluses followed by titrated infusion
- Ketamine infusion: start at 1 mg/kg/hr and titrate

Coughing on the tube causes a rise in intracranial pressure and, particularly in head injured patients, it is essential to ensure adequate sedation. Additional opioid analgesia and further doses of muscle relaxant should be considered, particularly if the patient is to be moved (for example to the computed tomography (CT) scanner or intensive care unit (ICU).

Mechanical ventilation

General approach

Following successful intubation the patient is connected to a mechanical ventilator to provide continued ventilatory support. Because ventilated patients may be managed for some time in the ED, it is important that recommendations for optimal mechanical ventilation are implemented in the ED.

A tidal volume of 8 mL/kg and a respiratory rate of 10–14 breaths/min are considered safe for most patients with normal lungs. In general, 5 cm of positive end-expiratory pressure (PEEP) is provided.

An arterial blood gas should be obtained to titrate respiratory rate to $PaCO_2$. The $PaCO_2$ target will depend on the injuries found: In isolated thoracic injuries, the priority of gentle ventilation may warrant a degree of permissive hypercapnia. In head injured patients normocapnia should be maintained, aiming for $PaCO_2$ of 35 to 40 mmHg as part of neuroprotection. Hyperoxia and hypoxia have both been shown to be associated with worse outcomes after traumatic brain injury and normoxia should also be a target (PaO_2 >70 mmHg). Ventilator settings for a variety of clinical scenarios are highlighted in Table 2.1.2.

Lung protective ventilation

Patients with acute lung injury may have reduced pulmonary compliance and elevated peak inspiratory and plateau pressures. These patients should receive a 'protective lung ventilation strategy'.[16] This involves limiting the tidal volume to 6 mL/kg, with the respiratory rate setting increased to 14 to 18 breaths/min to prevent excessive hypercapnia. If hypoxia persists (PaO_2 < 60 mmHg), then additional PEEP is indicated. This may be titrated in steps of 2.5 mmHg towards a maximum of 22 mmHg.

Extubation in the emergency department

Increasingly, patients who are intubated pre-hospital by paramedics or by a physician in the ED may be considered for planned extubation in the ED, after investigation and treatment have excluded the requirement for mechanical ventilation in ICU. Examples include a patient with a drug overdose or those requiring brief general anaesthesia for a procedure.

In general, patients should be lightly sedated with a short-acting sedative, such as propofol, able to follow commands and able to cough adequately to tracheal suction. Ideally, a trial of spontaneous breathing with the ventilator set to a CPAP of 5 cm H_2O, with minimal inspiratory pressure support (i.e. 5 to 10 cm H_2O) with modest supplemental oxygen (i.e. <50% oxygen) is necessary. Also, the stomach should be emptied via an orogastric or nasogastric tube prior to extubation. Equipment and drugs available for airway management and potential reintubation must be at hand and the airway plan discussed with the team prior to the extubation occurring.

Governance

Documentation

The layrngoscopist is responsible for documentation of the intubation in the medical record and a minimum data set template is recommended to ensure a complete and accurate record.

Minimum suggested data set

- Indication
- Laryngoscopist (name, specialty, seniority)
- Ease of BVM ± adjuncts
- Induction agents (drug and dose)
- Laryngoscope ± adjuncts (e.g. bougie/stylet)
- Grade (DL and VL)
- ETT size and depth
- Number of attempts
- Complications

Audit and education

It is essential that performance at RSI is monitored and opportunities to improve practice are identified. Ongoing audit of every emergency department RSI[17] allows tailored education which should include regular in-situ multidisciplinary simulation training of nurses and doctors together.

Table 2.1.2 Initial Ventilator Settings in Different Clinical Scenarios

	Normal lungs	*Traumatic Brain Injury*	*Acute Respiratory Distress Syndrome*	*Bronchospasm*	*Acidosis*
Goals	Initiate protective approach to limit ventilator harm	Protect cerebral perfusion by maintaining haemodynamics to prevent hypotension secondary to decreased venous return resulting from elevated intrathoracic pressure	Adequate oxygenation, alveolar recruitment, shunt reduction, avoid atelectasis	Oxygenation, prevent dynamic hyperinflation and barotrauma	Optimized respiratory rate to compensate and correct metabolic acidosis
Ventilator Mode	Volume Control (SIMV)	Volume Control (SIMV)	Volume Control (SIMV)	Volume Control (SIMV)	Volume Control (SIMV)
FiO_2	Start with FiO_2 of 1.0, titrate down to 0.4, avoiding prolonged hyperoxia. Aim for O_2 saturation ~95% with PO_2 > 60 mm Hg				
RR	14	16	14	8–10	20
VT (mL/kg) PBW	8	6–8	6	5–8	8
PEEP (cm H_2O)	5	5	10–15	0–5	5
I:E ratio	1:2	1:2	1:1	1:4	1:2

I:E, Inspiration:expiration; *PBW*, predicted body weight; *PEEP*, positive end-expiratory pressure; *RR*, respiratory rate; *VT*, tidal volume.

Credentialing

Effective airway practitioners of all disciplines must attain and maintain a combination of technical and non-technical skills that achieves a safe approach to any airway emergency. Credentialing of emergency physicians should focus on ensuring that they achieve excellent technical skills, particularly laryngoscopy and cricothyroidotomy, with time spent in the operating theatre and through tailored emergency airway courses. Moreover, they must develop an appreciation of the human factors associated with difficult airway management and strategies to ensure an effective team response to challenging cases.

CONTROVERSIES

- Training and skills maintenance of airway management techniques in the ED, including the use of standardized airway algorithms
- The effect of cricoid pressure on risk of aspiration and the possible impairment of view at laryngoscopy
- The increasing role of video-laryngoscopy
- The optimal surgical airway technique in the 'can't intubate–can't oxygenate' scenario

2.2 Oxygen therapy

David R. Smart

ESSENTIALS

1 **Oxygen is the most frequently used 'drug' in emergency medicine.**

2 **Oxygen-delivery systems may be divided into variable-performance (delivering a variable concentration of oxygen) and fixed-performance (delivering a fixed concentration of oxygen, including systems that deliver 100% oxygen) types.**

3 **Fixed-performance systems are essential where precise titration of oxygen dose is required, as with chronic obstructive pulmonary disease (COPD) or where 100% oxygen is indicated.**

4 **Free-flowing circuits are least efficient at attempting to deliver 100% oxygen. A reservoir or demand system improves efficiency and a closed-circuit delivery system is most efficient.**

5 **One hundred percent oxygen is indicated when treating divers or patients with carbon monoxide or cyanide poisoning.**

6 **There is increasing evidence for goal-directed oxygen therapy, which should be regarded as a drug prescribed in therapeutic doses titrated to SaO_2, rather than applied in a variable manner.**

7 **Titrated-dose oxygen therapy is required in treating patients with COPD, commencing with 24% to 28%. Response to therapy in these patients should be monitored with blood gases measurements.**

8 **Oxygen should never be abruptly withdrawn from patients in circumstances of suspected CO_2 narcosis.**

9 **Pulse oximetry provides valuable feedback regarding the appropriateness of oxygen dose provided to individual patients, but it should not be used as a measure of ventilatory adequacy; this should be monitored by end-tidal CO_2, arterial blood gases, and the patient's conscious state.**

Introduction

Oxygen was first discovered by Priestley in 1772 and was first used therapeutically by Beddoes in 1794. It now forms one of the cornerstones of medical therapy.

Oxygen (O_2) constitutes 21% of dry air by volume. It is essential to life. Cellular hypoxia results from a deficiency of oxygen regardless of aetiology. Hypoxaemia is a state of reduced oxygen carriage in the blood. Hypoxia leads to anaerobic metabolism, which is inefficient and may lead to death if not corrected. A major priority in acute medical management is the correction of hypoxia; hence oxygen is the most frequently administered drug in emergency medicine. There are sound physiological reasons for the use of supplemental oxygen in the management of acutely ill and injured patients.

Uses of supplemental oxygen

- To correct defects in the delivery of inspired gas to the lungs. A clear airway is essential
- Where there is inadequate oxygenation of blood due to defects in pulmonary gas exchange
- To maximize oxygen saturation of the arterial blood (SaO_2) where there is inadequate oxygen transport by the cardiovascular system
- To maximize oxygen partial pressure and content in the blood in circumstances of increased or inefficient tissue oxygen demand
- To provide 100% oxygen where clinically indicated
- To titrate oxygen dose in patients with impaired ventilatory response to carbon dioxide

Physiology of oxygen[1]

Oxygen transport chain

Oxygen proceeds from inspired air to the mitochondria via a number of steps known as the oxygen transport chain. These steps include

- Ventilation
- Pulmonary gas exchange
- Oxygen carriage in the blood
- Local tissue perfusion
- Diffusion at tissue level
- Tissue utilization of oxygen

Ventilation

The normal partial pressure of inspired air oxygen (P_IO_2) is approximately 20 kPa (150 mm Hg) at sea level. If there is a reduction in the fraction of inspired oxygen (F_IO_2), as occurs at altitude, hypoxia results. This is relevant in the transport of patients at 2400 m in commercial 'pressurized' aircraft, where ambient cabin pressures of 74.8 kPa (562 mm Hg) results in a P_IO_2 of 14.4 kPa (108 mm Hg).

Hypoxia can result from inadequate delivery of inspired gas to the lung. The many causes include airway obstruction, respiratory muscle weakness, neurological disorders interfering with respiratory drive (seizures, head injury), disruption of chest mechanics (chest injury), or extrinsic disease interfering with ventilation (intra-abdominal pathology). These processes interfere with the maintenance of an adequate alveolar oxygen partial pressure (P_AO_2), which is approximately 13.7 kPa (103 mm Hg) in a healthy individual.

Alveolar gas equation An approximation of the alveolar gas equation permits rapid calculation of the alveolar oxygen partial pressures, as follows:

$$P_AO_2 = F_IO_2 \times (\text{barometric pressure} - 47) - P_aCO_2/0.8$$

Pulmonary gas exchange

Oxygen diffuses across the alveoli and into pulmonary capillaries and carbon dioxide diffuses in the opposite direction. The process is passive, occurring down concentration gradients. The Fick law summarizes the process of diffusion of gases through tissues:

$$\dot{V}O_2 \propto A/T \times Sol/\sqrt{MW} \times (P_AO_2 - P_{pa}O_2)$$

Where $\dot{V}O_2$ = rate of gas (oxygen) transfer, $\propto$ = proportional to, A= area of tissue, T = tissue

thickness, Sol = solubility of the gas, MW = molecular weight, P_A = alveolar partial pressure and P_{pa} = pulmonary artery partial pressure.

In healthy persons, oxygen rapidly passes from the alveoli to the blood and, after 0.25 seconds, pulmonary capillary blood is almost fully saturated with oxygen, resulting in a systemic arterial oxygen partial pressure (P_aO_2) of approximately 13.3 kPa (100 mm Hg). The difference between the P_AO_2 and the P_aO_2 is known as the alveolar to arterial oxygen gradient (A – a gradient). It is usually small and increases with age.

Expected A–a gradient The expected A–a gradient when breathing air approximates to Age (years) ÷ 4 + 4.

An approximation of the actual value can be calculated as follows:

$$A - a\ O_2\ \text{gradient} \approx 140 - (P_aO_2 + P_aCO_2)$$

There is a defect in pulmonary gas exchange if the calculated value exceeds the expected value. The A–a O_2 gradient is increased if there is a barrier to diffusion, such as pulmonary fibrosis or oedema or a deficit in perfusion, such as a pulmonary embolism. An increased A–a gradient also reflects widespread ventilation/perfusion mismatch.

In circumstances of impaired diffusion in the lung, raising the F_IO_2 assists oxygen transfer by creating a greater pressure gradient from the alveoli to the pulmonary capillary. The increase in F_IO_2 may not be as helpful when lung perfusion is impaired as a result of increased intrapulmonary shunting.

Oxygen carriage in the blood

Four steps are required to deliver oxygen to the periphery:

- Uptake of oxygen by haemoglobin (Hb)
- Cardiac output to carry the oxygenated haemoglobin to the peripheral tissues
- Dissociation of oxygen from haemoglobin into dissolved oxygen in plasma
- Diffusion of dissolved oxygen from blood to cells via plasma, extracellular fluid (ECF), and finally, intracellular fluid (ICF)

Haemoglobin–oxygen dissociation curve The haemoglobin–oxygen ($Hb–O_2$) dissociation curve is depicted in Fig. 2.2.1, which also summarizes the factors that influence the position of the curve. If the curve is shifted to the left, this favours the affinity of haemoglobin for oxygen. These conditions are encountered when deoxygenated blood returns to the lung. A shift of the curve to the right favours unloading of oxygen and subsequent delivery to the tissues.

A number of advantages are conferred by the shape of the $Hb–O_2$ dissociation curve that favour uptake of oxygen in the lung and delivery to the tissues. They are as follows:

- The flat upper portion of the curve allows some reserve in the P_AO_2 required to keep the haemoglobin fully saturated; a reduction in P_AO_2 of 20% will have minimal effect on the oxygen loading of Hb.
- The flat upper portion of the curve also ensures that a large difference remains between P_AO_2 and the pulmonary capillary oxygen partial pressure ($P_{pc}O_2$), even when much of the haemoglobin has been loaded with oxygen. This pressure difference favours maximal $Hb–O_2$ loading.
- The lower part of the curve is steeper, which favours offloading of oxygen in peripheral tissues with only small falls in capillary PO_2. This maintains a higher driving pressure of oxygen, facilitating diffusion into cells
- The right shift of the $Hb–O_2$ curve in circumstances of increased temperature, fall in pH, increased PCO_2 and increased erythrocyte 2,3 diphosphoglycerate (2,3-DPG) assists in further offloading of oxygen, even when the driving pressure has fallen and PO_2 has reached 5.3 kPa (40 mm Hg) (i.e. venous blood which is still 75% saturated with oxygen).

Oxygen is carried in the blood as dissolved gas in combination with haemoglobin. At sea level (101.3 kPa), breathing air (F_IO_2 = 0.21), the amount of oxygen dissolved in plasma is small (0.03 mL oxygen per litre of blood for each 1 mmHg P_aO_2). Hence at a P_aO_2 of 100 mm Hg, 3 mL of oxygen is dissolved in each litre of plasma. Dissolved oxygen is important because it is the first available oxygen to diffuse into the tissues. The dissolved component assumes greater significance in the hyperbaric environment, where, at 284 kPa and an F_IO_2 of 1.0, up to 60 mL oxygen can be carried dissolved per litre of blood.

Haemoglobin carries 1.34 to 1.39 mL of oxygen per gram when fully saturated. Blood with a haemoglobin concentration of 150 g/L carries approximately 200 mL oxygen per litre.

Oxygen flux The total amount of oxygen delivered to the body per minute is known as oxygen flux.

$$\begin{aligned}\text{Oxygen Flux} = {} & (\text{oxyhaemoglobin} \\ & + \text{dissolved } O_2) \times \text{cardiac output} \\ = {} & 1.39 \times Hb \times S_aO_2/100 \\ & + 0.03 \times P_aO_2 \times Q\end{aligned}$$

where Hb = haemoglobin concentration g/L; S_aO_2 = arterial oxygen saturation (percentage); P_aO_2 = partial pressure of arterial oxygen (mm Hg); Q = cardiac output (L/min).

A healthy individual breathing air transports approximately 1000 mL of oxygen per minute to the tissues, based on a cardiac output of 5 L/min; 30% or 300 mL/min of this oxygen is not available, because at least 2.7 kPa (20 mm Hg) driving pressure is required to allow oxygen to enter the mitochondria. Therefore approximately 700 mL/min is available for use by peripheral tissues. This provides a considerable reserve above the 250 mL/min consumed by a healthy resting adult.

In illness or injury, this reserve may be considerably eroded. Factors that reduce oxygen flux include a fall in cardiac output of any aetiology (including shock states), anaemia or a reduction in functional haemoglobin (carbon monoxide poisoning) and a drop in the S_aO_2. These situations are frequently encountered in the emergency department. Supplemental oxygen is required in addition to specific therapy, such as volume replacement, transfusion, and measures to improve cardiac output.

Local tissue perfusion and diffusion

Cellular hypoxia results if there is impairment of perfusion to local tissues. Oedema associated with medical illness or local injury increases the diffusion distance between blood and the cell, thus mandating a higher P_aO_2 to ensure adequate tissue oxygen delivery.

Tissue utilization of oxygen

Increased oxygen flux is required if either

- Tissue demands for oxygen are higher than normal
- Tissue utilization of oxygen is impaired

Elevation of cardiac output increases oxygen flux in these circumstances, but frequently this too is significantly impaired by the disease state.

Tissue demands for oxygen increase by 7% for each degree Celsius elevation in body temperature and considerably greater increases in demand occur in seizures, sepsis, severe dyspnoea, restlessness and shivering.

Tissue extraction of oxygen is impaired in sepsis and by poisons, such as carbon monoxide or cyanide. In all cases, oxygen therapy must be combined with general measures, such as reduction of fever and specific treatment of the primary disease process.

Oxygen delivery systems

Oxygen delivery systems are classified into three groups (Box 2.2.1)[1]:

- Variable-performance systems
- Fixed-performance systems
- 100% oxygen systems

Definitions

Variable-performance oxygen delivery systems

These systems deliver a variable F_IO_2 to the patient, which is altered by the inspiratory flow

Box 2.2.1 Oxygen delivery systems

Variable-performance systems

Self-refilling circuits
Soft reservoir bags
Oxygen-powered resuscitators
Partial rebreathing circuits
Closed-circuit systems

rate, the minute volume of the patient, and the physical characteristics of the delivery system.

Fixed-performance oxygen delivery systems

These systems deliver a specified F_IO_2 to the patient that is not altered by changes in ventilatory pattern, volume, or inspiratory flow rate.

One hundred percent (100%) oxygen systems

This is a subgroup of fixed-performance systems wherein 100% oxygen is delivered to the patient.

General principles

The oxygen source in most Australian and New Zealand emergency departments consists of a wall-mounted flowmeter capable of delivering oxygen up to 15 L/min, with most available oxygen delivery systems connecting to this apparatus. A flow rate of 15 L/min limits the delivery of high F_IO_2 to adults for the following reasons:

- The quietly breathing adult has a peak inspiratory flow rate (PIFR) of approximately 30 to 40 L/min, which exceeds the oxygen supply. Hence a free-flowing system, such as a Hudson mask, must entrain air into the system in order to match the patient's PIFR, with a resultant reduction in F_IO_2 to a maximum of 0.6.
- The quietly breathing adult has a respiratory minute volume (RMV) of 4 to 8 L; in a child, this value is approximately 150 mL/kg. Oxygen is stored during expiration by incorporating a reservoir into the circuit for use during inspiration, with a considerable improvement in the economy of oxygen use. This system is limited by the patient's minute volume. If the minute volume exceeds 15 L, there is a danger of the patient asphyxiating due to insufficient gas supply or, if safety valves allow air into the system, the F_IO_2 falls.

If higher flows are needed, some oxygen ports provide up to 25 L/min. More efficient control of flow is achieved via higher-output or dial-up flowmeters. An extra source of oxygen flow may cause variable-performance systems such as the Hudson mask to become fixed-performance systems. Hence the terms *variable performance* and *fixed performance* are loosely applied and are largely dependent on whether or not the gas flow delivered is sufficient to match the patient's ventilatory requirements.

An example of this is in paediatric oxygen delivery. A high F_IO_2 can be delivered using a standard 15 L/min oxygen source because the child's ventilatory requirements are smaller in proportion to the available oxygen supply.

The oxygen delivery systems available for use in emergency medicine, summarized in Box 2.2.1, can be further subdivided according to economy of oxygen use and whether or not the system can be used to ventilate the patient manually.

Table 2.2.1 Variable-performance oxygen delivery systems

Apparatus	*Oxygen flow (L/min)*	*Oxygen concentration (%)*
Nasal catheters	1–4	24–40
Semi-rigid mask	6–15	35–60
Semi-rigid mask and double O_2 supply	15–30	Up to 80
Semi-rigid mask and reservoir bag	12–15	60–90

Variable-performance systems

The F_IO_2 delivered by these systems is summarized in Table 2.2.1. Options available for use in emergency medicine include

- Nasal cannulae
- Face masks with air inlets with or without reservoirs
- T pieces and Y connectors

Nasal cannulae

The system must be used at flow rates of 4 L/min or less to avoid drying of the nasal mucosa.

The inspired oxygen concentration is a function of the patient's inspiratory flow rate and is usually in the vicinity of 22% to 28%. At flow rates of 2 to 4 L/min, the nasopharynx acts as a partial reservoir during the expiratory pause, resulting in an increased F_IO_2. The delivered F_IO_2 is then influenced by the pattern of breathing (mouth or nose) and the positioning of the nasal cannula.

Nasal cannulae provide a higher F_IO_2 in paediatric patients and nose breathers. They are less effective in dyspnoeic patients because of the greater amounts of air inspired through the mouth. They are frequently used in patients with *stable* COPD because of the absence of dead space that prevents CO_2 rebreathing. Provided that S_aO_2 is monitored, nasal cannulae have been effectively used in the prehospital setting to titrate oxygen therapy to patients with COPD. If nasal cannulae are used, there should be strict titration of flow rates to a target S_aO_2. Fluctuations in F_IO_2 make nasal cannulae less than ideal in the management of patients who rely on hypoxic respiratory drive. They are the second choice after oxygen blenders in the ED, where humidification can be added.

Advantages of nasal prongs for ward or home therapy include the ability to eat and drink, less noise than masks, and economy of oxygen use.

Face-masks (e.g. Hudson, Edinburgh, Medishield)

A small reservoir of oxygen is provided by these masks, but this has little effect on F_IO_2. The small increase in dead space created by the mask necessitates a flow rate greater than 6 L/min to prevent rebreathing of CO_2. Two factors influence the F_IO_2 provided by this system:

- Patient's inspiratory flow rate
- Source oxygen supply flow rate

At flow rates of 6 to 14 L/min, the delivered F_IO_2 varies from 0.35 to 0.6. This will be less in a dyspnoeic patient because of the higher inspiratory flow rate and greater in paediatric patients, as the converse applies. If the PIFR increases, greater amounts of air will be entrained into the mask, diluting the oxygen. During expiration, the exhaled gas and excess oxygen are vented through the side perforations.

Attaching a reservoir bag to this mask improves the economy of oxygen use by storing inflowing oxygen during the patient's exhalation phase. This increases the delivered F_IO_2 but may be at the expense of increased CO_2 rebreathing. Commercially available reservoir bags have a volume of 750 mL to 1 L, which may be inadequate for some dyspnoeic patient. Using a source oxygen supply of 15 L/min, the maximum F_IO_2 delivered via a Hudson mask to a quietly breathing adult is 0.6. In most cases this will suffice for titrated oxygen therapy; however, it is insufficient where 100% oxygen is required. If greater flow rates are required to maintain S_aO_2, use of an oxygen blender with humidification may be more effective.

T pieces and Y connectors

The term *T piece* has been used to describe a number of different oxygen delivery systems, including the T piece for supplying humidified oxygen to patients with a tracheostomy and the 'Ayre's T piece', which is a Mapleson E circuit. T pieces or Y connectors have been used in the past in emergency medicine to supplement an existing oxygen supply with

- Extra oxygen
- Nebulized medication
- Humidification

There are many disadvantages of these systems: several oxygen ports are necessary, loss of economy of oxygen use because of higher flow rates, and wastage of oxygen. They have largely been replaced by oxygen blenders, which supply much higher flow rates.

Fixed-performance systems

Two systems are available for use in emergency departments:

- High-flow Venturi masks
- Oxygen blenders

High-flow Venturi mask

Oxygen flow through a Venturi system results in air entrainment with delivery of a fixed concentration of oxygen to the patient. The masks deliver F_IO_2 values from 0.24, 0.28, 0.35, 0.40 and 0.50 to 0.60, using different colour-coded adaptors or by varying the position of a dial on the mask connector. Many studies have validated their accuracy. The patient receives the stated F_IO_2 provided that the total flow rate exceeds 60 L/min or is 30% higher than the patient's PIFR. As the patient's PIFR increases, the system's performance becomes variable.

In supplying an F_IO_2 of 0.24 using a flow rate of 6 L/min oxygen, the total flow rate delivered to the patient is 120 L/min. This falls to 30 L/min total flow for an F_IO_2 of 0.6 using 15 L/min oxygen supply. This is just equal to the PIFR of a quietly breathing adult and unlikely to be sufficient to provide consistent performance in delivery of the stated F_IO_2. In severe dyspnoea, these masks may therefore not deliver the stated F_IO_2.

Increasing the oxygen flow rate above the manufacturer's recommendations will increase the total gas flow to the mask, whereas maintaining the stipulated F_IO_2. At very high flow rates, however, turbulence is likely to reduce the performance of the system.

Venturi masks provide an economical means of managing a patient with chronic obstructive pulmonary disease (COPD) in the ED because they provide a predictable F_IO_2 and the air entrained is marginally more humid than fresh oxygen (see further on). The entrained gas mixture can be further heated and humidified to assist with sputum clearance. High gas flows minimize rebreathing of CO_2 and claustrophobia but cause problems with sleeping due to noise.

Oxygen blenders

Air is blended with oxygen from a number of inlet ports to supply a fixed F_IO_2 to the patient. It is a high-flow system and fine-tuning of F_IO_2 from 0.21 to 1.0 is possible, as well as humidification. The resultant mixture can then be channelled to the patient through systems such as a continuous positive airway pressure (CPAP) apparatus. Oxygen blenders are increasingly being used in emergency departments. Lack of portability and high cost are disadvantages.

One hundred percent oxygen delivery systems

These systems vary in their economy of oxygen use and are summarized in Table 2.2.2. The least economical is the free-flowing system, as it can only deliver 100% oxygen if the flow rate exceeds the patient's PIFR. Incorporating a reservoir and unidirectional valves into the circuit enables greater economy of oxygen use by storing oxygen during expiration ready for the inspiratory phase.

Devices incorporating a reservoir into the circuit are capable of delivering 100% oxygen only when the total oxygen flow equals or exceeds the patient's RMV, plus there are no leaks in the system. The reservoir volume must exceed the patient's tidal volume, otherwise storage of oxygen is inefficient, fresh gas loss occurs when the reservoir is full, and there is the risk of asphyxia during inspiration.

A demand valve system delivers precisely the patient's minute volume without the added bulk and problems of a reservoir. It is able to cope with changes in RMV provided fresh gas flow always exceeds the patient's PIFR. Closed-circuit systems are the most economical in oxygen consumption. Carbon dioxide is absorbed by soda lime and low-flow fresh oxygen replaces that consumed during metabolism (approximately 250 to 1000 mL/min), which is considerably less than the patient's RMV.

Classification

One hundred percent oxygen-delivery systems available for use in emergency medicine are summarized in Table 2.2.2.

Free-flowing circuits

Flow rates in excess of the patient's PIFR are required to provide 100% oxygen using a free-flowing system, which would necessitate the use of multiple oxygen ports. The system may not deliver 100% oxygen, is wasteful of oxygen and may be untidy, thus restricting patient mobility for investigations.

Soft reservoir circuits

These are nonrebreathing systems incorporating unidirectional valves to channel fresh oxygen to the patient and exhaled gas to the atmosphere. With one oxygen supply port, the system delivers 100% oxygen provided that the patient's minute volume is less than 15 L/min. Higher flow first-stage regulators enable delivery of up to 25 L/min. Fresh gas flow is titrated to the patient's minute volume by watching the reservoir bag, which should be fully distended at the start of inspiration and more than one-third full when inspiration is complete.

The reservoir bag has a minimum volume of 2.5 L and, for optimal performance, the patient's tidal volume should not exceed 2 L. A soft silicone mask is strapped to the head to ensure a firm but comfortable fit without leaks. The system cannot be used to ventilate patients manually and may be hazardous if the patient has an impaired conscious state owing to the risk of aspiration if they vomit and asphyxiation if there is a fall in fresh gas flow or a sudden rise in minute volume. A similar circuit using a snorkel has potential for field use in conscious divers. Complications are avoided with clinical vigilance and the use of safety valves to entrain air if the oxygen supply ceases.

Self-refilling nonrebreathing resuscitators

Most Australasian emergency departments possess at least one type of self-refilling system. These systems can be used to ventilate a patient manually as well to allow spontaneous ventilation. Some systems have three sizes—for adults, children, and infants—and there are multiple manufacturers of self-refilling resuscitators, including cheap single-use versions. (Table 2.2.3).

Advantages

- Self-inflation and hence the ability to ventilate patients with air if oxygen supply is exhausted.
- Low-resistance unidirectional valves prevent rebreathing of CO_2.
- Use in spontaneously ventilating patients and for manual ventilation.
- System is capable of delivering close to an F_IO_2 of 1.0 provided fresh gas flow exceeds minute volume and the reservoir bag is attached. Without the reservoir bag, an approximate F_IO_2 of 0.6 is obtainable.
- A safety valve entrains air into the system to prevent asphyxiation if there is a sudden rise in minute volume, but this is at the expense of F_IO_2.
- Overpressure relief valves are incorporated into some paediatric and infant apparatus to prevent barotrauma in these patients.
- Addition of positive end-expiratory pressure (PEEP) to the system is possible by attach-

Table 2.2.2 Classification of 100% oxygen systems

System	*Rebreathing of gases*	*Fresh gas flow to deliver 100% O_2*	*Use for spontaneous and/or manual ventilation*	*Comments*
Free-flowing systems	Non-rebreathing	45–90 L/min	Spontaneous	High fresh gas flow prevents CO_2 rebreathing
Soft reservoir bag circuit	Non-rebreathing	7–15 L/min	Spontaneous	Can increase to 15–30 L/min with dual supply to maintain F_IO_2 = 1.0
Self-refilling resuscitators	Non-rebreathing	15 L/min	Spontaneous/manual	Manual ventilation possible with air if no oxygen available. F_IO_2 <1.0 if minute volume exceeds O_2 flow
Demand valve system	Non-rebreathing	Delivers up to 120 L/min for inspiration only; usual RMV = 7–15 L/min	Spontaneous/manual	Actual delivered volume of O_2 equals minute volume
Mapleson circuits	Partial rebreathing	15–40 L/min	Spontaneous/manual	Fresh gas flow must be at least double minute volume to avoid CO_2 build-up
Oxygen rebreather resuscitator	Closed circuit rebreathing	0.5–2 L/min	Spontaneous/manual	Requires intermittent purging of reservoir to remove exhaled nitrogen from functional residual capacity

(From Smart DR, Mark PD. Oxygen therapy in emergency medicine Part 1. Physiology and delivery systems. *Emerg Med (Fremantle).* 1992;4:163–178.)

Table 2.2.3 Self-refilling non-rebreathing resuscitators

	Self-refilling bag volume (mL)	*Reservoir bag volume*
Adult size	1600	2600
Child size	500	2600
Infant size	240	600

ing a PEEP valve to the expiratory limb. Close apposition of the mask to the face or endotracheal intubation is required for this to be effective.

Disadvantages

- Reduction in F_IO_2 occurs when minute volume exceeds fresh gas flow.
- Unit is bulky and disconnections sometimes occur.
- There is less 'feel' during manual ventilation than with soft bag circuits. Inflation of the stomach may be more likely during bag/mask ventilation, especially if there is airway obstruction or reduced pulmonary compliance.

Oxygen-powered resuscitators

Examples of this type of system include the Oxy Viva, Laerdal, and DAN demand valve systems. High-pressure oxygen is fed to a demand valve, which delivers high-flow oxygen to the patient. The system can be used in a spontaneously breathing patient and, for manual ventilation, by depressing a manual override button if present. Spontaneously ventilating patients initiate an oxygen flow of up to 120 L/min by generating a negative pressure of 0.3 kPa (2.25 mm Hg) at the start of inspiration. Fresh gas flow is delivered at a pressure of up to 5.3 kPa (40 mm Hg).

Advantages

- Portability, as it is easy to attach to an oxygen cylinder and take to the field. There are no bulky reservoir bags.
- Economy of oxygen use as the patient's minute volume is precisely delivered at sufficient flow rates to match the PIFR. Provided there are no leaks, the system delivers an F_IO_2 of 1.0.

Disadvantages

- Increased work of breathing for spontaneous ventilation as negative pressure must be generated to initiate oxygen flow.
- System cannot function when fresh gas supply is exhausted.
- During manual ventilation, it is almost impossible to judge ventilatory volume except by observing the patient's chest. The safety overpressure relief valve may not prevent barotrauma, especially in children.
- Absence of 'feel' during manual ventilation, which may lead to over-inflation of the stomach if there is airway obstruction or reduced pulmonary compliance.

Mapleson circuits

Mapleson circuits are still used in some emergency departments. Partial rebreathing of gases occurs with all of the circuits, but CO_2 retention can be avoided if fresh gas flow exceeds minute volume by a ratio of 2 to 2.5:1.

The most commonly used versions are the Mapleson B and the Mapleson F, which are covered under paediatric considerations. Mapleson A, C, D and E circuits are not discussed further.

Advantages of the Mapleson B circuit

- Used for both spontaneous and manual ventilation. Its performance is similar in both circumstances.
- Soft bag has excellent 'feel' for manual ventilation and it is easy to monitor spontaneous ventilation by observing the filling and emptying of the reservoir bag.

Disadvantages

- Carbon dioxide build-up with lower oxygen flow rates. This can be avoided with higher flow rates or by intermittently purging the reservoir bag.
- System cannot function without a fresh gas supply.
- System may be difficult to use when ventilating a patient manually using a mask.
- Valve assembly may occasionally 'stick'.

Closed-circuit systems

The circuit is similar to the Boyle's anaesthetic circle system. A soda lime canister absorbs exhaled CO_2 and a low-flow oxygen supply replaces oxygen consumed by metabolism at approximately 0.5 to 2 L/min. Considerable economy of oxygen use is thus achieved by rebreathing from the circuit.

Advantages

- Economy of oxygen use. More than 6 hours of oxygen can be provided by a 'C'-sized oxygen cylinder at 1 L/min. This markedly exceeds the endurance of the cylinder using other systems.
- Can be used for spontaneous or manual ventilation. A soft reservoir bag provides excellent 'feel' for ventilation.

- Pressure on the system is controlled by the operator during manual ventilation. This minimizes gastric distension.
- Portable and can easily be taken to the field.

Disadvantages

- Circuit ceases to function when fresh gas flow is exhausted.
- Exhaled nitrogen from the patient's early breaths may enter the circuit and reduce F_IO_2 below 1.0. This can be prevented by intermittent purging of the reservoir.
- CO_2 may accumulate if the soda lime canister is old or stops functioning.
- Incorrect packing of the soda lime canister may result in inhalation of soda lime dust (which is extremely rare).
- Reservoir bag is remote from the patient mask and the system may be cumbersome to operate.

Helium and oxygen mixtures

Over the last decade, there has been interest in adding helium to oxygen (maximum 30% oxygen, also known as Heliox). Heliox has a lower density than air, with the potential to reduce airway resistance and hence the work of breathing when treating disease processes such as COPD, asthma, and bronchiolitis. Helium (He, MW = 4) is much lighter than nitrogen and therefore significantly lowers the density of the gas mix when combined with oxygen in the range of F_IO_2 of 0.2 to 0.4. This advantage is lost when F_IO_2 is greater than 0.4. Despite lower density, the viscosity of Heliox is not significantly lower than that of air. Its main theoretical advantage is if there is turbulent gas flow that is density dependent. This may occur with COPD or asthma where there is a combination of small and medium airways disease. Despite the potential advantages, the clinical evidence for the use of Heliox in COPD or asthma is not strong.[2,3] The evidence for and clinical use of Heliox in these conditions is covered in other chapters.

Measurement of oxygenation

Clinical assessment of oxygenation is unreliable and the time-honoured sign of cyanosis varies with the level of haemoglobin, skin pigmentation, perfusion and external light. Arterial blood gases and pulse oximetry provide an objective measurement of oxygenation and enable precise titration of oxygen therapy to the clinical situation.

Pulse oximetry

Pulse oximetry is the most frequently used indicator of oxygenation in emergency medicine as it is non-invasive. It is regarded as the 'fifth vital sign' and provides continuous real-time assessment of a patient's oxygenation and response to therapy. It has a proven role in emergency medicine and is an excellent clinical tool provided that the limitations are understood.

It is important to recognize that SaO_2 is not an adequate marker of ventilatory function and will not detect rising P_aCO_2 in respiratory failure or a sedated patient until late, when conscious state becomes depressed or there is respiratory arrest.[4] Hence all patients with potential respiratory compromise due to disease or sedative medication require careful monitoring of vital signs, conscious state and CO_2 via end-tidal CO_2 monitoring or arterial blood gases. Recent literature suggests a fall in SaO_2 may precede CO_2 accumulation during procedural sedation and analgesia in children.

A detailed knowledge of the haemoglobin–oxygen dissociation curve is required to interpret pulse oximetry, as well as the factors that influence readings obtained by this equipment. These factors are summarized in Table 2.2.4.

Paediatric considerations in oxygen therapy

The general principles of oxygen therapy and its indications apply equally well for children as for adults, but there are a number of important differences in relation to body size, psychology, and oxygen toxicity.

Body size

Children are smaller than adults both anatomically and physiologically, so that any increase in equipment dead space will significantly increase CO_2 retention. Children are less able to tolerate increased resistance to ventilation, particularly if negative pressure must be generated to open valves in the apparatus.

PIFR and RMV are lower; hence a given oxygen supply flow rate will produce a higher F_IO_2 in a child than in an adult. A Hudson mask at 8 L/min may supply an F_IO_2 of 0.8 in a young child. Reservoir bags are not required to deliver F_IO_2 values near 1.0 to children weighing less than 15 kg as available supply flow rates (maximum 15 L/min) exceed the child's PIFR.

Appropriately sized equipment is essential: a range of sizes of oxygen masks, oximeter probes, laryngoscopes, and endotracheal tubes must be available to manage children of different ages as serious barotrauma may result from the use of excessive volume during manual ventilation. Resuscitator bags are available with paediatric and infant-sized reservoirs. These units should have a pressure relief valve to prevent barotrauma. Pressure rises rapidly as the child's lung reaches full inflation.

Jackson-Rees (Mapleson F) circuit

A smaller Mapleson circuit, the Jackson-Rees (Mapleson F) circuit, is available to ventilate children, which can be used for both spontaneous and manual ventilation. Rebreathing of carbon dioxide does not occur provided the fresh gas flow is two to three times minute volume and the bag is separated from the patient by a tube of internal volume greater than the patient's tidal volume. The overall relationship between fresh gas flow, minute volume and P_aCO_2 is complex.

The principal advantages of the Mapleson F circuit are that the operator can observe bag movement in spontaneous respiration and has a better 'feel' for airway obstruction in manual ventilation. However, considerable skill and experience are required to use the system safely.

Psychological considerations

Gaining the trust and confidence of an ill child is an art learnt with experience. Children frequently respond with fear when oxygen therapy is administered, so it is helpful to ask a parent to comfort the child during treatment. A tight-fitting mask is less important in a child because source flow rate more closely approximates PIFR. Parents may assist by holding the oxygen mask close to the child's face or by directing high-flow oxygen straight at the child's mouth using a tube only. A cupped hand with the oxygen tube held between middle and ring fingers can serve as a surrogate oxygen 'mask'.

Oxygen toxicity

Prolonged administration of oxygen at F_IO_2 greater than 0.6 for longer than 24 hours may be toxic to infants. This toxicity may not become apparent during their acute stay in the emergency department, but the oxygen dose received there contributes to the cumulative toxicity. Appropriate monitoring using pulse oximetry ensures administration of the correct dose and minimizes the risk of toxicity. However, supplemental oxygen should never be withheld because of fear of toxicity.

Transfer of patients on oxygen therapy

Supplemental oxygen therapy is a vital part of transporting the ill patient and is especially important for air travel where lower ambient P_IO_2 may exacerbate hypoxia already present as a result of the patient's disease process. Patients with decompression illness or arterial gas embolism should not be transported at cabin pressures lower than 101.3 kPa (1 atmosphere absolute, ATA) because lower ambient pressure exacerbates their disease process by increasing bubble size. A number of factors must be considered for successful oxygen therapy during transport of a patient.

Knowledge of the oxygen delivery apparatus and its maximum rate of delivery are essential for

Table 2.2.4 Factors that influence pulse oximetry readings

Factor	*Cause*
Signal interference	High-intensity external light source Diathermy Shivering/movement of digit
Reduced light transmission	Dark-coloured nail polish Dirt (NB: melanin pigment/jaundice have no effect)
Reduced plethysmographic volume	Peripheral vasoconstriction (shock, hypothermia)
Inaccurate readings due to abnormal haemoglobin	COHb causes overestimation as it is not distinguished from O_2Hb Methaemoglobin > 10% causes oximeter to read 85% saturation, regardless of true O_2 saturation Profound anaemia— insufficient haemoglobin for accurate signal
Falsely low readings	Intravenous dyes with absorption spectra near 660 nm (e.g. methylene blue) Stagnation of blood flow

estimating transport oxygen requirements. These estimates must take into account current oxygen consumption, duration of transport (including delays), oxygen required in the event of deterioration, and a safety factor of at least 50%.

The sizes of oxygen cylinders available in Australasia, their filling pressures, and approximate endurances are summarized in Table 2.2.5. The most economical circuit for prolonged transport maintaining close to an F_IO_2 of 1.0 is a closed circuit with a CO_2 absorber and the least economical is a free-flowing circuit.

Monitoring during transport should be of the same standard as that initiated in the emergency department. Pulse oximetry is an essential tool to detect hypoxia during transport and should include audible and visual alarms. Oxygen therapy can be titrated against SaO_2, which is particularly important in air travel where P_IO_2 varies with ascent and descent. All the usual clinical parameters must also be monitored.

Oxygen therapy in specific circumstances

Asthma

Hypoxia in asthma results from ventilation/perfusion mismatch created by bronchospasm, secretions, airway inflammation, and oedema. Supplemental oxygen should be titrated to provide an SaO_2 greater than 90% (preferably 94%) and must be continued during the interval between doses of inhaled bronchodilators.[5,6]

Initial management should include a Hudson mask at a flow rate of 8 L/min, with SaO_2 monitored continuously by pulse oximetry. The oxygen dose should be rapidly increased up to 100% if the patient remains hypoxic. Bronchodilator therapy is administered proportionate to the severity of the attack, using oxygen to drive the nebulizer. Oxygen should not be withheld or administered in low doses for fear of respiratory depression. Hypercapnia is an indication of extreme airway obstruction, and its presence mandates aggressive therapy and/or mechanical ventilation.

Mechanical ventilation in asthma

Mechanical ventilation requires an F_IO_2 of 1.0, high inspiratory flow rate (100 L/min), low tidal volume (6 to 8 mL/kg), a prolonged I:E ratio of at least 1:3, and a low ventilation rate (6 to 10 breaths/min or less), to reduce the risks of progressive dynamic hyperinflation with the development of auto-PEEP (iPEEP), thus reducing venous return and hence preload, and of barotrauma with the development of a pneumothorax. Permissive hypercapnia is accepted with mechanical ventilation.

Occasionally patients with asthma become hypoxic during nebulizer therapy because the oxygen flow rates driving the nebulizer (6 to 8 L/min) are lower than the flow rate required to maintain an SaO_2 greater than 90%. In these circumstances, extra oxygen is supplied to maintain SaO_2 via a T piece or Y connector during nebulizer therapy.

Chronic obstructive pulmonary disease

Most ED patients with COPD have a degree of acute respiratory failure that caused their emergency presentation. This may be due to infection, bronchospasm, retention of secretions, coexistent left ventricular failure, worsening right heart failure, pulmonary embolism, pneumothorax, and/or sedation or reduction of regular therapy, such as inhaled or oral steroids. Clues to the degree of severity and chronicity of the COPD are obtained from the patient's history, past clinical records, emergency department blood gases and the response to initial oxygen therapy.

Clinical indicators of patients at risk of CO_2 retention include a housebound patient, FEV_1 below 1 L, polycythaemia, a warm vasodilated periphery, and cor pulmonale. In the acutely unwell patient, treatment may be required before the history can be obtained.

Chronic obstructive pulmonary disease groups

Patients with COPD fall into two groups as regards management, although this classification is still debated.

- Normal ventilatory response to CO_2 ('can't breathe' being the most common). Gas exchange and air flow into the lungs are impaired but ventilatory drive is normal.
- Impaired ventilatory response to CO_2 ('won't breathe' being less common). Ventilation does not increase in response to hypercapnia and acidosis.

There is overlap in the advanced stages of illness. The aims of oxygen therapy are targeted to produce an SaO_2 of 88% to 90% and to identify the second group of patients such that the oxygen dose can be titrated to achieve an acceptable clinical response without excessive elevation of P_aCO_2. Serial blood gas analysis is essential in their management.

The majority will have a normal ventilatory response to CO_2. Hypercapnia indicates that ventilatory failure is developing, with a danger of respiratory arrest if the patient's disease is severe and progressive. This can also result from uncontrolled oxygen therapy with failure to monitor the patient's clinical status and arterial blood gases. Any patient with impaired consciousness due to respiratory failure should be manually ventilated while being clinically assessed and treated.

Controlled titration of oxygen dose in chronic obstructive pulmonary disease

Successful management of the cooperative patient with COPD necessitates controlled titration of oxygen dose. Variable-performance oxygen masks do not have a role in the emergency management of COPD, unless there is careful monitoring of SaO_2 and $ETCO_2$. A consistent initial approach to oxygen therapy for a conscious patient with advanced COPD is used as, at the time of presentation, their ventilatory response to CO_2 is unknown.

In most patients, the administration of 24% to 28% oxygen by oxygen blender or Venturi mask will improve oxygenation, with a target SaO_2 of about 88% to 92%. It is also acceptable initially to titrate oxygen therapy to a target SaO_2 range. In the prehospital setting, there was lower mortality for patients with COPD if they received titrated oxygen therapy by nasal prongs aiming for an SaO_2 range of

Table 2.2.5 Oxygen cylinder sizes for patient transport

Cylinder size	Water capacity (kg)	Volume at 15,000 kPa 15°C (L)	Approximate endurance at 8 L/min	15 L/min	30 L/min
C	2.8	420	52 min	28 min	14 min
D	9.5	1387	173 min	92 min	46 min
E	23.8	3570	446 min	238 min	119 min
G	48	7200	900 min	480 min	240 min

about 88% to 92%, as opposed to uncontrolled oxygen delivery.[7] All nebulizer therapy was administered by air.

Below 90% saturation, the Hb–O_2 dissociation curve falls steeply and, unless a pulmonary shunt is present, even small increments in oxygen will make a positive difference. The patient's response to initial oxygen therapy (F_IO_2 = 0.24–0.28) will direct further oxygen dose changes and identify any patients not already known to be suffering chronic hypercapnia.

A repeat blood gas sample should be taken after 10 minutes of breathing yielding an F_IO_2 of 0.24 to 0.28. The P_aCO_2 may rise slightly because of the 'Haldane effect'. If this rise is excessive (>1–1.3 kPa [8–10 mm Hg]), it is consistent with an impaired ventilatory response to CO_2. The F_IO_2 should then be adjusted downwards in steps to achieve a satisfactory pulse oximetry reading that is compatible with an acceptable CO_2 level. In a patient with COPD, an acceptable range for SaO_2 is 88% to 92%. Patients with a normal ventilatory response to CO_2 will not exhibit a significant elevation of P_aCO_2 in response to oxygen therapy. If hypoxaemia persists and the P_aCO_2 remains stable, then the oxygen dose may be increased incrementally until the desired oxygen saturation is achieved.

Blood gas samples taken during the initial assessment of these patients (breathing air or controlled oxygen) can be helpful to management. Venous samples are acceptable, provided they are used consistently to monitor trends. If the bicarbonate level is greater than 30 mmol/L or is elevated by more than 4 mmol/L for each 1.3 kPa (10 mm Hg) rise in P_aCO_2 above normal (5.3 kPa, 40 mm Hg), this provides strong evidence of chronic hypercapnia provided that there is no other cause of a metabolic alkalosis.

Non-invasive positive-pressure ventilation (NIPPV) is supported by level 1 evidence if the patient remains hypoxic or becomes progressively more hypoxic and the elevation of P_aCO_2 persists or worsens or their conscious state deteriorates.[8] Intubation and ventilation may be required, which should be regarded as a last resort (and will not be covered in this chapter). Supplemental oxygen should never be abruptly withdrawn from a patient with COPD, as a catastrophic fall in P_aO_2 will occur. All reductions in controlled oxygen dose should be in a stepwise manner, similar to incremental increases.

In the majority of cases, an acceptable balance between P_aO_2 and P_aCO_2 can be achieved, where both hypoxia and hypercarbia are reversed by specific therapy. Treating the cause of the ventilatory failure is a priority.

Goal-directed oxygen therapy

The oxygen dose in the initial management of many medical conditions—including myocardial infarction, asthma and even pneumonia—has been questioned. A recent randomized controlled trial (RCT) assessed patients given oxygen at 8 L/min compared with those who received titrated supplemental oxygen (only provided if SaO_2 < 94%) for ST-segment elevation myocardial infarction in the prehospital setting.[9] There was an increase in the rate of arrhythmias, recurrent myocardial infarction and infarct size in the oxygen-treated group. Whether or not these end points are clinically significant will require further research. The study was not powered to assess mortality, an important clinical end point, which was lower in the oxygen-treated group but not statistically significant.

Studies of titrated oxygen therapy for asthma, pneumonia and other conditions are ongoing. Current trends in clinical evidence suggest that oxygen should be treated in the same way as any other drug—that is, to provide the optimum dosage appropriately titrated to the clinical needs of the patient.[5] In principle, goal-directed oxygen therapy does not differ from many other therapies for physiological disturbance.

Special delivery systems

Oxygen humidification

Humidification is desirable when prolonged use of supplemental oxygen is required. Oxygen is totally dry, possessing no water vapor. Humidification is particularly important in a patient ventilated with an endotracheal tube, as the natural humidification that occurs in the nose, mouth and nasopharynx are bypassed. Patients with COPD and retained secretions benefit from humidification.

Additional heat is required to provide effective humidification by vaporization of water. Various systems are available to humidify inspired gas and, ideally, they should be able to deliver inspired gas to the trachea at 32°C to 36°C with low resistance and at greater than 90% humidity. These devices should be simple to use and able to maintain temperature and humidity at varying gas flows and F_IO_2. There should also be safety alarms monitoring temperature and humidity. Modern oxygen blenders are able to satisfy these requirements. Humidification of warmed inspired gas also enables heat transfer to hypothermic patients and is essential in treating the pulmonary complications of near drowning.

Box 2.2.2 Indications for acute treatment with hyperbaric oxygen

- Decompression illness
- Air or gas embolism (diving or iatrogenic)
- Carbon monoxide poisoning
- Gas gangrene and anaerobic fasciitis
- Necrotizing soft tissue infections
- Acute crush injury with compartment syndrome
- Acutely compromised skin flaps or grafts, due to injury or postsurgery

(From Weaver LK. *Hyperbaric Oxygen Therapy Indications*. 13th ed. Florida: Undersea and Hyperbaric Medical Society. Best Publishing Company; 2014.)

Continuous positive airways pressure

CPAP has a role in the management of pulmonary oedema, pneumonia, bronchiolitis, respiratory tract burns and acute respiratory failure. Benefit to the patient is achieved as a result of increasing functional residual capacity and reduced pulmonary compliance. Hypoxaemia is reversed by reduction in intrapulmonary shunting and the work of breathing is reduced.

Circuit designs for continuous positive airways pressure

Circuit designs usually consist of a reservoir based on the Mapleson D circuit or a high-flow turbine system. Humidification can be added to the system and is considered essential for long-term use. Use of an oxygen blender enables variable F_IO_2 to be administered. CPAP has a proven role in the emergency department in the acute management of cardiogenic pulmonary oedema. Reduced requirements for endotracheal intubation have been demonstrated when CPAP is used for severely ill patients. Complications of CPAP include aspiration and pulmonary barotrauma. It may elevate intracranial pressure and precipitate hypotension by reducing venous return to the thorax.

Hyperbaric oxygen treatment

Hyperbaric oxygen (HBO) treatment consists of administering oxygen at pressures greater than 101.3 kPa, (1 ATA), usually in the range of 203 to 284 kPa. This requires a hyperbaric chamber that is pressurized with air while the patient breathes an F_IO_2 of 1.0 from various delivery systems for periods of 2 to 7 hours. The high P_IO_2 results in a

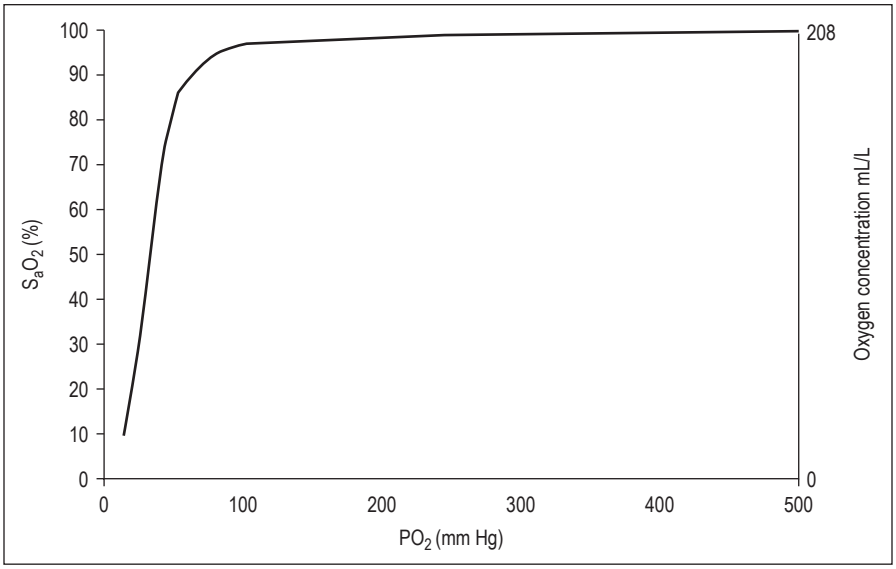

FIG. 2.2.1 The haemoglobin–oxygen dissociation curve.

P_aO_2 of up to 267 kPa (2000 mm Hg) if 284 kPa treatment pressure is used. This is beneficial, as there is increased dissolved oxygen in the plasma (up to 300 mL oxygen may be carried to the periphery each minute in the dissolved form), which maintains oxygen flux even if haemoglobin is non-functional—for instance, in carbon monoxide poisoning. Increased P_IO_2 enables more rapid elimination of toxic gases from the body—for example, carbon monoxide or hydrogen sulphide.

Uses of hyperbaric oxygen

HBO treatment has a number of benefits in treating gas embolism and decompression illness (DCI). It provides extra oxygen to tissues rendered ischaemic by nitrogen bubbles and the increased pressure reduces bubble size and enhances nitrogen removal from the body. The increased PO_2 also creates a greater driving pressure of oxygen into ischaemic tissues in problem wounds and reduces swelling by vasoconstriction in crush injury. In addition, HBO treatment is used in anaerobic infections by virtue of being bacteriocidal to anaerobes, inhibiting clostridial alpha toxin and stimulating host defences via granulocyte function. Recognized indications for acute referral to a hyperbaric facility for HBO treatment are summarized in Box 2.2.2 (see Section 24.3).[10]

Complications of oxygen therapy

These can be classified into three categories:

- Equipment-related complications
- Carbon dioxide narcosis
- Oxygen toxicity

Equipment-related complications

These are entirely preventable with careful supervision and monitoring. Tight-fitting masks may cause asphyxia if there is insufficient oxygen reservoir or flow and aspiration of vomitus may occur if the patient has depressed airway reflexes. Use of appropriate oxygen flow rates with rebreathing circuits prevents CO_2 accumulation.

Barotrauma can be prevented during mechanical ventilation by the use of appropriate volumes and pressures, although it can be difficult to avoid when there is reduced lung compliance, as in the moribund asthmatic. Knowledge of potential equipment complications enables prompt intervention should they arise. When investigating a sudden deterioration in the patient's condition, a thorough check of the equipment in use is mandatory.

Carbon dioxide narcosis

This can be prevented by controlled oxygen therapy titrating the F_IO_2 against SaO_2, arterial blood gases and conscious state (see earlier). An unconscious patient should be intubated and manually ventilated using high F_IO_2, preferably 100% oxygen. A patient with a deteriorating conscious state and respiration due to CO_2 narcosis should be vigorously stimulated and encouraged to breathe while F_IO_2 is reduced in a stepwise manner. Oxygen should never be suddenly withdrawn, as this precipitates severe hypoxia. Reversible causes of respiratory failure should be treated and non-invasive ventilation instituted.

Oxygen toxicity

Oxygen is toxic in high doses, which is a function of P_IO_2 and duration of exposure. Toxicity is thought to occur by the formation of free radicals and toxic lipid peroxides, inhibition of enzyme systems and direct toxic effects on cerebral metabolism. Toxicity is mainly restricted to the respiratory system and central nervous system (CNS), although it can affect other regions such as the eye. Premature infants develop retrolental fibroplasia after prolonged exposure to high F_IO_2. CNS oxygen toxicity manifested by neuromuscular irritability and, rarely, seizures (Paul Bert effect) is restricted to hyperbaric exposures.

Pulmonary oxygen toxicity (Lorrain Smith effect) is of relevance to emergency medicine, although exposures of 0.6 to 1 ATA for more than 24 hours are required to produce demonstrable evidence of lung injury. Acute changes such as pulmonary oedema, haemorrhage and proteinaceous exudates are reversible on withdrawal of oxygen. Longer durations of high P_IO_2 may lead to permanent pulmonary fibrosis and emphysema. Physicians should be alert to acute symptoms of cough, dyspnoea and retrosternal pain, although these are non-specific symptoms of oxygen toxicity. A progressive reduction in vital capacity may be demonstrated. As with all drugs, oxygen dose should be monitored and carefully titrated against SaO_2 and clinical effect. However, oxygen therapy should never be withheld acutely because of fear of toxicity.

CONTROVERSIES/EMERGING ISSUES

- Is oxygen a drug with a therapeutic window?
- In what clinical conditions could oxygen be harmful?
- Should we monitor all patients with COPD and asthma using CO_2 measuring devices?
- What is the best device for monitoring CO_2 during emergency treatment?
- Goal-directed oxygen therapy titrated to target SaO_2 for specific disease processes will be the future best practice for oxygen therapy.

2.3 Haemodynamic monitoring

Craig Hore

ESSENTIALS

1 **Haemodynamic monitoring includes observation of the complex physiology of blood flow, with the aim of providing data that can be used to improve patient management and outcomes.**

2 **Numerous methods are available that should be considered in a stepwise fashion, from simple clinical assessment to highly technical, invasive procedures, such as use of the pulmonary artery catheter.**

3 **Effective use of haemodynamic monitoring devices requires an understanding of cardiovascular physiology.**

4 **Currently there is a move away from simple blood pressure measurements towards targeting end-organ perfusion and the adequacy of cardiac output.**

5 **Use of any monitoring technology in the emergency department (ED) must consider the time associated with its introduction, the skill levels required, and the clinical benefits provided.**

6 **No monitoring modality improves outcome unless it is linked to a valid treatment pathway.**

7 **The pulmonary artery (Swan–Ganz) catheter was for many years considered a 'gold standard' for haemodynamic monitoring, but evidence suggests no improvements in patient outcome. It should therefore not be used in the ED.**

8 **Less invasive devices have been developed in recent years. Their role in the ED is yet to be fully elucidated.**

9 **Further developments will likely result in greater use of less invasive methods for haemodynamic monitoring, with an increased ability to monitor at the microcirculation and/or cellular level and better correlation between observed events and final diagnosis.**

Introduction

Haemodynamics is concerned with the physiology of blood flow and the forces involved within the circulation. *Haemodynamic monitoring* involves the study of this complex physiology using various forms of technology to understand these forces and put them into a clinical context that can be used to direct therapy. The utility of basic monitoring is universally accepted. However, the maxim that '*not everything that counts can be counted and not everything that can be counted counts*' (Albert Einstein, 1879–1955) should be borne in mind.

This is particularly salient in the emergency department (ED), where the pressure of work and the diversity of patients do not allow the unlimited use of complex and expensive monitoring systems.

This chapter provides an outline of current approaches to the various technologies available for haemodynamic monitoring and their applicability in the ED. Many methods are available, which should be thought of in a stepwise progression from simple clinical assessment to invasive, highly technical methods using sophisticated devices.

Historical background

As recently as 100 years ago, only temperature, pulse and respirations were measured and used to manage patients. The technology for auscultatory blood pressure measurement was available but did not come into regular use until the 1920s.

Intensive care as a medical/nursing specialty evolved in tandem with the electronic revolution of the 1960s. At the same time, increasingly sophisticated haemodynamic and laboratory techniques vastly improved diagnosis and provided a way to evaluate therapy further. Despite these major advances in the ability to monitor multiple physiological variables, there is little evidence to suggest that they have resulted in tangible improvements in patient outcome.

Practical use of monitoring

The practical use of any monitoring device must be appropriate to the individual clinical environment. Thus it may be reasonable to insert a pulmonary artery Swan–Ganz catheter in the intensive care unit (ICU), where the necessary time can be taken, yet impractical and potentially unsafe in a busy ED. Another consideration is that haemodynamic monitoring should be used only when the clinical outcome may be influenced and potentially improved. Once irreversible cellular damage has occurred, there is no benefit no matter how far therapy is maximized.

Further, haemodynamic monitoring may not improve patient outcome unless it is linked to a

valid clinical management pathway. Clinicians should introduce monitoring equipment only if it will have a direct influence on their choice of therapy, as the use of invasive monitoring carries potential risks of harm to the patient. The injudicious use of physiologically based treatment protocols may lead to worse outcomes. All monitored variables must be evaluated and applied in a manner proven to lead to benefit in terms of both the diagnosis and management.

Overview of cardiovascular physiology

One possible reason that haemodynamic monitoring has not been associated with improvements in outcome is the inability to understand and manipulate patients' physiology effectively.

Circulatory model

Haemodynamic data are traditionally considered in the context of a circulatory model. This model varies but usually consists of a non-pulsatile pump and a hydraulic circuit with discrete sites of flow resistance alongside the Frank–Starling mechanism with its concepts of preload, contractility and afterload.

Cardiac output

Cardiac output (CO) is the volume of blood pumped by the heart per unit of time, usually expressed in litres per minute (L/min). The heart operates as a pump and ejects a bolus of blood known as the *stroke volume* (SV) with each cardiac cycle. CO is the product of SV and heart rate (HR).

A complex set of interrelated physiological variables determines the magnitude of CO, including the volume of blood in the heart *(preload)*, the downstream resistance to the ejection of this blood *(afterload)* and the *contractility* of the heart muscle. However, it is the *metabolic requirements* of the body that are the most potent determinant of CO.

Regulation of cardiac output

The regulation of CO is therefore complex. A single measurement represents the summation of many interacting physiological processes. Basal CO is related to body size and varies from 4 to 7 L/min in adults. This value divided by the body surface area enables comparison between patients with different body sizes, giving the *cardiac index* (CI).

Bedside methods do not measure CO directly, meaning that the values obtained are only estimates. Assessment of CO is therefore not done routinely. Indeed, misuse of CO data may worsen outcomes. The European Society of Intensive Care Medicine Consensus on Circulatory Shock and Haemodynamic Monitoring (2014) did not recommend routine measurement of CO for patients with shock with a clear diagnosis or in patients responding to initial therapy.

Cardiac index

CI measurement is valued over simple blood pressure recording as it describes the total volume of blood flow in the circulation per unit of time and hence serves as an indicator of oxygen delivery to the tissues. The CI is also useful for understanding and manipulating the pump activity of the heart.

Role of haemodynamic monitoring in the emergency department

The role of haemodynamic monitoring in the ED is even less well defined. Given the plethora of devices but the lack of a 'gold standard', there are insufficient data to recommend any one method over another.

Nevertheless, the Surviving Sepsis Campaign Guidelines (2016) emphasize that resuscitation of a patient with severe sepsis, for example, should begin as soon as the diagnosis is made and not be delayed until ICU admission. The use of such an approach based on strict treatment protocols has been shown to reduce morbidity and mortality (see Chapter 2.5). Obstacles include a lack of skill to perform the initial procedures and difficulty in providing the required higher level of care due to ED staffing and patient flow constraints. However, with a potential patient stay in an ED (with finite critical care resources) of up to 24 hours, approximately 15% of critical care is already being provided in this setting.

Clinical assessment

Current guidelines on haemodynamic monitoring recommend frequent measurement of blood pressure and physical examination variables, including signs of hypoperfusion, such as reduced urine output and abnormal mental status. Clinical examination is 'low risk' yet may yield much important information, but the sensitivity and specificity are low, even when individual elements are interpreted in isolation. Also, clinical assessment of the circulatory state may be misleading.

Nevertheless, clinical assessment still has an important role in the initial assessment of a critically ill patient. Paradoxically, the development of haemodynamic measuring devices was driven by the poor ability to assess the critically ill patient clinically, yet patients managed simply by clinical assessment may do better than those managed with invasive, complex devices.

Key properties of an 'ideal' haemodynamic monitoring system include the following:

- Measurement of variables that are clinically relevant
- Measurements that are accurate and reproducible
- Measurements that are continuous
- Generation of data that are clinically interpretable and useful for guiding therapy
- Operation that is simple and user-independent
- Operation and utility that result in clinical benefit to the patient
- Operation and utility that cause no harm to the patient
- Operation and utility that are cost-effective

Clinical markers of cardiac output

The underlying issue is not what a patient's CO *is* but rather whether this CO is *effective* for that particular patient. Trends are more important than specific single-point values in guiding therapy. An effective CO should need no compensation; therefore a patient should have warm toes simultaneously with a normal BP and HR. One of the advantages of *clinical end points* is that they remain the same whatever the phase of the illness.

Clinical end points

Clinical end points that are important in the management of septic shock were set out by the American College of Critical Care Medicine (ACCM) in 1999 and again in 2007 and 2012 by an International Consensus Conference. These are essentially markers of perfusion and include skin temperature, urine output and cerebral function.

In patients with heart failure, simple clinical assessment of perfusion and congestion can define profiles (dry–warm, wet–warm, wet–cold, dry–cold) that may be used to guide therapy and investigations. Further, in advanced heart failure, orthopnoea (≥2 pillows), jugular vein pulse (JVP) and a global assessment of perfusion ('cold' profile) help detect a reduced CI.

Physiological measurements and clinical endpoints should be viewed as complementary. Physiological measurements combined with clinical examination may provide a numeric target for a management strategy. Measurements also provide a universal language for information exchange.

Sound clinical evaluation in the ED in terms of markers of effective CO is helpful in the early diagnosis and implementation of early goal-directed therapy (EGDT). Abnormal findings also suggest the need for more invasive haemodynamic monitoring and the need to involve the ICU team early in the patient's management.

Blood pressure monitoring

The pressure under which blood flows is related to the force generated by the heart and the resistance to flow in arteries. Measurement of mean arterial pressure (MAP) is a more reliable measure of blood pressure than either the systolic or diastolic pressures. It is least dependent on the site or method of measurement, least affected by measurement damping and determines the actual tissue blood flow.

Traditionally, low blood pressure was used to reflect shock and haemodynamic instability. This approach is being challenged as more reliance is placed on concepts of global tissue hypoxia and the estimation of CO and its adequacy. Although Ohm's law predicts a relationship between MAP and CO, MAP is a physiologically regulated variable and therefore can be a weak predictor of acute increases and decreases in CO.

Non-invasive blood pressure measurement

Non-invasive blood pressure (NIBP) measurements using a sphygmomanometer and palpation were first proposed in the late 1800s, before Korotkoff introduced the auscultatory method in 1905. Originally, routine blood pressure measurements were not a regular part of clinical patient assessment. Today, non-invasive or indirect blood pressure measurement is the most common method used in the initial assessment of a patient's cardiovascular status.

Although there are significant differences between direct (i.e. invasive) and indirect measurements, non-invasive measurements should rightly form part of every patient's assessment and management in the ED.

Non-invasive blood pressure devices

Non-invasive measurement techniques use blood flow within a limb to measure pressure. Automated oscillometric devices are now the standard, with manual methods (using either palpation or auscultation) becoming increasingly obsolete in clinical ED practice.

The cuff width should be about 40% of the mid-circumference of the limb. Failure to use the appropriate size of cuff leads to inaccurate and misleading measurements. The cuff is inflated until all oscillations in cuff pressure cease; then the occluding pressure is gradually reduced and proprietary algorithms compute mean, systolic and diastolic pressures.

The 95% confidence limits in the normotensive range are ±15 mm Hg; but, in states of hypotension and hypertension, oscillometry tends to over- and underestimate, respectively, the pressures. Complications are unusual, although repeated measurements could cause skin bruising, oedema and even ulceration.

Other non-invasive monitoring methods for cardiac output

The ideal device has yet to be developed for the non-invasive measurement of CO and other related variables in the ED. Devices that are available do not compare reliably with invasive methods and are not suited to all patient cohorts and/or may be too elaborate or time-consuming for a busy ED.

Ultrasonic cardiac output monitor

This device was developed in Australia and introduced for clinical use in 2001. It provides non-invasive transcutaneous estimation of CO based on continuous-wave Doppler ultrasound. An ultrasound transducer is used to obtain a Doppler flow profile (velocity–time graph) from either the aortic (suprasternal notch) or pulmonary (left of sternum, below the second intercostal space) window. The transducer is manipulated to get the best flow profile and audible feedback. CO is calculated from the product of the velocity–time integral (VTI) and the cross-sectional area of the target valve.

The device performs well in terms of the time taken to become competent and the reproducibility of its readings. It appears to provide a rapid and safe estimate of CO and may assist in the prompt starting of EGDT by emergency physicians, including pre-hospital and retrieval situations.

The correlation of ultrasonic cardiac output monitoring (USCOM) with standard estimates of CO, as by thermodilution using a pulmonary artery catheter (PAC), has been reported as good, although studies are conflicting. Concerns have also been raised that reliability is affected by patient pathology and the severity of illness.

More is needed to clearly define the utility of USCOM in the ED. The device can be used as part of the overall clinical assessment, but it should not be used in isolation. It may be best at looking at responses to treatment, such as changes in CO associated with a fluid bolus.

Oesophageal Doppler

Estimation of CO using various Doppler-based techniques has been extensively studied. The main difficulties are an inability to obtain acceptable flow signals with the transthoracic approach and problems in the measurement of the cross-sectional area using flow. The transoesophageal approach (TOE) is more reliable than the transthoracic.

The oesophageal Doppler device requires minimal training, and volume challenge protocols can be developed such that nursing staff may use them at the bedside. However, this technique is not well tolerated by the awake patient and thus has limited application in the ED.

Transthoracic echocardiography

Transthoracic echocardiography (TTE) is used to determine left ventricular size, thickness and performance. It can also help identify a patient who requires fluids. The use of TTE has increased as the technology and familiarity have improved, with training in TTE for intensive care specialists and emergency physicians widespread.

Treatment decisions

Effective treatment decisions can be based on the TTE screen and on subsequent assessment of left ventricular function. One widely used parameter is respiratory variation of the vena cava diameter for assessment of intravascular volume and fluid responsiveness in shock. This is quantified by measuring the decrease in the inferior vena cava (IVC) diameter with inspiration compared with expiration, expressed as the IVC caval index or the IVC collapsibility index (IVC–CI). Higher IVC–CI values have been correlated with lower right atrial (RA) filling pressures, and lower values have been correlated with higher RA filling pressures.

The utility of the IVC caval index in the ED for the assessment of volume responsiveness and fluid management is unclear. One issue is its applicability in the spontaneously breathing patient, as using the IVC caval index for fluid responsiveness in mechanically ventilated ICU patients appears to be of more value. Further, other factors can affect IVC diameter and collapsibility, including left and right ventricular function, pulmonary hypertension and tricuspid valve dysfunction, which need to be considered when interpreting the findings.

Left ventricular systolic function

The most common initial technique in the ICU for TTE assessment of left ventricular systolic function is simply looking at the amount of endocardial border excursion toward the centre of the left ventricle and at increasing wall thickness during contraction. Using these, at a minimum the systolic function of the left ventricle may be described as being normal, hyperdynamic or having moderate or severe dysfunction.

Other useful TTE information with significant haemodynamic and therapeutic value includes valvular function, right ventricular function and evidence of pericardial tamponade, regional left ventricular hypokinesis, transient apical ballooning and left ventricular outflow tract (LVOT) obstruction. One major criticism as regards TTE for haemodynamic monitoring is that it cannot be done continuously. Other problems include the skill base needed and having to reassess variables after changes in patient management. Knowledge and skills are rapidly increasing and, with the development of handheld and compact portable devices, the use of TTE will become even more common in the ED.

Invasive devices

Invasive blood pressure measurement

Arterial cannulation allows continuous blood pressure measurement, beat-to-beat waveform display and repeated blood sampling. A cannula inserted into an artery is connected via fluid-filled, non-compliant tubing less than 1 m in length to a linearly responsive pressure transducer. The system is then zeroed with reference to the phlebostatic axis (the midaxillary line in the fourth intercostal space). Modern transducers are pre-calibrated and therefore no further calibration is needed.

Sites and safety of arterial cannulation

The most common site for cannulation is the radial artery, as it is easy to access during placement and subsequent manipulations, the wrist has a dual arterial supply and there is a low complication rate. Temporary occlusion of the artery may occur; in a small number of cases, this may be permanent. Other complications can include haematoma formation, bleeding, cellulitis and complications associated with the catheter itself.

Alternative arterial cannulation sites are femoral, axillary and brachial, but all have similar complications. Arterial cannulation is a safe procedure if the optimal site for insertion is selected carefully for each patient. The preference in the ED is for the radial and femoral sites.

Use of invasive blood pressure monitoring

Invasive blood pressure monitoring should be used in all haemodynamically unstable patients and when vasopressor or vasodilator therapy is used. Relying on external NIBP monitoring to guide diagnosis and therapy does not provide sufficient diagnostic data, particularly in sepsis. Additional methods of haemodynamic monitoring may be considered in these patients, with early involvement of the intensive care department.

The remainder of this chapter discusses some of the supplementary methods available to assess important physiological measures that guide the management of the haemodynamically unstable patient.

Central venous pressure monitoring

Central venous access was first performed in Germany in the late 1920s, but the utility of the process was not really appreciated until the 1950s. This led to the development of cardiac angiography, central blood oxygenation determination and pressure recordings. The technique and clinical relevance of continuous central venous pressure (CVP) monitoring were first described in 1962, as it allowed direct determination of right heart function and assessment of intravascular volume status.

However, correlation with left heart function was found to be unpredictable and unreliable in the critically ill. Thus the physiological meaning of the values obtained and their role in patient management are not clear. Problems result from errors in measurement and failure to understand the underlying pathophysiology.

Central venous access

Central venous access is obtained in the ED by inserting a catheter into a peripheral or central vein and is defined by the position of the catheter tip, which should be positioned at the junction of the proximal superior vena cava and right atrium.

There is no ideal insertion site. Selection depends on the experience of the operator and patient factors, such as body habitus, disease or injury sustained and coagulation profile. The main routes used are the internal jugular, subclavian and femoral veins.

Indications for central venous access

Indications include fluid and electrolyte replacement; drug therapy where peripheral use is contraindicated, such as vasopressors; monitoring of the CVP to guide management; sampling of central venous blood to monitor central venous oxygen saturation ($ScvO_2$); venous access for insertion of a PAC or transvenous pacemaker; and a lack of an accessible peripheral vein.

Complications of central venous access

Complications related to insertion are divided into early and late. Relevant *early* complications in the ED include pneumothorax, haemothorax, dysrhythmias and injury to surrounding structures, including arterial puncture, nerve injury and tracheal injury. *Late* complications include catheter-related sepsis, superior vena cava erosion with cardiac tamponade and venous thrombosis.

The CVP is often used as a marker of preload and is considered an estimate of right atrial pressure (RAP). The normal CVP in the spontaneously breathing supine patient is 0 to 5 mm Hg, with 10 mm Hg considered an upper limit of normal in those being mechanically ventilated. The CVP also correlates with left ventricular end-diastolic pressure (LVEDP) in a patient with normal heart and lungs. However, in disease states this relationship is frequently abnormal. Thus the CVP can be only a rough guide to right ventricular preload, with emphasis on dynamic changes rather than absolute values.

Central venous oxygen saturation

$ScvO_2$ is measured in blood taken via the central venous catheter and reflects the balance between oxygen delivery and oxygen consumption. Oxygen extraction in health is normally about 25% to 30% and an $ScvO_2$ greater than 65% reflects an optimal balance. For example, in postoperative surgical patients in the ICU, $ScvO_2$ levels below 70% have been independently associated with a higher rate of complications and increased length of hospital stay. Continuous measurement of $ScvO_2$ is possible in the ED, where central venous catheterization is commonly performed and when the alternative of pulmonary artery insertion is impractical. $ScvO_2$ has been shown to correlate well with mixed venous oxygen saturations (SvO_2) obtained via a PAC.

Rivers et al. reported in 2001 that, in septic shock, early aggressive resuscitation (EGDT guided by CVP, MAP and continuous $ScvO_2$ monitoring significantly reduced 28-day mortality rates. However, subsequent large multicentre randomized trials—including Australasian Resuscitation in Sepsis trial (ARISE) (2014), Protocolised Care for Early Septic Shock trial (PROCESS) (2014) and Protocolised Management in Sepsis trial (PROMISE) (2015)—did not show any difference in all-cause mortality at 90 days between patients assigned to EGDT and those given standard treatments. Hence EGDT and the continuous monitoring of $ScvO_2$ in sepsis is not routine.

Pulse contour techniques for cardiac output

The use of pulse contour techniques to obtain a continuous estimation of CO by analysis of the arterial waveform dates back over 100 years. Erlanger and Hooker first proposed a correlation between SV and changes in arterial pressure and suggested that there was a correlation between CO and the arterial pulse contour. Advances in computer technology have since led to the development of complex algorithms relating the arterial pulse contour and CO.

The appeal of arterial waveform monitoring is that it can now be performed using a minimally invasive technique, with several companies producing devices that take measurements from an arterial line. The pulse-induced contour cardiac output (PiCCO) system (Pulsion Medical Systems, Munich, Germany) is one of the most established of the commercially available systems.

The pulse-induced contour cardiac output system of arterial waveform monitoring

The PiCCO system uses pulse contour analysis to provide a continuous display of CO according to a modified version of Wesseling's algorithm. The patient requires a central line preferably sited in either the internal jugular or the subclavian vein so that the venous injectate port is placed in the central cardiopulmonary circulation. If the femoral vein is accessed the intrathoracic volumetric measurements may be overestimated, although the transpulmonary thermodilution CO measurement may still be reliable. An arterial catheter with a thermistor is also required, which must be placed in one of the larger arteries, such as the femoral or brachial-axillary access.

The PiCCO system combines the pulse contour method for continuous CO measurement and a transpulmonary thermodilution technique to offer complete haemodynamic monitoring. Transpulmonary thermodilution works on the principle that a known volume of thermal indicator (cold 0.9% NaCl) is injected into a central vein. The injectate rapidly disperses both volumetrically and thermally within the pulmonary and cardiac volumes. This volume of distribution is termed the intrathoracic volume (ITV). When the temperature signal reaches the arterial thermistor, a temperature difference is detected and a dissipation curve is generated. The Stewart–Hamilton equation is applied to this curve and the CO is calculated.

Transpulmonary thermodilution This transpulmonary thermodilution also gives measures of preload and volume responsiveness in terms of global end-diastolic blood volume (GEDV) as well as intrathoracic blood volume (ITBV). The extravascular lung water (EVLW) provides a measure of water content outside the pulmonary vasculature, including the interstitium and any alveolar fluid and may be useful as an indicator of pulmonary oedema. The technique of transpulmonary thermodilution appears to be comparable in accuracy to pulmonary artery thermodilution. Following calibration by thermodilution, the PiCCO then continually quantifies parameters such as the following:

- PiCCO
- Arterial blood pressure
- HR
- SV
- Systemic vascular resistance (SVR)
- ITBV
- EVLW
- Cardiac function index (CFI)

Decision trees to guide the use of the last three parameters in the clinical setting have been devised. ITBV is used as an indicator of cardiac preload and may be helpful in guiding fluid therapy. It is derived from the GEDV and its clinical utility is likely to be equivalent. GEDV and ITBV may be of greatest clinical value when dynamic measures of volume responsiveness, such as stroke volume variation (SVV) and systolic pressure variation (SPV), cannot be used.

EVLW correlates with extravascular thermal volume in the lungs. The EVLW may also be used to guide fluid management, especially in patients already known to have pulmonary oedema.

The CFI is the ratio of CO to GEDV. It aids in evaluating the contractile state of the heart and hence overall cardiac performance. It is a preload-independent variable and reflects the inotropic state of the heart. The CFI has the potential to become a routine parameter of cardiac performance, but it is a derived variable and its benefit over the individual components that comprise it (CO and GEDV) is not clear.

Advantages of the pulse-induced contour cardiac output system The main advantage of the PiCCO system is that it is less invasive than a PAC, requiring only a central line and an arterial line, which most critically ill patients already have. This, in turn, leads to fewer complications. The data collected are extensive and allow for the manipulation of haemodynamics using reliable parameters.

Contraindications to using the PiCCO include situations where access to the femoral artery is restricted, as in burns. The PiCCO may also give inaccurate thermodilution measurements in the presence of intracardiac shunts, an aortic aneurysm, aortic stenosis, pneumonectomy, rapid changes in body temperature and during extracorporeal circulation. There can also be drift in measured values when there is a major change in vascular compliance.

The use of the PiCCO system in the ED is plausible. The technique is relatively non-invasive and uses access lines that are already used in the management of the critically ill. The device can aid diagnosis and also provide a monitoring tool for clinical decision making regarding fluid replacement. Further validation studies and technological advances will consolidate its potential.

Pulmonary artery Swan–Ganz catheter

The PAC or Swan–Ganz catheter was long considered the gold standard for monitoring unstable circulation, for example in patients with advanced heart failure. Since its introduction in the 1970s, it was assumed that the information provided improved patient outcome. However, various observational studies have now shown that its use does not improve outcomes and may even be associated with a worse outcome. Hence use of the PAC without targeting specific end points confers no benefit to the patient.

Disadvantages of pulmonary artery catheters

The insertion of a PAC is time-consuming and requires both skill and experience. The technique also has significant complications (e.g. haematoma, arterial puncture, infection, pulmonary infarction, pulmonary artery perforation, arrhythmias, catheter knotting), and the data generated can be difficult to interpret. Current guidelines recommend that the PAC not be used routinely in the management of shock; therefore its use in the ED should *not* be considered.

Conclusion

The challenge in emergency medicine is to select those haemodynamic monitoring methods and technologies that are best suited to the clinical environment and are able to influence both the diagnosis positively as well the subsequent management to improve patient outcome. Currently the best approach is to begin with sound clinical assessment and then to increase the invasiveness of monitoring in tandem with the patient's suspected diagnosis and response.

Future developments

- There is interest in the microcirculation and metabolic assessment at a cellular level. Methods to assess these include near-infrared spectroscopy (NIRS) and nicotinamide adenine dinucleotide phosphate in the reduced form (NADPH) fluorescence, a novel method using fluorescence microscopy for real-time assessment of adenosine triphosphate (ATP) release from individual cells. Both may have a role in the management of shock.
- NIRS appears to be the most advanced and promising modality, with reported use in a number of settings including the military and cases of trauma, congestive cardiac failure and sepsis. It continuously and non-invasively measures peripheral tissue oxygen saturation (StO_2) utilizing oxygenation variables, such as deoxyhaemoglobin (HHb), oxyhaemoglobin (HbO_2) and total haemoglobin (HbT). How best to use this technology and the threshold StO_2 that should prompt intervention are not yet clear.
- Direct assessment of the microcirculation (e.g. sublingual) using orthogonal polarization spectral (OPS) or sidestream dark-field (SDF) videomicroscopy.
- Non-invasive tonometry may be used to reconstruct central aortic pressures from radial artery pressure waveforms.

CONTROVERSIES

- Whether the PAC data are in fact of value but interpretation of them is lacking or whether the detailed haemodynamic data cannot ultimately be translated to the benefit of the patient
- Whether any monitoring technology taken in isolation, rather than in an evidence-based protocol, influences patient outcome
- The best haemodynamic monitoring devices to use and what physiological variables are important to measure

2.4 Shock overview

Gerard McCarthy

ESSENTIALS

1 **Broad categories of shock include disorders of intravascular volume, vascular resistance, cardiac filling and the myocardial pump. Overlapping aetiologies are commonly encountered.**

2 **Hypotension is only one characteristic of shock, which should be considered a late and concerning finding.**

3 **Hypovolaemia and hence the need for volume resuscitation is a concern in every patient with shock.**

4 **Interventions in any form of shock are initially directed at the physiological deficit and act as a test of the underlying clinical hypothesis. Continuous reassessment is required.**

5 **Common errors in management are late diagnosis, inadequate control of the primary problem, inadequate fluid loading, delayed ventilatory assistance and excessive reliance on inappropriate adjuncts. There is not sufficient evidence that any one of the investigated vasopressors is clearly superior to others.**

6 **Mortality following cardiogenic shock is improved by revascularization strategies and cardiothoracic surgical intervention. Thrombolysis alone is unproven, as is intra-aortic balloon counterpulsation.**

7 **Currently no adjunctive therapies are of benefit in septic shock over adequate fluid resuscitation, vasopressors and inotropes, timely and appropriate antibiotics and/or source control.**

Introduction

Shock is a clinical syndrome where tissue perfusion, and hence oxygenation, is inadequate to maintain normal metabolic function of the cells and organs. Although the effects of inadequate perfusion are initially reversible, prolonged oxygen deprivation leads to generalized cellular hypoxia with disruption of critical biochemical processes, eventually resulting in cell membrane ion pump dysfunction, inadequate regulation of intracellular pH, intracellular oedema and cell death.

Shock is traditionally classified and managed according to the presumed aetiology, but a common approach in practice is to attend urgently to the cardiorespiratory physiological abnormalities and to assess the response to adjust the working diagnosis, with later attention to the underlying diagnosis.

Recognizing shock may be difficult, particularly at the extremes of age. Pre-existing disease and the use of medications modify the compensatory mechanisms that safeguard perfusion of vital organs. Consider the possibility of inadequate tissue perfusion ('shock') in any emergency presentation with symptoms, signs or laboratory findings of abnormal end-organ function. Early, aggressive and targeted treatment of shock is associated with an improved outcome.

Aetiology and epidemiology

Shock is due to malfunction of components of the cardiovascular system, not uncommonly with more than one contributing mechanism. If the aetiology is apparent, classification based on the mechanism—such as hypovolaemic, cardiogenic, septic, neurogenic or anaphylactic shock—will guide therapy.

When the aetiology is unclear or the shock fails to respond to therapy, the following physiologically based classification assists in decision making (Boxes 2.4.1–2.4.4).

Reduced return to the heart—reduced preload—*hypovolaemia* (see Box 2.4.1)

- Intravascular compartment
- Extravascular loss

Box 2.4.1 Volume loss contributing to shock: '*hypovolaemic shock*'

Intravascular compartment
Blood loss
External bleeding
- Trauma
- Gastrointestinal tract bleeding

Internal (concealed) bleeding
- Haemothorax
- Haemoperitoneum (ruptured abdominal aortic aneurysm, ruptured ectopic pregnancy)
- Retroperitoneum (ruptured abdominal aortic aneurysm, pelvic trauma)

Plasma loss
- Burns
- Sweating/dehydration
- Pancreatitis
- Ascites (peritonitis, liver disease)
- Toxic epidermal necrolysis (TEN), erythroderma, pemphigus

Extravascular loss
Gastrointestinal tract
- Vomiting
- Diarrhoea
- Bowel obstruction

Renal tract
- Adrenal insufficiency (aldosterone deficiency)
- Diabetes mellitus (polyuria)
- Diabetes insipidus (polyuria)
- Diuretics
- Polyuric intrinsic renal disease

Reduced total peripheral resistance—reduced afterload—*distributive* (see Box 2.4.2)

- Arterial vasodilatation
- Altered venous capacitance

Obstruction to filling—*obstructive* (see Box 2.4.3)

- Tension pneumothorax
- Pericardial tamponade
- Large pulmonary embolism/pulmonary hypertension
- Atrial myxoma

Pump dysfunction—*cardiogenic* (see Box 2.4.4)

- Reduced contractility—systolic dysfunction
- Impaired relaxation—diastolic dysfunction/right ventricular (RV) infarction
- Abnormal cardiac rate or rhythm
- Forward flow failure—valvular dysfunction

Box 2.4.2 Shock resulting from altered venous capacitance and/or reduced vascular tone: '*distributive shock*'

- Septic shock
- Anaphylactic shock
- Neurogenic shock
- Vasoactive drugs (vasodilators, sedatives or toxins)
- Adrenal insufficiency (cortisol deficiency)
- Thyrotoxicosis/thyroid storm
- Liver failure
- Systemic inflammatory response features (e.g. pancreatitis, trauma, burns)
- Prolonged shock from any cause—'decompensated shock'

Box 2.4.3 Inadequate filling due to extrinsic obstruction: '*obstructive shock*'

- Tension pneumothorax
- Pericardial tamponade/other pericardial disease
- Pulmonary hypertension (large pulmonary embolus, chronic pulmonary hypertension)
- Atrial myxoma and left atrial mural thrombus

Box 2.4.4 Myocardial dysfunction resulting in shock: '*cardiogenic shock*'

- Reduced contractility (systolic dysfunction)
  - Ischaemia (acute myocardial infarction)
  - Myocarditis (infectious, hypersensitivity)
  - Myocardial contusion
  - Cardiomyopathy
  - Toxins/drugs (calcium channel blockers, doxorubicin)
- Inadequate filling (due to intrinsic problem)
  - Diastolic dysfunction
  - Right ventricular infarction
- Arrhythmia
  - Ventricular tachycardia
  - Atrial fibrillation (when cardiac output is dependent on atrial priming)
  - Bradycardia (heart block, drugs)
- Failure of forward flow
  - Ruptured ventricular septum or free wall
  - Chordae tendineae rupture or papillary muscle dysfunction (post-myocardial infarction)
  - Critical mitral or aortic stenosis
  - Mitral or aortic regurgitation
  - Prosthetic valve thrombus/dysfunction

No classification is exhaustive, and contributory causes may feature in more than one category.

Pathophysiology

Most organs and tissues are able to autoregulate or adjust their flow according to metabolic demand as long as flow is adequate. This flow is dependent on a gradient between an area of higher pressure (mean arterial pressure [MAP]) and the lower-pressure side of the venous system (represented by a central venous pressure [CVP]).

The MAP may fall if the cardiac output (CO) is reduced or if the total peripheral resistance (TPR) in the arterial tree falls; that is,

$$MAP = CO \times TPR$$

CO is determined by the stroke volume (SV) and heart rate (HR). The heart is a relatively simple pump and hence preload (the volume of blood in the left ventricle at the end of filling or the amount of stretch of the left ventricle) determines SV until disease states intervene, as represented by

$$CO = SV \times HR$$

Relaxation of the arterial and venous tone by vasoactive mediators or lack of vasotonic mediators results in reduced resistance and increased capacitance as well as lower pressures in both the arterial and venous systems. Any injury to the endothelium will result in loss of volume and the failure of vascular autoregulation. Additionally, if there is a defective valve causing regurgitation of blood and repumping or a fixed narrow orifice, there is a failure in forward flow.

Compensatory mechanisms

Compensatory mechanisms are provoked by the combination of lowered pressure and inadequate perfusion of tissues and contribute to the symptoms and signs of shock. Neurohumoral stimulation produces increased circulating catecholamines, angiotensin, aldosterone and vasopressin, manifesting clinically with anxiety, thirst, restlessness, tachycardia, diversion of blood from the skin bed and a reduction in urinary output and urinary sodium. Blood flow to the brain and heart is maintained at the expense of renal, splanchnic, skin and muscle blood flow.[1] Significant fluid shifts occur from the interstitium to the intravascular compartment, which may falsely maintain haematocrit.

Decompensated shock

The ultimate consequence of shock, if tissue perfusion is not returned by compensatory measures or resuscitation, is inadequate regeneration of adenosine triphosphate (ATP), causing failure of membrane ion pumps to maintain the function and structural integrity of the cell.

This cellular dysfunction manifests in the myocardium as systolic contractile dysfunction (also due in part to reduction in sensitivity to catecholamines and circulating myocardial depressant factors) and impaired ventricular relaxation (lusitropy). This myocardial failure, along with failure of vascular beds despite the increased circulating catecholamines, contributes to what is described as 'decompensated shock'.

Clinical features

The clinical features in the initial diagnosis of shock are due to inadequate perfusion of tissues and resulting multiorgan dysfunction of the body's compensatory mechanisms.[2] Clinicians should not wait for physical observations to trigger a preconceived blood pressure (BP) limit before considering shock but should actively look for signs of inadequate perfusion in any patient presenting with abnormal organ function:

- Mental state reflecting reduced cerebral perfusion, which may range from anxiety or confusion to coma.
- Patients may describe thirst, coldness or impending doom and have presyncopal symptoms including nausea, yawning and preferring to lie down.
- Retrospectively, the patient may have been a challenge to assess, with vital signs hard to elicit or variable and venepuncture or intravenous access difficult.
- Peripheral circulation reveals venoconstriction, with decreased peripheral temperature, pallor and mottling. Capillary return may be prolonged beyond 4 seconds, although peripheral mottling and central cyanosis are late signs. However, with vascular tone failure—such as spinal, anaphylactic, neurogenic shock and sepsis—the skin may initially be warm and dry and capillary refill indeterminate as a consequence of vasodilatation.
- Hypotension is a cardinal clinical sign, defined as a systolic blood pressure (SBP) less than 90 mm Hg or a reduction of more than 30 mm Hg in a previously hypertensive patient. Shock can be present despite an elevated BP, and a low SBP may not be associated with other signs of shock or be physiological in young thin females.
- A low SBP should be considered a highly significant if not late finding in shock. MAP is increasingly considered more relevant and accurate as a measured parameter.[3] Tachycardia is frequently present but may be masked by drugs or advanced age.
- The trend with serial observations is more significant than absolute values. Bradycardia can occur in younger patients or following an inferior myocardial infarction (MI).
- Tachypnoea is regarded as a sensitive but non-specific predictor of deterioration and is part of the shock syndrome.[4]
- Core temperature may be low, normal or elevated and will be affected by age,

environment, volume status, coexisting disease, drug therapy and pre-hospital interventions.
- Oliguria.

Initial management of shock

A structured framework, such as that advocated by early management of severe trauma (EMST/advanced trauma life support [ATLS]) or advanced cardiac life support (ACLS), promotes both a systematic survey and effective therapy to occur simultaneously. Treatments based on an initial working diagnosis are modified by the observed responses to therapy and/or the results of investigations. Frequent reassessment of status and adequacy of response is vital. Once shock has been recognized as present, a high chance of death is implied; thus urgent escalation to management by a multidisciplinary team in a monitored resuscitation area is indicated, with a designated team leader and communication being vital.[5,6]

Primary survey

- Assess and support airway and ventilation. Give supplemental high-flow oxygen to ensure maximal arterial oxygen saturation. Consider tracheal intubation and mechanical ventilation in the significantly shocked patient for reasons over and above the standard indications of airway protection and intractable hypoxaemia in order to divert needed CO to other hypoperfused organs, reduce oxygen consumption from respiratory musculature, maximize arterial oxygenation, manage respiratory acidosis, facilitate invasive monitoring procedures and guard against sudden catastrophic respiratory decompensation. The role of non-invasive ventilation is unproven in this setting. Positive-pressure ventilation and anaesthesia will have a significant effect in the setting of inadequate preload, so prior fluid resuscitation is vital (see Chapter 2.1, Fig. 2.1.3).
- Circulation with haemorrhage control. Within the skill level of the operator, obtain and secure intravenous access in more than one site with short, large-bore peripheral cannulae. Central venous access is rarely required in an emergency and may increase delay and morbidity. Consider a supine/head-up position and elevation of the legs if tolerated.[7]
- Draw blood for investigations, including immediate bedside glucose level and venous or arterial blood gases.
- Infuse fluid as the initial correction of shock with hypotension. Hypovolaemia and hence the need for volume resuscitation should be assumed in every patient with shock, until proven otherwise. Close observation of the response to fluid boluses will guide further boluses.
- The usual initial fluid is isotonic normal saline or Hartmann (lactated Ringer) solution.
- Use immediately available blood products (O-negative or group-specific) warmed by a cartridge-warming device for haemorrhagic shock or where haemoglobin may fall to a point where oxygen carriage is compromised (7 to 9 g/dL except in patients with acute haemorrhage or significant coronary artery disease).
- Add an effective vasopressor/inotrope, such as epinephrine (adrenaline), by infusion if, despite ongoing rapid fluid volume resuscitation, hypotension and inadequate perfusion persist (see 'Goal-directed resuscitation', further on). However, this may achieve an adequate BP only at the expense of correct fluid volume replenishment.

Secondary survey

- Review vital signs and any available history followed by a directed physical examination. Cardiac rhythm and pulse oximetry (SaO_2) are monitored continuously. All observations, including temperature, are recorded regularly.
- At this point, obtain a chest x-ray, electrocardiogram (ECG) and other bedside emergency testing, such as ultrasound, that may point to the aetiology (e.g. a ruptured aortic aneurysm or ectopic pregnancy, cardiac tamponade or RV failure).
- Place an indwelling urinary catheter in any shocked patient.
- Anticipate complications and interventions and organize definitive care and disposal. Liaise with surgeons, radiologists and other specialists early. The complications of hypothermia, coagulopathy, hypoglycaemia, hypokalaemia and respiratory failure should be actively sought, prepared for and prevented. The need to move the patient to imaging or theatre should be anticipated and communicated to team members to allow for early preparation of the patient and monitoring setup.

Guidance for interventions and treatments

A key goal in the treatment of shock during and after the initial resuscitation is correction of the underlying problem. Methods used to guide resuscitation are discussed in the following text.

Emergency department observations

The presence and progress of shock is detected in the emergency department (ED) by careful recording of vital signs and *frequent* and *repeated* clinical assessment.

- 'Vital signs'—pulse, respirations, BP and temperature—are measured regularly and observed for absolute values, trend and adequacy of response to therapy. Accuracy and frequency of temperature measurement is facilitated by an indwelling catheter with temperature probe.
- ECG monitoring, if calibrated, provides an assessment of HR and ST-segment changes suggesting inadequate myocardial perfusion.
- Continuous pulse oximetry provides assessment of hypoxaemia, as the management of shock necessitates the adequate delivery of oxygen to tissues.
- Non-invasive oscillometric blood pressure (NIBP) measurement is convenient and set to frequent automated measurement. Accuracy is affected by cuff size, age, movement, some disease states and extremes of hypotension or hypertension. MAP is more accurately and reliably measured than systolic.[3,8]
- Urine output is the most apparent bedside monitor of the adequacy of end-organ perfusion. Levels below 0.5 mL/kg/h suggest underperfusion of the renal bed. Diuretics can both confuse and exacerbate the shock state.

Emergency department investigations

- Bedside tests should include blood sugar to exclude hypoglycaemia, which will compromise resuscitation efforts.
- Arterial or venous blood gas measurements are available rapidly and contain information to assess the cause (e.g. haemoglobin level), guide the interventions required (hyperkalaemia correction, assisted ventilation) and monitor the adequacy of tissue perfusion by tracking lactate or changes in base deficit (BD) with resuscitation.
- Lactate measurements are an objective marker of the presence and severity of shock. Normal levels are below 2 mmol/L; levels greater than 4 mmol/L are associated with increased mortality. Lactate and BD are used to assess the adequacy of resuscitation and have been used to predict mortality, transfusion requirements, the need for intensive care unit (ICU) placement, and the length of stay.[9,10]
- Full blood count, coagulation profile, electrolytes, liver function tests and troponin, with a chest x-ray and ECG, are usually enough to commence a working diagnosis of the aetiology of the shock.
- Bedside-focused ultrasound (FAST) examination or a formal trans-thoracic

echocardiogram (TTE), if available, is now incorporated in many resuscitation algorithms. FAST is used to assess for free abdominal fluid and exclude pericardial tamponade. More advanced ultrasound allows assessment for intrathoracic free fluid, aortic or vena caval diameter and assessment of cardiac function including ventricular cavity dimensions (adequate filling), ventricular ejection fraction, regional wall motion abnormalities indicating ischaemia, and valvular dysfunction.

Invasive monitoring

Invasive monitoring in the ED may include the following:

- Intra-arterial BP monitoring, which gives more reliable arterial pressures and detects hypotension earlier than intermittent non-invasive means.[3]
- Systolic pressure variation or 'swing' of the arterial waveform baseline during respiration (usually with mechanical ventilation) is at least as sensitive as CVP or pulmonary artery (PA) wedge pressure as a marker of the need for more fluid.[11]
- SV variation is the measured difference between the maximal and minimal SBP values during one (mechanical) breath, and 'delta down' is the component of this variation from apnoea to minimal SBP. A variation of greater than 5 mm Hg suggests fluid responsiveness.[12]
- Response and trends in CVP are followed after volume loading.
- End-tidal CO_2 in a ventilated patient may be compared to arterial $PaCO_2$. A difference of more than a few mm Hg may suggest a shunt due to inadequate lung perfusion and has been used to track the adequacy of resuscitation.[13]
- Central venous oxygen saturation can be measured using a specific central venous line (CVL) or aspirating blood. Lower levels than 65% to 75% suggest imbalance between oxygen delivery and consumption.
- Pulse contour analysis devices (e.g. Flowtrac, Edwards Lifesciences) use the arterial pulse wave contour and an algorithm to present CO and other derived parameters, which may be used to track responses in resuscitation.
- Pulmonary artery catheterization, peripheral invasive cardiac output monitors (PiCCOs), gastric tonometry, sublingual capnometry, transoesophageal echocardiography (TOE), Doppler CO studies and other more sophisticated investigations are best performed in an intensive care environment (see Chapter 2.3, "Essentials").

Goal-directed resuscitation

The concept of achieving specific levels of CO by manipulating haemoglobin concentration, inotropes, vasopressors, vasodilators and fluid volumes has been promoted. Early hypotheses suffered from biases associated with observational studies, and subsequent literature suggested that 'supranormal' COs or oxygen delivery was *not* beneficial in undefined groups or trauma.[14,15] A seminal single-centre study by Rivers in 2001 proposed that, in severe sepsis in the ED, a resuscitation algorithm guided by CVP, MAP and central venous saturation 'goals' led to an improvement in survival. However, subsequent large multicentre randomized controlled trials (RCTs) have produced contrary results.[16–18] The commonest intervention change was an increase in fluid resuscitation volume.[19]

Having clear clinical goals communicated during resuscitation does allow the team to focus together. These targets can be physiological and/or time or intervention based. Therapeutic goals may be convenient but should be customized for individual patients.

Interventions in shock

Fluid therapy

Choice of fluid

A sensible maxim is 'Replace that which is lost, at the rate at which it is lost'.

- There is no evidence that any one fluid type is superior in undifferentiated shock; thus the commonest choice in the emergency situation remains 'isotonic' 0.9% normal saline. There is retrospective evidence that hypotonic fluids and glucose-containing fluid are detrimental in the critically ill.[20] Hartmann (or similar strong ion 'balanced') solution reduces the risk of hyperchloraemic acidosis from normal saline use, but this appears to be clinically irrelevant.[21]
- The SAFE (Saline vs. Albumin Fluid Evaluation Study) study investigators demonstrated that there was no difference in outcome, or any clinically significant measure, between those resuscitated with saline versus human albumin solution.[22,23] Hydroxyethyl starch has no clinical advantage over saline and has more complications.[24] The theoretical advantages of hypertonic saline have not been demonstrated.[24]
- When blood is lost or diluted by large volumes of fluid, both oxygen carriage and coagulation activity must be maintained. Retrospective and prospective studies on transfusion triggers suggest that Hb levels of 70 to 90 g/L are appropriate in most patients and levels of 100 g/L are tolerated by patients with ischaemic heart disease.[25,26] Aiming for a higher target Hb (>100 g/L or HCt > 0.4) may be sensible in those who are shocked due to active bleeding.
- Dilutional coagulopathy during resuscitation is sought for or proactively avoided by administering fresh frozen plasma (FFP). Clinical coagulopathy may be present before laboratory parameters alter.

Fluid administration

Aliquots of between 10 and 40 mL/kg (averaging 20 mL/kg) at free flow or 'stat' over minutes are recommended. If the heart is suspected of having abnormal compliance or being too 'full', a smaller bolus is given equally rapidly and the clinical response closely observed.

Cannulae sized 16 and 20 gauge may achieve flow rates of 1 L over 5 and 10 minutes, respectively.[27] In the emergency situation, hand-pump infusion lines or gravity or pressure bag–driven infusion will deliver volumes effectively. Volumetric infusion pumps or lines should not be used in resuscitation, as the maximum rate of infusion is inadequate and alarm features may delay infusion. Pressure infusion pumps can achieve high rates but at a significant risk of complications.[28]

Route of fluid therapy

Large volumes can be delivered by any route, but central lines, smaller peripheral inserted catheters and intraosseous needles may require a driving pressure. The last may fail unless it is carefully supervised. The antecubital, saphenous and femoral veins are reliably accessed with few complications. Ultrasound-guided access may be considered in difficult situations.

Titration targets

Defining a target for 'how much is enough' is problematic, as each shock scenario has a different aetiology, clinical features and monitoring requirements. Traditionally the return of physiological variables towards normal and set perfusion targets are used (Table 2.4.1). Decisions are made using multiple inputs, preferably using the technique of fluid challenge and review of response to each challenge.

Complications of fluid therapy

- Hypothermia is likely after large volumes of fluid have been infused and should be monitored for. Each ED should be proactive in including a warmed environment, warmed fluid and blanket stores and active warming devices. The use of a commercial warming cartridge may be considered for all resuscitations anticipated above a certain volume and/or when a massive transfusion protocol is instituted.
- Coagulopathy may be due to dilution, sepsis, hypothermia or acidosis. FFP will not

Table 2.4.1 Targeted physiological, perfusion and invasive parameters in the management of shock

Traditional physiological targets	*Perfusion targets*	*Invasive measurement targets*
Return of systolic BP to >90 mm Hg or to normal for that person	Urine output of >0.5 mL/kg/h	Stroke volume variation <5 mm Hg
MAP >65 mm Hg	Lactate <2 mmol/L	Cardiac index of >2.5 L/min/m^2
Pulse rate <100/min	Resolving base deficit	Pulmonary artery occlusion pressure >15 mm Hg
CVP >10 mm Hg	Central venous oximetry levels of 70%–80%	Echocardiogram assessment of left ventricular end-diastolic volume and cardiac output
Sustained rise of CVP >7 mm Hg in response to fluid	Capillary refill times <4 s	Mixed venous oximetry of 70%–75%
Reduction in pressor/inotrope requirement	Clinical impression of improved skin perfusion and peripheral pulses	

BP, blood pressure; *CVP*, central venous pressure; *MAP*, mean arterial Pressure.

resolve the latter causes. Hypocalcaemia is rarely an issue.
- Tissue oedema is common and usually clinically irrelevant, but it may exacerbate limb and abdominal compartment syndromes.
- Pulmonary oedema is just as likely to be due to the inflammatory process accompanying significant shock as to excessive preload and is managed either by positive-pressure ventilation and/or diuresis if appropriate. Respiratory failure or the requirement for ventilation does not influence mortality in most ICU outcome studies. Conversely, renal failure and infarction of the myocardium, brain and gut are all major risk factors for death.
- Failure to recognize that ongoing fluid requirements are due to an unresolved primary process may cause later deterioration.
- Dilutional or 'hyperchloraemic' acidosis is common but clinically insignificant.
- Anaphylaxis to synthetic colloids or blood products does occur and will complicate the management of shock.

Inotropes and vasopressors

Choice of inotrope

- Drugs described as vasopressors and inotropes overlap considerably in activity; thus traditional descriptions using receptor-based categories may confuse. Familiarity, institutional preference and awareness of both the clinical and side effects, desired and undesired, should influence individual choice (Table 2.4.2).
- A 'vasopressor' affects the venous or arterial vascular tone and should raise TPR and hence mean arterial driving pressures as well as reducing venous capacitance and increasing preload/filling. Other vasoregulatory drugs affect the responsiveness of the vasculature to endogenous and infused vasopressors, including vasopressin and steroids.
- An 'inotrope' increases the velocity and force of myocardial muscle fibres and should result in increased contractility. This increased contractility, if combined with adequate preload/filling, will increase the SV and hence CO and raise the BP. This will increase oxygen consumption, which may not be desirable, as in myocardial ischaemia.
- Expert opinion–based recommendations guide the choice of vasopressor/inotrope in septic shock,[29] neurogenic shock and anaphylactic shock (see further on). There is not sufficient evidence that any one of the investigated vasopressors is clearly superior over others.[30,31]
- Dopamine appears inferior to other catecholamines in shock, as it appears to increase the risk for arrhythmia.[32] It does not prevent or ameliorate the development of renal failure.[33]
- Dobutamine was frequently recommended, but its deleterious effect on BP means that it is to be avoided in hypotension or used in combination with norepinephrine or as guided by invasive monitoring.
- Dopexamine, levosimendan and the older phosphodiesterase inhibitors are rarely used in regular ED practice. They have not been convincingly shown to improve outcome in either undifferentiated or cardiogenic shock.[34] They can be used in specific and carefully monitored situations, such as shock with RV failure or shock with excessive β-blockade.

Administration

- This is for illustration only. Care should be taken to follow local recommendations and practice in prescribing and preparing these infusions. Norepinephrine, epinephrine can be made up as 6 mg in 100 mL (or 3 mg in 50 mL) given by infusion pump into a central vein. The advantage of this particular dose dilution is that an infusion rate of 1 mL/h equates to 1 μg/min.
- Dobutamine and dopamine are presented as 250- and 200-mg ampoules and may be made up as (weight (kg) × 6) mg in 100 mL or (weight (kg) × 3) mg in 50 mL to give a dose dilution where an infusion rate of 1 mL/h equates to 1 μg/kg/min.

Route

- Vasopressors/inotropes may be administered into a large peripheral vein with fast-flowing crystalloid in an emergency. The clinical effect may be variable and thrombophlebitis can occur.
- Dedicated lines and lumina without side injection ports should be used to avoid inadvertent boluses.
- Placement of CVLs or peripherally inserted central catheters (PICCs) is performed under strict asepsis in an appropriate setting and may be required early in the ED for vasopressor/inotrope infusion.

Titration targets

- The use of vasopressors/inotropes without adequate preload is associated with a worse outcome,[35,36] so volume infusion should *always* precede their use unless there is unequivocal evidence that the heart is 'too full'. Even in cardiogenic shock, judicious boluses of fluid with close monitoring may result in improved CO.
- Add an effective inotrope if, despite ongoing rapid fluid volume resuscitation, CO markers such as MAP are low (see 'Goal-directed resuscitation', earlier) and titrate rapidly upwards until an effect is noted. Wean the inotrope/vasopressor as further volume infusion allows or evidence develops that the heart is overly full. Reassess frequently to judge whether further fluid is needed.
- The upper level of the infusion is titrated to effect and limited only by the development of undesired side effects or a lack of therapeutic effect. Thus any infusion is simply 'titrated to desired effect and monitored for undesired effect'.

Table 2.4.2 Clinical effects of inotropes and vasopressors

	Clinically observed		*Measured*		*Calculated*			
Drug infused	*Blood pressure (BP)*	*Heart rate (HR)*	*Cardiac contractility (stroke volume)*	*Cardiac output (CO)*	*Arterial vascular tone*	*Venous capacitance*	*Diastolic relaxation (lusitropy)*	*'Classical' receptor activity description*
Adrenaline	++	++	++	++	+	+	+	$\beta_1\beta_2\ \alpha_1\ (\alpha_2)$
Noradrenaline	++	o	+	+	+	++	–	$\beta_1,\ \alpha_1\ (\beta_2,\ \alpha_2)$
Dopamine	+	++	+	+	+	+	–	$\beta_1\alpha_1$ dopA1
Dobutamine	–	+	++	++	–	–	o	$\beta_1\beta_2$ (dopA1)
Metaraminol	++	o	o	o	+	++	o	α_1
Isoprenaline	–	++	+	+	–	–	o	$\beta_1\beta_2$
Levosimendan	+/–	+	++	++	o	o	+	Sensitizes troponin to Ca^{2+}
Vasopressin	+	o	o	o	++	+	o	$V_1\ V_2$

Complications

- Side effects include excessive tachycardia, hypertension, tremor, anxiety and raised intracranial pressure (if monitored). Conversely, watch for disconnection or failure to infuse, when parameters unexpectedly fall.
- Epinephrine causes metabolic effects including hyperglycaemia, hypokalaemia and lactic acidosis (usually clinically irrelevant).
- Increased myocardial oxygen consumption can worsen myocardial ischaemia and precipitate cardiac arrhythmias.
- Peripheral digit and skin infarction described in the past is likely due to endothelial injury from prolonged shock or the underlying primary cause (e.g. meningococcus), with no evidence that it was due to a vasoconstrictor effect.
- Splanchnic or MI, also described, is more likely to be due to inadequate resuscitation and hypotension rather than vasoconstriction, as these vessels are poorly reactive.
- 'Too large, too concentrated or too rapid' a bolus will cause severe hypertension and risks sequelae such as intracranial haemorrhage and myocardial damage.

Other interventions

- Corticosteroids in shock should be reserved for adrenal insufficiency or if the patient is already receiving corticosteroids.[37,38] There is no evidence to prove their efficacy, although, given their safety profile and probable role in reducing the incidence of biphasic reaction, they are still used in anaphylactic shock (see Chapter 2.8).
- Corticosteroids such as hydrocortisone 200 mg/day may improve haemodynamic parameters in unresponsive septic shock, but two controlled multicentre trials found that corticosteroids have no effect on mortality.[39,40] Steroids are still recommended in patients with bacterial meningitis in high-income countries to reduce hearing loss and neurological sequelae, but they do not reduce overall mortality.[41] Some spinal injury centres recommend high-dose methylprednisolone started within 8 hours of injury and given for 24 to 48 hours in spinal cord injury, but data are unconvincing.[42]
- Military anti-shock trousers (MASTs) or pneumatic anti-shock garments (PASGs) increase morbidity and mortality and are no longer used.[43]

Effects of shock on other interventions

- Hypoperfusion of tissues will affect the delivery of drugs, particularly orally and subcutaneously administered drugs, and also their pharmacokinetics, with a reduced clearance. Unpredictable delivery and efficacy may require dose changes or the use of alternate routes. Carefully titrated intravenous doses given centrally are advisable.
- Sedative, analgesic and anaesthetic drugs – particularly thiopentone, midazolam, propofol and even ketamine (when the sympathetic ganglia are exhausted of catecholamine)—have adverse effects on vascular tone and may worsen shock. These drugs also have a delayed circulation time and can appear not to be working, prompting inappropriate repeat dosing.
- Catecholamines are less effective in severe acidosis states, hence their theoretical but unproven use for sodium bicarbonate in severe resistant metabolic acidosis.
- Endotracheal intubation and positive-pressure ventilation reduce venous return, which may further reduce CO and SBP. Minimal initial tidal volume and positive end-expiratory pressure (PEEP) settings ameliorate this effect. Physiological dead space may be increased by positive-pressure ventilation, reducing lung perfusion; thus the arterial $PaCO_2$ may rise. 'Normalization' of $PaCO_2$ may then lead to an apparent worsening of compensated metabolic acidosis.
- Inotropes are arrhythmogenic, and this complication is increased in the setting of hypokalaemia, acidosis and poorly perfused myocardium.
- The stress response and some inotropes cause or exacerbate hyperglycaemia.
- Infused fluids will eventually redistribute to all tissues and produce widespread oedema. An example is the burns victim who may have minimal airway burns, but—after many litres of crystalloid—may have a compromised oedematous airway.

Management of specific shock syndromes

The following shock syndromes are discussed briefly here and in other chapters:

- Hypovolaemia (absolute)
- Hypovolaemia (relative)
- Neurogenic shock
- Anaphylactic shock (see Chapter 2.8)
- Hypoadrenal shock
- Cardiogenic shock
- Septic shock (see Chapter 2.5).

Absolute hypovolaemia

Clinical features

The history and examination may point to fluid loss from vessels, gut, kidneys or evaporation. Bleeding must be excluded in all cases of hypovolaemia (see Box 2.4.1). In addition to those described previously, clinical features will include signs of reduced preload, with flat neck veins as a consequence of a low CVP.

Relevant investigations

If hypovolaemia is due to bleeding, haemostasis by a surgeon or specialist is the most effective direct intervention and may parallel resuscitation and precede investigations. If initial resuscitation allows, investigations such as formal ultrasound or computed tomography (CT) with contrast angiography may identify the site of bleeding. Radiographic intervention, such as angiography with embolization, may be lifesaving in severe pelvic trauma.

Therapy

- Initial resuscitation as described previously while ensuring that all efforts are made to avoid hypothermia.
- Passive leg elevation is more effective in hypovolaemic shock than the Trendelenburg (head lower than the pelvis) body position in increasing left ventricular end-diastolic volume, SV and CO; but these effects are transient.[7]
- External haemorrhage is controlled with firm, direct manual pressure. Tourniquets are associated with morbidity but may be useful in the short term.[44]
- Surgical consultation is required urgently. Efforts to return the SBP to 'normal' in bleeding trauma patients may be counterproductive and occasionally harmful, particularly in penetrating truncal trauma. Surgical haemostasis must take priority and excessive resuscitation should be avoided by adopting a 'minimal-volume' approach. Thus patients with uncontrolled haemorrhage following penetrating truncal trauma who are in close proximity to facilities capable of definitive care should undergo minimal-volume or 'hypotense' fluid resuscitation pending prompt surgical intervention.[45] *Minimal volume* is interpreted variously as fluid sufficient to keep veins open (TKVO) or small (250 mL) boluses titrated to a palpable radial pulse or conscious level, with the aim to 'keep the brain and heart perfused'. Any minimal-volume approach is contraindicated when traumatic brain injury is associated with hypotension, as cerebral perfusion pressure is dependent on maintaining the MAP.
- Infuse packed red cells in major blood loss where oxygen delivery is known to be impaired or Hb is less than 70 g/L. Recognition or anticipation of coagulopathy will need FFP and platelets, as in a major transfusion protocol. Patients with lesser amounts of blood loss or controlled bleeding or those in non-haemorrhagic hypovolaemic shock can be managed with warmed crystalloid.[23]
- Hypertonic saline 3% or 7% was considered to improve outcome in a subgroup of patients with shock and traumatic brain injury, but this remains unproven. Despite this, hypertonic saline has been recommended as the initial fluid of choice in haemorrhaging battlefield casualties.[46]
- There are no current definitive recommendations concerning the use of blood substitutes, such as modified haemoglobin or non-blood perfluorocarbons.
- Other causes of impaired preload or contractility—such as tension pneumothorax, cardiac tamponade and myocardial contusion—must be considered in the hypotensive trauma patient. Increasing preload is still beneficial in these settings, and all trauma patients should be assumed to be hypovolaemic until proven otherwise. Urgent bedside ultrasound is essential.

Relative hypovolaemia

This may be due to anaphylaxis, addisonian crisis, neurogenic shock, septic shock or a drug or toxin effect.

Anaphylaxis

The mainstay of treatment in shock is the physiological antagonist epinephrine (adrenaline) plus oxygen and fluid, with the patient supine and the legs raised (see Chapter 2.8, Box 2.8.4).

Adrenal shock

Hypotension due to hypoadrenalism is uncommon but should be suspected in the acutely unwell patient with past or current steroid use or when hypotension occurs with relative polyuria or a relatively high urinary sodium (i.e. >20 mmol/L).[37,38]

Neurogenic shock

Neurogenic shock is manifested by the triad of hypotension, bradycardia and hypothermia in the setting of an acute spinal cord injury related to the loss of sympathetic nerve tone. One in four patients with a complete cervical cord injury may require haemodynamic support for hypotension.[47] Other causes of hypovolaemia or shock in the trauma patient should still be actively sought, such as concealed bleeding, tension pneumothorax and cardiac tamponade.

Septic shock

Septic shock is sepsis accompanied by hypotension or hypoperfusion and can be underappreciated, as the patient may have few signs of inadequate perfusion. Persistent hypotension and/or signs of organ hypoperfusion, despite ongoing rapid fluid resuscitation, are indications for early vasopressor/inotrope support. Vasopressin 0.04 U/min has no greater effect on survival.[48] A post hoc analysis of the SAFE study suggests that albumin may have a survival advantage.[23] Hydrocortisone may improve unresponsive shock, as can high-volume haemofiltration, but trials have found no overall effect on mortality (see Chapter 2.5).[36,39,40]

Drug effects

Multiple drugs or toxins cause hypotension by impairing vascular or cardiac muscle contractility or permeability. Intervention with increased fluid or inotropes/pressors will manage hypotension. If the drug affects an inotrope/vasopressor receptor, either physiological antagonism or alternative receptor stimulation can overcome this effect. When the toxin is a metabolic or mitochondrial poison, the general principles of removal and support are used.

Cardiac causes of shock: cardiogenic shock

Cardiogenic shock is the inability of the heart to deliver sufficient blood to the tissues to meet resting metabolic demands; it is clinically defined as a SBP of less than 90 mm Hg or MAP greater than 30 mm Hg below baseline for at least 30 minutes.

An alternative definition is a significant arteriovenous oxygen difference and a cardiac index of less than 2.2 L/min/m^2 where pulmonary capillary wedge pressure is greater than15 mm Hg. Failure to respond to correction of hypoxaemia, hypovolaemia, arrhythmias and acidosis is a requirement for the diagnosis.[49] There is clinical evidence of poor tissue perfusion in the form of oliguria, cyanosis and altered mentation.

Aetiology

The most common cause of cardiogenic shock is MI or ischaemia. Cardiogenic shock complicates 5% to 8% of patients with acute MI and has a mortality as high as 56% to 74%. It is the commonest cause of in-hospital death after infarction.[49,50] Only 10% of these patients develop cardiogenic shock in the ED, but this subgroup has a higher mortality.[50]

Other cardiac causes of shock include valvular rupture or degeneration, critical stenosis, septal or free wall rupture and atrial myxoma. Cardiac tamponade or a large pulmonary embolus are better considered as obstructive causes of shock, as the myocardial pump is initially unaffected.

Older patients with anterior MI, previous MI, diabetes, angina or congestive heart failure are at greatest risk of cardiogenic shock. There is a higher prevalence in patients with multivessel disease (e.g. diabetes) and when the left main coronary artery is involved.[51] Patients with persistent occlusion of the left anterior descending artery are at the highest risk of developing shock.[52] Only aggressive revascularization within 12 hours of symptoms improves outcome in these patients.

Pathophysiology

Activation of the sympathetic nervous and renin-angiotensin systems contributes to an increase in myocardial oxygen demand, which causes an increase in infarct size and further decreases contractility, CO and coronary perfusion pressure. Systolic dysfunction results in an increase in end-systolic volumes and reductions in ejection fraction, SV and CO. Diastolic dysfunction is also present. Pulmonary oedema exacerbates hypoxia and systemic tissue hypoperfusion, and selective vascular redistribution leads to organ failure and metabolic acidosis.

Clinical features

Clinical signs in cardiogenic shock in addition to those described previously include the following:

- Signs of excessive catecholamine outflow, such as tachycardia, pallor, poor capillary refill and evidence of low CO with a decreased urine output and raised lactate.
- BP that may initially remain within normal limits as a result of compensatory mechanisms, which also produce tachycardia and narrowed pulse pressure.
- Classic signs of left heart failure with a third heart sound gallop rhythm and basal crackles from pulmonary oedema. A 'gallop' or additional heart sound suggests reduced ventricular compliance (fourth heart sound) and increased ventricular diastolic pressure (third heart sound).
- Raised jugular venous pressure (JVP), hepatic congestion and peripheral oedema of RV failure may occur secondary to left heart failure or alone in RV infarction usually associated with an inferior MI. This can be inferred by ST-segment elevation in a right-sided V4 chest lead (V_4R).
- A loud murmur or thrill in systole may be due to mitral regurgitation or critical aortic stenosis and, rarely, rupture of the ventricular septum.

Investigations in cardiogenic shock

- A 12-lead ECG may define territory and the need for reperfusion therapy. The addition of leads V_4R and $V_{7–9}$ is indicated to rule out RV and posterior MI, respectively.
- Troponin I (or T) levels.
- Chest x-ray to show pulmonary oedema and an enlarged cardiac silhouette.

Bedside TTE should be performed in any patient who remains with undiagnosed shock as an extension of the physical examination. Pericardial effusion or cardiac tamponade are excluded and global systolic function, filling and regional wall motion abnormalities assessed.

- TOE may additionally diagnose loculated cardiac tamponade, a haemodynamically significant pulmonary embolus and obscure valvular lesions.

Emergency department therapy

- Initial care and monitoring should be provided as described earlier, with management of the myocardial infarct according to local reperfusion policy. When cardiogenic shock is recognized, an immediate discussion regarding revascularization should be held with a referral centre, particularly if TTE does not show a mechanical cause of shock.[53]
- Tracheal intubation and ventilation should be considered early for cardiac 'respite' and continuous positive airway pressure (CPAP) or non-invasive ventilation with bi-level positive airway pressure (BIPAP) in selected patients. Invasive BP monitoring is recommended.[53]
- Arrhythmias considered contributory to the presence of cardiogenic shock should be treated according to standard ACLS principles.
- Hypovolaemia must be sought and corrected in all patients with 250-mL aliquots of fluid given as a bolus and the response assessed. Volume loading to maintain higher right atrial filling pressures is important in inferior MI with RV involvement, plus avoidance of drugs that reduce preload including nitrates, diuretics and excess opiates.
- Relevant targets should include evidence of perfusion, such as urine output, lactate and clinical signs of improved skin perfusion and resolution of pulmonary oedema. Coronary autoregulation occurs at a MAP of 60 mm Hg.
- Persistence of the shock state following adequate fluid challenge in the presence of end-organ dysfunction is an indication for urgent revascularization. An intra-aortic balloon pump (IABP), extracorporeal membrane oxygenation (ECMO) and/or inotropic support may be considered as a bridge to this.[51]
- Early revascularization by either percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG) is recommended for patients less than 75 years old with ST-segment elevation or new left bundle branch block (LBBB) who develop cardiogenic shock within 36 hours of acute MI and who are suitable for revascularization that can be performed within 18 hours of shock onset.[53] Early transfer and revascularization confers a survival advantage in patients with MI plus cardiogenic shock.[49–51,53]
- Initial therapy for patients who present to a facility without early primary PCI capability can include thrombolysis followed by urgent transfer.[51,52]
- The use of an IABP does not appear to reduce 12-month all-cause mortality in patients undergoing early revascularization for MI complicated by cardiogenic shock.[54] It increases aortic root diastolic pressure (and hence coronary perfusion) and the duration of apparent systole (and hence MAP, with no increase in oxygen demand. Complications include leg ischaemia, arterial dissection, thromboembolism and thrombocytopenia.[55,56]
- Use of inotropes and vasopressors in cardiogenic shock has not been shown to improve survival but may be needed to maintain perfusion.[53–55] Dobutamine and levosimendan have inotropic and vasodilator effects but are not recommended in hypotension. Norepinephrine (noradrenaline) is now the recommended inotrope/pressor,[53] allowing the later introduction of a vasodilator. Dopamine was previously used, but the tachycardia limits its efficacy by increasing myocardial oxygen demand. There is no evidence for a reduction in mortality with the use of any of the newer inodilators such as dopexamine, milrinone or levosimendan.[34,55]
- ECMO is being increasingly used as support for refractory cardiogenic shock with reasonable outcomes described, but no definitive trial exists.[55,57]
- Vasodilators can be considered when BP has been restored but fails to improve peripheral end-organ perfusion. Glyceryl trinitrate or angiotensin-converting enzyme inhibitors (ACEIs) can be given if titrated carefully, although precipitate hypotension may occur.
- Referral for emergency cardiac transplantation may be considered in the younger patient.
- Overall, those patients with large infarctions, a resting tachycardia and signs of poor tissue perfusion should be identified

early and managed aggressively with cardiology advice. There should be early discussion with a cardiac referral centre and, if the patient is unstable or unsuitable for transfer, an IABP can be considered with a lower threshold for thrombolysis if not contraindicated. Inotropes are a temporizing measure.

Pericardial tamponade

Pericardial (cardiac) tamponade causes a failure of filling of the right atrium as a result of increased pericardial pressure. The right ventricle, and subsequently the LV, has limited SV and CO, so tachycardia and raised peripheral resistance are compensatory mechanisms.

The presence of pericardial tamponade should also be suspected when there is unexplained shock with blunt or penetrating chest trauma, pericarditis, anticoagulant use or iatrogenic misadventure (e.g. CVP insertion).

Volume loading will raise right-sided filling pressures and volumes and tachycardia should be preserved. Vasopressor support will maintain MAP until surgical pericardiotomy (traumatic cause) or pericardiocentesis under echocardiographic guidance is performed.

Conclusion

The aetiology of shock in patients presenting to the ED is varied. Interventions in all forms of shock are simple and initially directed at the physiological deficit and should be seen as a test of the clinical hypothesis. Continuous reappraisal is required. Hypovolaemia should be sought in all cases, although further specific management will depend on the underlying cause or causes.

2.5 Sepsis and septic shock

Alan Watts

ESSENTIALS

1 **Early recognition and intervention in the emergency department reduces mortality in patients with sepsis and septic shock.**

2 **Appropriate broad-spectrum antibiotics should be administered within 1 hour of the recognition of sepsis.**

3 **Systemic blood pressure, serum lactate levels, and urine output should be monitored closely to determine the effectiveness of treatment.**

Introduction

Sepsis is a leading cause of preventable death worldwide. Current estimates are that globally over 30 million people may suffer from sepsis each year and cause or contribute to more than 5 million deaths per year.[1] Septic shock is a subset of sepsis in which circulatory dysfunction is profound enough to substantially increase mortality. Septic shock is associated with disparate mortality rates around the world. In the United States, septic shock mortality was reported at 39.3%, whereas in India it was 65.2%. In Australia and New Zealand, the reported mortality is substantially lower at 22.0% for septic patients admitted to an intensive care unit (ICU). Over the past decade, the incidence of sepsis has continually risen.[2–4] Optimal time-critical care of the septic patient in the ED is crucial, as early intervention in several areas has been shown to reduce mortality.

Aetiology and pathophysiology

The majority of organisms responsible for causing sepsis are bacterial, although changes in their distribution have occurred over time. A study of 14,000 ICU patients in 75 countries demonstrated that 70% of infected patients had positive microbial isolates. Of these, 62% were gram-negative (20% *Pseudomonas* spp. and 16% *Escherichia coli*), 47% were gram-positive (20% *Staphylococcus aureus*) and 19% were fungi.

The most common site of infection was the lungs (64%), followed by the abdomen (20%), bloodstream (15%) and renal/genitourinary tract (14%).[5]

The pathogenic mechanisms in sepsis are complex and involve proinflammatory and anti-inflammatory responses. The specific response in any patient, including duration and extent, depends on characteristics of both the pathogen and the host. Pathogen factors include virulence and microbial load, whereas host factors include age, comorbidities and genetics.

Pattern-recognition receptors are responsible for initiating the immune response following recognition of an invading pathogen. Receptors are found in the cell membrane (Toll-like receptors and C-type lectin receptors) and in the cytoplasm (nucleotide-binding oligomerization domain-like receptors and retinoic acid–inducible gene 1–like receptors).[6]

Inflammatory mediators, such as tumour necrosis factor α (TNF-α) and the interleukins, are produced by the host, resulting in the activation of neutrophils, direct injury to the endothelium with increased vascular permeability and the release of nitric oxide (NO), the latter resulting in vasodilation. Modification of the coagulation cascade causes an increase in procoagulant factors and lower levels of the anticoagulant factors protein C, protein S and antithrombin III. These pro-inflammatory and procoagulant responses lead to reduced vascular resistance, relative hypovolaemia, loss of vasoregulatory control in microvascular beds, reduced myocardial contractility, acute lung injury and renal dysfunction.[6,7]

Definitions

In 2016, a task force of the European Society of Intensive Care Medicine and the Society of Critical Care Medicine released the Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3), which included the following:

Sepsis is life-threatening organ dysfunction caused by a dysregulated host response to infection. Organ dysfunction can be identified as an acute change in the total Sequential (Sepsis-related) Organ Failure Assessment (SOFA) score of ≥2 points consequent to the infection.

Septic shock is a subset of sepsis in which underlying circulatory and cellular/metabolic abnormalities are profound enough to substantially increase mortality.[8]

Use of the Systemic Inflammatory Response Syndrome (SIRS) criteria to define sepsis and the term *severe sepsis* are no longer included in the Sepsis-3 definitions.

Screening

The Sepsis-3 Task Force proposed use of the quick SOFA (qSOFA) tool to identify adult patients with suspected infection who were likely to have poor outcomes. Clinicians should investigate for organ dysfunction when two or more of the following qSOFA criteria are positive: (1) respiratory rate of 22/min or greater, (2) altered mental state Glasgow Coma Scale (GCS < 15) and (3) systolic blood pressure of 100 mm Hg or less.

Patients with septic shock can be identified when sepsis is present with *both* of the following:

- persisting hypotension requiring vasopressors to maintain a mean arterial pressure (MAP) ≥ 65 mm Hg
- a serum lactate level greater than 2 mmol/L despite adequate volume resuscitation[8]

Despite its exclusion by the Sepsis-3 Task Force, the modified SIRS criteria can still be useful in the identification of infection. Additionally, infection in the presence of two or more SIRS criteria may identify patients without organ dysfunction who are no longer defined as having sepsis but are an 'at risk' population. The modified SIRS criteria are (1) temperature above 38.3 or below 36.0°C, (2) heart rate above 90/min, (3) respiratory rate above 20/min, (4) new confusion/drowsiness, (5) white blood cells (WBCs) greater than 12.0 or less than 4.0 × 10^9/L and (6) blood glucose above 7.7 mmol/L (in the absence of diabetes).[9] Screening should also take into account risk factors that make patients more vulnerable for developing sepsis. These include people who

- are elderly or very frail
- have impaired immunity due to cancer/chemotherapy, immune dysfunction (e.g. diabetes, splenectomy, sickle cell disease, HIV/AIDS), are taking immunosuppressant medications (e.g. for rheumatoid arthritis or transplantation) or are on long-term steroids
- have had surgery or other invasive procedures in the last 6 weeks
- have any breach of skin integrity
- use drugs intravenously
- have indwelling lines or catheters[10]

History and examination

The diagnosis of sepsis can be challenging, as signs and symptoms can be vague and non-specific, leading to delays in early management. Temperature, heart rate, respiratory rate, blood pressure, level of consciousness and oxygen saturation should be assessed in all patients with suspected sepsis. Risk factors should be identified and patients asked about a history of productive cough, shortness of breath, dysuria, frequency of urination, offensive-smelling or discoloured urine, vomiting, diarrhoea, abdominal pain, breach of skin integrity (including insect bite, burns, wounds), headache, photophobia, non-blanching rash and joint swelling and pain.[9,10] A comprehensive examination should include the head and neck, oropharynx and ears, skin, chest including lungs and heart, abdomen, pelvis, limbs, and joints.

Patients may initially present with mild tachycardia and fever. As severity progresses, they may then develop signs of shock, including altered mental status, cyanosis, hypotension and oliguria.

Management

The Surviving Sepsis Campaign (SSC) highlights in its International Guidelines for Management of Sepsis and Septic Shock that sepsis and septic shock are medical emergencies; it recommends that treatment and resuscitation begin immediately. The SSC developed the 'sepsis bundle' approach, recognizing that elements of care implemented as a group have an effect on outcomes beyond the individual components taken separately. The SSC Bundle: 2018 Update revises the historical 3- and 6-hour bundles into a single 'Hour-1 Bundle'. The elements of the Hour-1 Bundle are outlined in the following text.

Measure lactate level

Serum lactate can be used as a surrogate marker of tissue perfusion. If the initial lactate is greater than 2 mmol/L, it should be measured again within 2 to 4 hours.[11]

Obtain blood cultures prior to administration of antibiotics

To optimize the correct identification of pathogens responsible for the infection, two sets of blood cultures (aerobic and anaerobic) should be obtained before antibiotics are administered. Nevertheless, antibiotic administration should not be delayed in order to obtain blood cultures.[11]

Administer broad-spectrum antibiotics

One or more intravenous (IV) broad-spectrum antibiotics to cover all likely pathogens should be started immediately in patients with sepsis and septic shock. Once the pathogen has been identified, antimicrobial therapy should be narrowed to consider established sensitivities or discontinued if appropriate.[11]

Begin rapid administration of 30 mL/kg crystalloid for hypotension or lactate at or above 4 mmol/L

Fluid resuscitation with IV crystalloid is necessary to stabilize tissue hypoperfusion caused by sepsis or septic shock. This should be started as soon as a patient is recognized as having sepsis and/or hypotension and elevated lactate. Initial fluid resuscitation should be completed within 3 hours.[11]

Apply vasopressors if patient is hypotensive during or after fluid resuscitation to maintain mean arterial pressure at or above 65 mm Hg

In order to achieve a MAP of at least 65 mm Hg, vasopressors should be started within the first hour if blood pressure is not restored after initial fluid resuscitation. Norepinephrine is recommended as the first-choice vasopressor. Vasopressin or epinephrine can be added to norepinephrine to aid in reaching the target MAP.[11,12]

Societies and governments have drafted their own guidelines. The UK Sepsis Trust and the Royal College of Emergency Medicine have developed a clinical tool kit compatible with the 2016 UK National Institute for Care Excellence (NICE) Clinical Guidelines on Sepsis.[13] The Clinical Excellence Commission in New South Wales introduced the Sepsis Kills! program, a quality-improvement initiative, whose focus is to RECOGNIZE risk factors, signs and symptoms of sepsis; RESUSCITATE with IV fluids and antibiotics; and REFER to senior clinicians and specialty teams. A review of the Sepsis Kills! database demonstrated that the proportion of patients who received antibiotics within 60 minutes increased from 29.3% in 2009 to 2011 (introduction of program) to 52.2% in 2013, and there was a reduction in mortality from 19.3% to 14.1% over the same period.[14]

Early goal-directed therapy

Early versions of the SSC Guidelines incorporated the principles of early goal-directed therapy (EGDT). EGDT was reported in 2001 by Rivers to confer a substantive mortality benefit of 16%.[15] EGDT was a structured treatment protocol designed to optimize tissue oxygen transport using continuous monitoring of pre-specified physiological targets, including central venous pressure as a surrogate for intravascular volume, MAP and central venous oxygen saturation ($ScvO_2$). Recently three independent randomized controlled trials evaluating EGDT have been published. These trials were Protocolized Care for Early Septic Shock (ProCESS) from the United States, Australasian Resuscitation in Sepsis Evaluation (ARISE), and Protocolised Management in Sepsis (ProMISe) in the United Kingdom.[16–18] The three trials separately reported no significant difference in hospital or 90-day mortality among patients receiving EGDT from those receiving usual resuscitation. Additionally, none of the trials demonstrated a difference in hospital length of stay.

Antimicrobial therapy

Observational data have demonstrated improved outcomes with the early administration of antibiotics. Additionally, delays have been shown to have a negative impact on secondary end points, including length of stay, acute kidney injury and acute lung injury. Choice of appropriate empiric antimicrobials is critical to outcomes. Factors that should be taken into account in choosing an antimicrobial regimen include (1) the anatomic site of infection, (2) prevalent pathogens within the community and hospital, (3) resistance patterns of those pathogens, (4) patients who have compromised immunity and (5) age and patient comorbidities. Early in the management phase of sepsis and septic shock, broad-spectrum antibiotics are usually appropriate. A broad-spectrum carbapenem (e.g. meropenem or imipenem/cilastin) or extended-range penicillin/β-lactamase inhibitor combination (e.g. piperacillin/tazobactam or ticarcillin/clavulanate) is usually used. Consideration should be given to adding vancomycin or teicoplanin to patients known to have methicillin-resistant *Staphylococcus aureus* (MRSA) or risk factors for MRSA. Empirical antifungal treatment is recommended in patients at high risk for invasive candidiasis, such as those who have been treated with prolonged broad-spectrum antibiotics, are immunosuppressed, have prolonged invasive vascular devices or have had *Candida* isolated from multiple sites. Fluconazole is a reasonable choice in the haemodynamically stable, whereas caspofungin, anidulafungin or micafungin should be used in patients with septic shock or those recently treated with other antifungals. Once the pathogen and its susceptibilities have been identified, more specific antibiotics should be prescribed and broad-spectrum agents discontinued. Because isolates are not detected in some patients with sepsis, clinical response and judgment should guide decisions to continue, narrow, or stop antimicrobials.[12] Table 2.5.1 outlines one approach to initial antibiotic choice. Local antibiotic guidelines should be followed when available.

Source

A search for the underlying source should include two sets of paired blood cultures peripherally and a set from any indwelling line or lines, urine microscopy and culture, chest x-ray, culture of any open wound and aspiration of any superficial collections.

In the absence of a clearly identified focus, abdominal computed tomography (CT) and, particularly if there is an altered mental state, CT-guided brain and lumbar puncture are usual unless contraindicated by the patient's clinical status.

Source control

Source control refers to physical measures to control or contain the focus of infection by drainage, debridement, removal of an infected device or anatomic repair of a source of ongoing microbial contamination. In principle, the removal of an infected nidus will help minimize the inflammatory response, but the size and site of the infective source will determine the feasibility and timing of source control. The focus in the ED is on identifying the likely source of infection and determining—in consultation with radiological, surgical and other specialties—the best method of drainage or containment.

Localized collections may be amenable to percutaneous drainage with or without radiological guidance. This is appropriate for renal, hepatic and other intra-abdominal abscesses and soft tissue collections. Immediate debridement of infected and necrotic tissue is mandatory for soft tissue infections such as necrotizing fasciitis, but more deep-seated necrosis, such as pancreatitis, may require delayed debridement, as early operative intervention in difficult-to-access areas is associated with significant morbidity.[20,21] Biliary tract obstruction with associated infection requires early decompression with percutaneous cholecystostomy or endoscopic retrograde cholangiopancreatography (ERCP). Urinary sepsis with shock in association with ureteric obstruction should be managed by urgent percutaneous nephrostomy. Except for contained perforations in diverticulitis, gastrointestinal perforation with leakage of luminal contents usually requires early surgical repair.

The best approach for sepsis associated with indwelling devices is removal of the device, but this must be balanced against the risks of removal and the ongoing medical need.[21,22]

Other therapies

Mechanical ventilation

Patients with sepsis and certainly those with septic shock will likely require respiratory support in addition to invasive monitoring and circulatory support. Non-invasive ventilation may be sufficient and can be delivered through a nasal/face mask, but patients with more severe pulmonary dysfunction will require intubation. Lung-protective strategies should be used.[9,12]

Corticosteroids

The results of systematic reviews and meta-analyses on the use of steroids in sepsis have been conflicting. The Adjunctive Corticosteroid Treatment in Critically Ill Patients (ADRENAL)[23] trial reported no difference in 90-day mortality in patients with septic shock undergoing mechanical ventilation and treated with a continuous infusion of hydrocortisone compared to placebo; the Activated Protein C and Corticosteroids for Human Septic Shock (APROCCHSS) trial demonstrated an improvement. The observed differences in primary outcomes in these largest steroid trials in septic shock to date may be due to a combination of factors including severity of illness of patients entering both trials; differences in type and method of intervention (infusion of hydrocortisone alone in ADRENAL versus bolus of hydrocortisone plus oral fludrocortisone in APROCCHSS); and differences in focus of infections among patients enrolled. Nevertheless, secondary outcomes in both trials demonstrated improved resolution of shock (i.e. removing vasopressor therapy) and decreased time to wean from mechanical ventilation. Clinicians will therefore need to be guided by individual patient presentation and deterioration (e.g. increasing vasopressor doses and types and poor response to standard strategies). In such patients and those in whom steroids are not contraindicated, low-dose hydrocortisone (e.g. 50mg IV q6h) should be considered.[25,26]

Table 2.5.1 Empirical initial intravenous antibiotic recommendations based on likely source of infection in a patient with severe sepsis

Source of infection	*Antibiotic regimen*[19]
Unknown source	Flucloxacillin 2 g q4h
	PLUS Gentamicin 7 mg/kg ideal body weight daily (subsequent doses to be determined according to creatinine level) If risk of MRSA, ADD vancomycin 25–30 mg/kg actual body weight loading dose (subsequent doses to be determined according to creatinine level) If mild penicillin hypersensitivity, substitute flucloxacillin with cephazolin 2 g q6h If immediate penicillin hypersensitivity, give vancomycin 25–30 mg/kg actual body weight loading dose (subsequent doses to be determined according to creatinine level) PLUS gentamicin 7 mg/kg ideal body weight daily (subsequent doses to be determined according to creatinine level)
Biliary/gastrointestinal	Amoxycillin/ampicillin 2 g q6h substitute with ceftriaxone 1 g q12h for mild penicillin hypersensitivity and omit for immediate penicillin hypersensitivity PLUS Gentamicin 7 mg/kg, ideal body weight daily (subsequent doses to be determined according to creatinine level) PLUS Metronidazole 500 mg IV q12h in patients with chronic biliary obstruction
Community-acquired pneumonia	azithromycin 500 mg, daily PLUS ceftriaxone 1 g q12h OR Benzylpenicillin 1.2 g q4h PLUS gentamicin 7 mg/kg ideal body weight (subsequent doses to be determined according to creatinine level) PLUS azithromycin 500 mg/day OR If severe immediate penicillin hypersensitivity, give moxifloxacin 400 mg/day
Hospital-acquired pneumonia	Piperacillin + tazobactam 4+0.5 g q6h PLUS vancomycin 25–30 mg/kg actual body weight loading dose (subsequent doses to be determined according to creatinine level)
Urinary tract	Amoxycillin/ampicillin 2 g q6h omit in immediate penicillin hypersensitivity PLUS Gentamicin 7 mg/kg daily (subsequent doses adjusted to be determined according to creatinine level) If ESBL-producing organisms are known or suspected, give amikacin 16–20 mg/kg daily OR meropenem 1g IV q8h
Cellulitis	Flucloxacillin 2 g q6h If severe immediate penicillin hypersensitivity, give vancomycin 25–30 mg/kg actual body weight loading dose (subsequent doses to be determined according to creatinine level) If risk of MRSA, ADD vancomycin 25–30 mg/kg actual body weight loading dose (subsequent doses to be determined according to creatinine level) If gram-negative organisms are suspected, ADD gentamicin 7 mg/kg ideal body weight (subsequent doses adjusted to be determined according to creatinine level)
Neurological, including meningitis	Dexamethasone 10 mg with or before the first dose of the antibiotic, then q6h for 4 days PLUS ceftriaxone 4 g, daily or 2 g q12h and review within 48 h. If risk of *Listeria*, ADD benzylpenicillin 2.4 g q4h If immediate penicillin hypersensitivity, give dexamethasone as above PLUS vancomycin 25–30 mg/kg actual body weight loading dose (subsequent doses to be determined according to creatinine level) PLUS ciprofloxacin 400 mg, q8h. If risk of *Listeria*, ADD trimethoprim + sulfamethoxazole 160 + 800 mg q6h

ESBL, extended-spectrum beta lactamase; *MRSA*, methicillin-resistant *Staphylococcus aureus*.

Renal replacement therapy

Patients in septic shock often experience circulatory dysfunction, with reduced cardiac output and hypoperfusion leading to acute kidney injury. Continuous renal replacement therapy (CRRT) is favoured in patients who require management of fluid balance and are haemodynamically unstable. The need for nephrotoxic drugs should be established and the use of such drugs limited whenever possible.[9,12]

Miscellaneous

1. Red blood cell transfusion should occur only when haemoglobin concentrations fall to less than 7.0 g/dL in the absence of specific situations (e.g. myocardial infarction, severe hypoxaemia, or acute haemorrhage).[12]
2. Following initial stabilization, glycaemic control is indicated if the blood sugar level (BSL) is greater than 10 mmol/L. Aiming for tighter BSL targets has been shown to increase the risk of hypoglycaemia, with no mortality benefit. Treatment should be aimed at ensuring that patients do not become hypo- or hyperglycaemic.[12,27]
3. Procalcitonin levels can be used to support stopping antibiotics in patients who have limited evidence of infection.[12]

Post-sepsis syndrome

After surviving sepsis, many patients report new medical problems or new symptoms. Some of these include muscle weakness, vertigo, joint pains, lethargy, depression, anxiety, difficulty concentrating and problems with sleeping and/or swallowing. Patients are at higher risk of infection, as their immune systems may not have fully recovered. Indeed, as many as one-third of patients will have another hospitalization within 3 months of having sepsis. Sepsis survivors require close follow-up and may need specialist review. Rehabilitation and support programs should be offered to survivors of sepsis to mitigate the effects of post-sepsis syndrome (PSS).[9,28]

CONTROVERSIES

- The Sepsis-3 definitions have not been unanimously accepted.
- A 2018 systematic review and meta-analysis comparing qSOFA to SIRS demonstrated that SIRS was significantly superior to qSOFA for sepsis diagnosis, but qSOFA was slightly better than SIRS in predicting hospital mortality.[29]
- Leaders in critical care and emergency medicine have petitioned the SSC to retract its 2018 update on the basis of the lack of supporting quality evidence and incorporation of clinician judgment.
- The strong recommendation to give rapid administration of 30 mL/kg of IV fluid has also been controversial, and the evidence to do so is graded as low quality. Fluid therapy should be guided by dynamic assessments of responsiveness, including passive leg raise.

2.6 Arterial blood gases

Anthony D. Holley

ESSENTIALS

1 The value of arterial blood gas analysis is dependent on understanding and correctly interpreting the results in the clinical context.

2 When abnormalities are detected with arterial blood gas analysis, make sure that the sample was obtained, transported and analysed appropriately.

3 An arterial blood gas result assists in the assessment of a patient's gas exchange, ventilatory control and acid–base balance.

4 Common sampling sites include the radial, femoral, brachial and dorsalis pedis arteries. There is no evidence for the superiority of any site.

5 The alveolar gas equation establishes the alveolar partial pressure of oxygen (PaO_2). The alveolar–arterial difference can then be calculated. An elevated value indicates a ventilation–perfusion defect (high A–a gradient).

6 Isolated hypoxaemia is referred to as type I respiratory failure; type II respiratory failure is characterized by a partial pressure carbon dioxide ($PaCO_2$) higher than 50 mm Hg (6.7 kPA).

7 Any of five pathophysiological mechanisms may be responsible for hypoxaemia; they include decreased inspired fractional oxygen, impaired diffusion, shunting, ventilation–perfusion (V/Q) mismatch and hypoventilation.

8 Type II respiratory failure (hypercapnia) is due to inadequate alveolar ventilation, commonly secondary to poor central respiratory drive, neuromuscular disease or significant mechanical disruption of the lungs or chest wall.

9 The primary acid–base disturbance is established by assessing the relationship between the direction of change in the pH and the direction of change in the $PaCO_2$.

10 When a metabolic acidosis is diagnosed, calculate the anion gap and delta ratio to narrow the differential diagnosis.

11 In the presence of a metabolic alkalosis, establish both an initiating and maintaining factor.

12 Venous pH, bicarbonate and base excess have sufficient agreement to be clinically interchangeable with arterial values in patients who are not shocked.

Introduction

Arterial blood gas analysis is an essential tool for diagnosing and managing the critically ill emergency department (ED) patient's respiratory status and acid–base balance (Box 2.6.1). It is, however, imperative to understand and interpret the results correctly to effectively manage patients.

Technical aspects of arterial blood gas analysis

The technology for arterial blood gas analysis became available more than 50 years ago with the development of electrodes that allowed the measurement of partial pressures of oxygen (PaO_2) and carbon dioxide ($PaCO_2$) in arterial blood samples taken directly from the patient.[1]

Blood gas analysers and applied physiology

The Clarke oxygen electrode constitutes a platinum probe suspended in an electrolyte solution and separated from the blood sample by a membrane permeable to oxygen. Oxygen molecules diffuse from blood through the membrane to the electrode, where they are reduced to hydroxyl ions. The partial pressure of oxygen is directly proportional to the current measured from this reduction reaction.

A pH-sensitive glass probe maintained in a bicarbonate solution and protected by a carbon dioxide (CO_2)–permeable membrane constitutes the Severinghaus CO_2 electrode. In this model, the measured $PaCO_2$ is proportional to the hydrogen ions produced, as CO_2 reacts with water to form hydrogen and bicarbonate ions.[1]

The pH of arterial blood is measured directly by an electrode that then allows the blood gas analyser's software to calculate the base excess (BE) and bicarbonate concentration.

The arterial oxygen saturation (SaO_2) can be calculated from the PaO_2; however, this may still be unreliable even if the shifts in haemoglobin–oxygen affinity secondary to acid–base disturbances are accounted for in this calculation. Most modern blood gas analysers now include a co-oximeter that is capable of measuring concentrations of saturated haemoglobin, reduced haemoglobin, carboxyhaemoglobin and methaemoglobin.[2] Wavelengths of light corresponding to unique absorption spectra for each haemoglobin species allow for these measurements to be determined.

Modern automated blood gas analysers report the pH, PaO_2 and $PaCO_2$ at either 37°C (the temperature at which the values are measured by the blood gas analyser) or at the patient's body temperature. Most machines report the values of pH, PCO_2 and PaO_2 at 37°C regardless of the patient's actual temperature. The corrections are generally minimal and corrected values are no more clinically useful than 37°C values.

Collection and handling

Accurate results for arterial blood gases are dependent on appropriate collection and handling. Prepared syringes are pretreated with sodium or lithium heparin to prevent coagulation of the specimen. The presence of air bubbles in the sample syringe that

Box 2.6.1 Indications for arterial blood gas analysis

1. Determination of the partial pressures of gases reflective of gas exchange and ventilation
2. Monitoring gas exchange and ventilation in response to interventions or therapy
3. Identification of acid–base disorders
4. Monitoring of acid–base status in response to interventions or therapy
5. Identification of dyshaemoglobinaemias (e.g. carboxyhaemoglobin and methaemoglobin)

exceed 1% to 2% of the blood volume can spuriously elevate PaO_2 but has little effect on pH and $PaCO_2$. Delaying the processing of a specimen beyond 20 minutes may result in a reduction in PaO_2 and pH, with a concomitant elevation in $PaCO_2$. These changes reflect ongoing cellular metabolism, which is more pronounced in the presence of a leucocytosis or thrombocytosis. Erythrocytes in the arterial blood sample continue to undergo anaerobic glycolysis, generating lactic acid and thereby lowering the pH of the sample. Placing the specimen on ice immediately after drawing will improve its stability.

Arterial puncture technique

The most commonly accessed artery is the radial; other potential sites include the femoral, brachial, dorsalis pedis and axillary arteries. The radial artery is the most frequently accessed as it is convenient and accessible and its puncture is well tolerated. There is no evidence that any single site is superior.

Modified Allen test

The Allen test or modified Allen test may be performed in patients undergoing radial artery puncture to ensure that there is reliable collateral flow.[3] Although the modified Allen test has been the most frequently used method clinically to assess the adequacy of ulnar artery collateral flow, there is controversy as to whether it can reliably predict ischaemic complications. Its use is recommended as it is easily performed and, acknowledging its limitations, the results may be useful.

The patient's clenched fist is elevated with both the ulnar and radial arteries occluded. Subsequently the hand is lowered, the fist released and occlusion of the ulnar artery removed. Rapid colour return to the hand confirms both that the ulnar artery is patent and the superficial palmar arch is functional. The test is considered abnormal if there is a delay (>6 seconds) before the colour returns to the hand, in which case an alternate puncture site should be considered. Ideally the non-dominant hand is selected when the radial artery is being cannulated.

Indwelling arterial catheter

An indwelling arterial catheter may be required in the ED for continuous blood pressure monitoring and/or regular blood gas sampling. A meticulous aseptic technique is needed during insertion and with catheter maintenance to decrease the risk of catheter-related infection. Complications of radial artery cannulation/puncture include haematoma, local infection, bleeding, sepsis, pseudoaneurysm formation and permanent ischaemic injury secondary to embolization or thrombosis.[4]

Table 2.6.1 Normal arterial blood gas values on room air (FiO_2 = 0.21)

Parameter	*Reference rang*
pH	7.35–7.45
PaO_2	80–100 mm Hg (10.7–13.3 kPA)
$PaCO_2$	35–45 mm Hg (4.7–6 kPA)
HCO_3^-	22–26 mmol/L
Base excess	−2 to +2 mmol/L

FiO_2, Fractional inspired oxygen

Interpretation

An arterial blood gas sample is useful in the evaluation of a patient's gas exchange, assessment of ventilatory function and determination of acid–base status. It is important that all measurements are evaluated in the context of the clinical history, examination findings and the normal values (Table 2.6.1).

Gas exchange

Respiration is the process whereby oxygen is delivered to metabolically active tissues and the CO_2 produced from this metabolism is subsequently removed. Respiratory failure occurs when the system can no longer effectively maintain this gas exchange, resulting in organ dysfunction or death. If oxygenation is principally affected, the result is hypoxaemia; if ventilation is impaired, hypercapnia and respiratory acidosis may supervene. It is important to recognize that these processes frequently occur together.

Oxygenation of tissues is dependent on arterial oxygen content, delivery and consumption. Oxygen content is expressed by the following equation:

$$\text{Arterial oxygen content} = \text{Haemoglobin (g/dL)} \times \text{Oxygen saturation (\%)} \times 1.34 + (PaO_2 \times 0.0031)$$

where 1.34 represents the amount of oxygen (in millilitres) carried by haemoglobin (in grams). Therefore it is the oxygen saturation, rather than the PaO_2, that is important in determining oxygen delivery to the tissues.

Hypoxaemic respiratory failure is defined as a clinically significant decrease in PaO_2, conventionally considered to be a PaO_2 less than 60 mm Hg (<8 kPA). Although a definition based on an absolute PaO_2 value may be an oversimplification, it is useful in the context of the oxygen–haemoglobin dissociation curve (Fig. 2.6.1). Importantly, when the PaO_2 declines below 60 mm Hg, the haemoglobin oxygen saturation falls precipitously with any further decrease in PaO_2.

The position of the oxyhaemoglobin dissociation curve is modified by alterations in the $PaCO_2$, temperature and the presence of acidosis or red blood cell 2,3-diphosphoglycerate (2,3-DPG). The curve is displaced to the right by an increase in $PaCO_2$, a temperature rise, acidosis or an increase in 2,3-DPG concentration. This right shift facilitates more effective delivery of oxygen to peripheral tissues, which is beneficial in the presence of hypoxia. The P_{50} is used to reference the oxygen dissociation curve (see Fig. 2.6.1).[5] It is the partial pressure of oxygen at which 50% of the haemoglobin is saturated with oxygen and specifies the position of the oxygen dissociation curve. Normally, a PaO_2 of 26.6 mm Hg (3.5 kPA) corresponds to 50% haemoglobin saturation. Modern arterial blood gas machines routinely report this value.

Alveolar–arterial oxygen gradient

The alveolar–arterial PO_2 gradient (A–a) PO_2 is determined to evaluate a patient's oxygenation. This gradient is defined by the difference between the partial pressure of O_2 in the alveoli (PAO_2) and the partial pressure of O_2 dissolved in the arterial blood plasma (PAO_2–PaO_2). The partial pressure of O_2 in the alveoli (PAO_2) is established by using the alveolar gas equation:

$$P_AO_2 = FiO_2 (P_{atm} - P_{H_2O}) - (PaCO_2)/R$$

where FiO_2 = fraction of inspired oxygen, P_{atm} = atmospheric pressure (760 mm Hg [101 kPA] at sea level, decreasing progressively with increasing altitude), P_{H_2O} = partial pressure of saturated vapour (47 mm Hg [6.3 kPA] at 37°C) and R=the respiratory quotient (≈0.8).

The normal reference range for the alveolar–arterial gradient is 5 to 15 mm Hg (0.7 to 2 kPA), with increases encountered from cigarette smoking, increasing FiO_2 and advancing age. An approximate expected $P(A–a)O_2$ can be determined using the following formula:

$$P(A - a)O_2 = \text{Age}/4 + 4$$

Pathophysiology of hypoxaemic respiratory failure

There are five potential mechanisms responsible for hypoxaemia in determining the aetiology of a patient's respiratory failure. These are decreased inspired fractional oxygen, impaired diffusion, shunting, ventilation–perfusion (V/Q) mismatch and hypoventilation. Isolated hypoxaemia is often referred to as type I respiratory failure, with type II respiratory failure characterized by a $PaCO_2$ higher than 50 mmHg (6.7 kPA).

Mechanisms responsible for hypoxaemia are discussed in the following paragraphs.

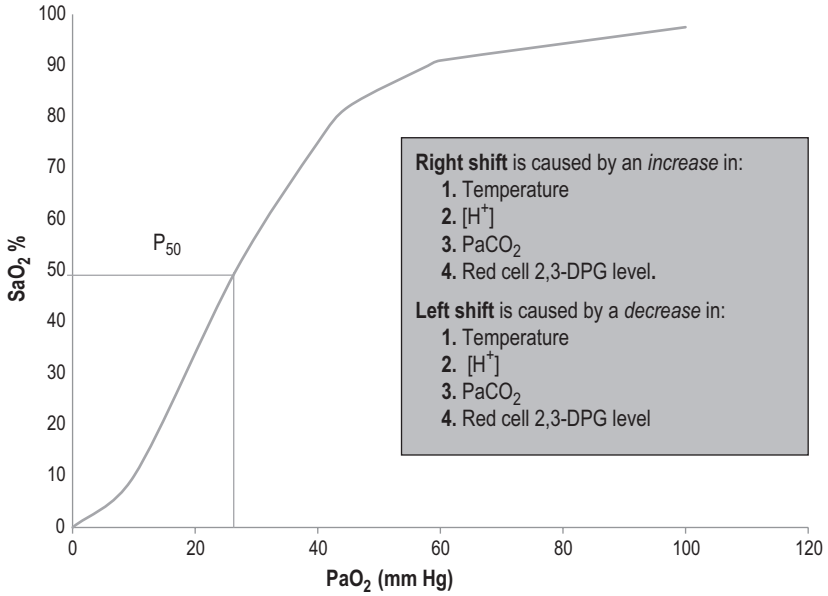

FIG. 2.6.1 Oxygen dissociation curve.

Decreased inspired fraction of oxygen

This is not common in clinical practice but may be encountered in environments where the gas mixture is oxygen-depleted.

Impaired diffusion

Diffusion impairment secondary to thickening of the membrane between the capillary and alveolus is a rare mechanism. Thickening of the blood–gas barrier is found in diseases such as diffuse interstitial fibrosis. Under normal resting conditions, oxygen diffusion at the alveolar–capillary barrier requires only one-third of the circulatory time available for equilibration to be complete. Therefore even in the presence of a moderate diffusion impairment, there is sufficient 'diffusion time' to compensate.

Severe impairments of diffusion become clinically significant, particularly during exercise, when blood flow rates are increased and the time for diffusion equilibration is restricted. Shunting or V/Q mismatches almost always coexists with a diffusion defect and are likely, quantitatively, to be more significant as a cause of hypoxemia.

Shunt

Hypoxaemic respiratory failure may result from either extrapulmonary or intrapulmonary shunts, with a shunt defined as the movement of blood from the venous to the arterial circulation without transiting ventilated lung tissue and thus not afforded the opportunity to be oxygenated.

The clinical feature suggestive of a shunt is the failure of PaO_2 to rise despite inhalation of 100% oxygen (FiO_2 1.0). Extrapulmonary shunts are encountered in the setting of acquired or congenital cardiac abnormalities, where the ventricles or the atria communicate secondary to septal defects. When the pressure gradient favours blood bypassing the pulmonary circulation, a shunt is established.

Intrapulmonary shunts occur in severe pneumonia, atelectasis, pulmonary arteriovenous malformations or the hepatopulmonary syndrome (regional dilation of pulmonary capillaries). The situation where there is alveolar consolidation or collapse such that there is unventilated but perfused lung, may also be considered an extreme V/Q mismatch. This is distinguished from a shunt by virtue of the correction of PaO_2 in response to enhanced O_2 administration. The shunt fraction can be calculated with the following equation:

$$Q_S/Q_T = (Cc'O_2 - CaO_2) / (Cc'O_2 - CvO_2)$$

where Q_S = shunt flow, Q_T = total blood flow, $Cc'O_2$ = end-capillary oxygen content derived from PAO_2, CaO_2 = arterial oxygen content, CvO_2 = mixed venous oxygen content

A calculated shunt of less than 20% seldom requires support, whereas a calculated shunt greater than 30% usually needs cardiopulmonary intervention. However, the shunt equation is limited in clinical practice by the need for sampling mixed venous blood and hence the presence of a pulmonary artery catheter.

Ventilation–perfusion (V/Q) mismatch

All the blood circulating through the lungs must perfuse individual ventilated lung units for effective gas exchange to occur. Theoretically the ideal ratio of perfusion to ventilation (V/Q ratio) should numerically be 1.[6] Under normal physiological conditions, perfusion is more pronounced at the lung bases as compared with the apices, whereas the converse is true for ventilation.[7] Therefore the usual overall V/Q ratio is approximately 0.8.

V/Q ratios demonstrate a wide spectrum of abnormalities: in some situations where alveolar units receive no ventilation but are fully perfused, the result is a V/Q ratio of 0. This constitutes a shunt and may be either cardiac or pulmonary in aetiology. Alternatively, the alveolar units may be fully ventilated but receive no perfusion, producing a V/Q ratio that trends to infinity. A clinical example of this is a massive pulmonary embolus. Non-perfused alveolar units are referred to as physiological 'dead space'.

Derangements of V/Q matching are the most common clinical cause of gas exchange impairment and are characterized by hypoxaemia, hypercapnia or a combination of both. The presence of an increased alveolar–arterial PO_2 gradient helps the physician identify a V/Q abnormality.

Hypoventilation

The $PaCO_2$ in arterial blood is determined by the production of CO_2 (VCO_2) and alveolar ventilation (VA), as follows:

$$PaCO_2 = (VCO_2 \times K)/VA$$

where alveolar ventilation (VA) = (tidal volume [Tv]) – dead space [VD]) × respiratory rate.

Type II respiratory failure is characterized by a $PaCO_2$ greater than 50 mm Hg (6.7 kPA) and is commonly encountered in clinical practice (Table 2.6.2).

Table 2.6.2 Causes of hypoventilation resulting in type II respiratory failure

Mechanism	*Disease*
Airway-induced	Foreign body Bronchospasm—asthma, anaphylaxis Chronic obstructive pulmonary disease
Central nervous system depression	Alcohol intoxication Opiate overdose Over-sedation High spinal/epidural anaesthesia
Hypoventilation secondary to neuromuscular disease	Myasthenia gravis Spinal cord injury/trauma Transverse myelitis Guillain-Barré syndrome Muscular dystrophy
Chest wall trauma	Pneumothorax Flail chest
Obesity with decreased alveolar ventilation	Obstructive sleep apnoea (OSA)

Table 2.6.3 Six-step approach to evaluate respiratory failure using arterial blood gases

Step	*Parameter*
1	Confirm the presence of hypoxaemia by determining the PaO_2 < 60 mm Hg (8 kPA) or SaO_2 < 90%.
2	Establish if there is an increased alveolar–arterial oxygen tension gradient ↑(A–a) PO_2.
3	Determine if there is evidence for hypoventilation. If the $PaCO_2$ > 50 mm Hg (6.7 kPA), then alveolar hypoventilation is present.
4	If there is hypoxaemia, a normal alveolar–arterial oxygen tension gradient (A–a) PO_2 and the $PaCO_2$ is not elevated, the patient is in a hypoxic environment (e.g. altitude).
5	Determine if the hypoxaemia is entirely accounted for by hypoventilation, established by calculating the alveolar–arterial oxygen tension gradient (A–a) PO_2. If the gradient is normal (<15), hypoventilation alone is the cause, such as from central nervous system depression or respiratory muscular failure. Conversely, if the alveolar–arterial oxygen tension gradient (A–a) PO_2 is elevated, other conditions including pneumonia or acute respiratory distress syndrome are likely responsible.
6	If the $PaCO_2$ is normal, hypoxaemia is present and there is an increased alveolar–arterial oxygen tension gradient (A–a) PO_2, the response to breathing an enhanced O_2 mixture discriminates between a ventilation/perfusion mismatch and a shunt.

The alveolar gas equation demonstrates how significant alveolar hypoventilation can result in a proportional decrease in alveolar oxygen pressure P_AO_2. When the respiratory quotient (R = 0.8) remains constant, an increase in $PaCO_2$ will be associated with a concomitant reduction in P_AO_2, which, in profound hypercapnia, may then result in hypoxaemia. If hypoventilation is the presumed mechanism of the hypoxaemia, then the alveolar–arterial oxygen tension gradient (A–a) PO_2 should be calculated. This gradient will be normal when the hypoxaemia is entirely secondary to hypercapnia, but it will be increased if there are other mechanisms, such as an impaired V/Q ratio or the presence of a shunt contributing to the hypoxaemia.

It is important when any blood gas is being interpreted that a standard, structured evaluation be undertaken to determine the aetiology of the respiratory failure (Table 2.6.3 and Fig. 2.6.2).

Acid–base balance

Although this chapter principally addresses the respiratory aspects of arterial blood gas analysis, it is impossible to separate clinically the component information provided by arterial blood sampling. Under normal physiological conditions, humans maintain a closely regulated acid–base homeostasis as required for normal cellular activity. This homeostasis results from a complex series of interactions between the lungs and kidneys, moderated by a range of physiological buffers. The resultant blood hydrogen ion concentration (pH) is a function of the ratio of bicarbonate concentration and the partial pressure of CO_2 in arterial blood.

Acid–base disorders

Primary metabolic acid–base disorders and the secondary metabolic compensation for primary respiratory disturbances are reflected by changes in the serum bicarbonate concentration. Primary respiratory acid–base disorders and the secondary respiratory compensation for primary metabolic disturbances result in changes in the measured $PaCO_2$ (Table 2.6.4). Similarly to the evaluation of respiratory failure, evaluation of an acid–base abnormality requires a systematic approach:

Step 1: First determine whether alkalaemia or acidaemia is present, as simply defined by the following: pH < 7.35 = acidaemia or pH > 7.45 = alkalaemia.

Step 2: Then determine whether the primary disturbance is respiratory or metabolic in origin by assessing the relationship between the direction of change in the pH and the direction of change in the $PaCO_2$.

Step 3: Then assess whether the primary disturbance has been compensated (Table 2.6.5), acknowledging that compensation does not return the pH to normal. If the expected compensation is not present, it is likely that a mixed acid–base disorder exists.[7]

Step 4: Calculate the anion gap in the presence of a metabolic acidosis to allow for formulation of the differential diagnosis (high or normal anion gap):

$$\text{Anion gap} = [Na^+] - ([Cl^-] + [HCO_3^-]) = 12 \pm 2$$

A high anion gap acidosis is most commonly secondary to lactate or ketones (Table 2.6.6). Lactic acidosis was classified in 1976 into types A and B, based on the absence or presence of adequate tissue oxygenation. Lactic acidosis is a common life-threatening form of metabolic acidosis in the critically ill.

The differential diagnosis of a non–anion gap metabolic acidosis includes conditions characterized by bicarbonate loss, excess chloride or ingestions (Table 2.6.7).

If the anion gap is elevated (>12) and not explained by an obvious aetiology, then, under appropriate clinical circumstances, a toxic ingestion, such as methanol or ethylene glycol is considered. This is associated with a high osmolal gap, the difference between the measured serum osmolality and the calculated osmolality, which, under normal physiological conditions, should be <10 mmol/L:

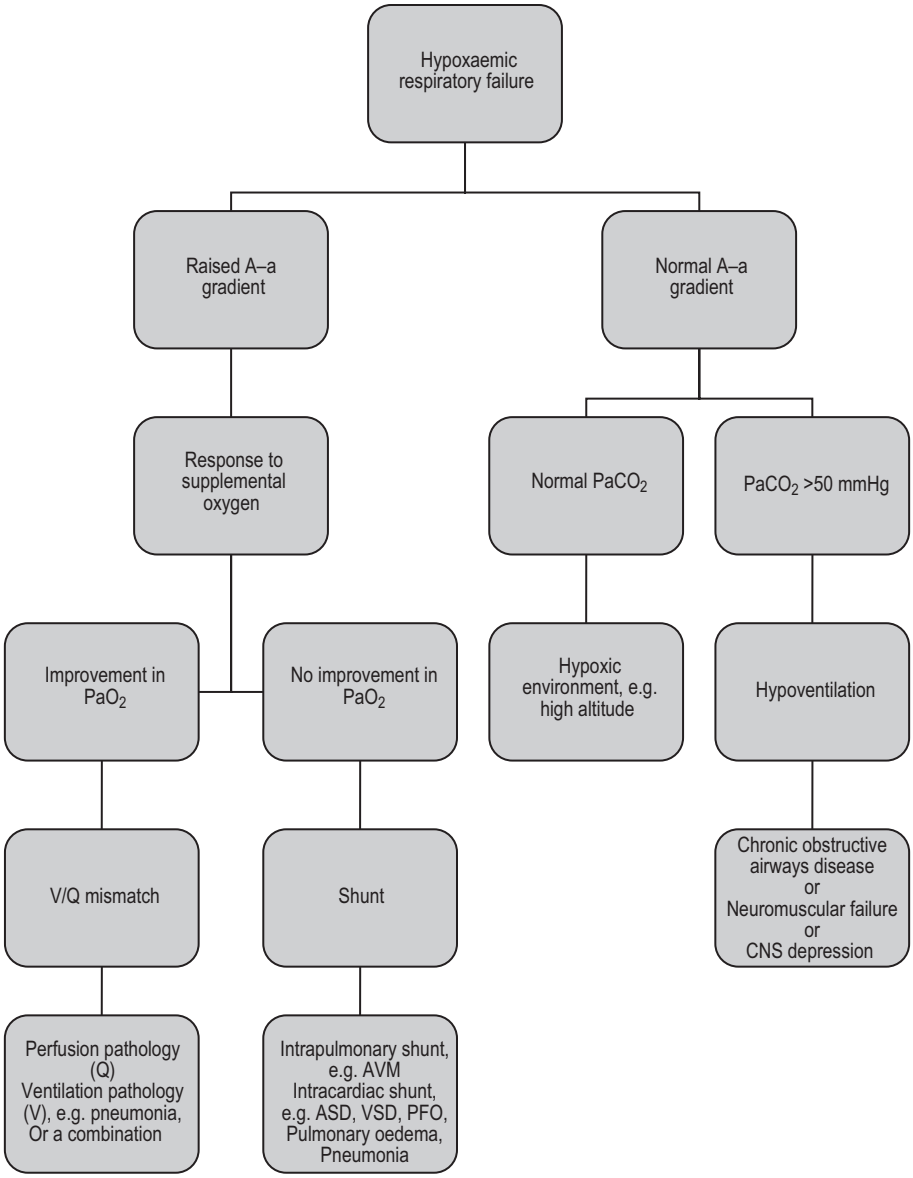

FIG. 2.6.2 Evaluating respiratory failure using arterial blood gases. *ASD*, atrial septal defect; *AVM*, arteriovenous malformation; *CNS*, central nervous system; *PFO*, patent foramen ovale; *VSD*, ventricular septal defect

$$\text{Osmolol gap} = \text{Measured} - \text{Calculated osmolality, where calculated osmolality (mmol/L)} = 2 \times [\text{Na}] + \text{Glucose} + \text{Urea}$$

Step 5: If an increased anion gap is present, then determine the delta ratio to establish whether a mixed acid–base disorder is present. This is deduced from assessing the relationship between the increased anion gap and the decrease in bicarbonate.

$$\text{Delta ratio} = \frac{\Delta \text{Anion gap}}{\Delta [HCO_3^-]} = \frac{\text{Measured anion gap} - \text{Normal anion gap}}{\text{Normal } [HCO_3^-] - \text{Measured } [HCO_3^-]} = \frac{\text{Measured anion gap} - 12}{(24 - [HCO_3^-])}$$

Table 2.6.4 Determining the primary acid–base disorder

Primary disturbance	*pH*	*$PaCO_2$*	*Anticipated compensation*
Respiratory acidosis	↓	↑	↑ HCO_3^-
Respiratory alkalosis	↑	↓	↓ HCO_3^-
Metabolic acidosis	↓	↓	↓ $PaCO_2$
Metabolic alkalosis	↑	↑	↑ $PaCO_2$

The magnitude of the delta ratio can range from less than 0.4 to more than 2 and allows for refinement of the differential diagnosis (Table 2.6.8).

Step 6: If there is a primary metabolic alkalosis, identify the 'initiating factor'. This may include loss of hydrogen ions from the gastrointestinal system, transcellular hydrogen shifts, mineralocorticoid excess or addition of alkali. Furthermore, a 'maintenance' factor is required to preserve the metabolic alkalosis because, in the presence of an elevated serum bicarbonate,

Table 2.6.5 Predicting compensation for primary acid–base disorders

Primary disorder	*Expected compensation*
Metabolic acidosis	$PaCO_2 = (1.5 \times HCO_3^-) + 8$.
Acute respiratory acidosis	For every 10 mm Hg increase in PCO_2, the HCO_3^- should increase by 1 mmol/L.
Chronic respiratory acidosis (3–5 days)	For every 10 mm Hg increase in PCO_2, the HCO_3^- should increase by 3–4 mmol/L over 4 days.
Metabolic alkalosis	$PaCO_2 = 0.8 \times HCO_3^- + 20$.
Acute respiratory alkalosis	For every 10 mm Hg decrease in PCO_2, the HCO_3^- should decrease by 1 mmol/L.
Chronic respiratory alkalosis	For every 10 mm Hg (1.3 kPA) decrease in PCO_2, the HCO_3^- should decrease by 2 mmol/L.

Table 2.6.6 Causes of a high anion gap metabolic acidosis

Mechanism	*Clinical example*
Lactic acidosis type A	Shock Hypoxia
Lactic acidosis type B1	Hepatic failure Sepsis Haematological malignancies Renal failure Thiamine deficiency Thyroid storm
Lactic acidosis type B2	Drug-induced, including paracetamol biguanides cocaine diethyl ether adrenaline ethanol ethylene glycol isoniazid methanol antiretroviral therapy salbutamol
Lactic acidosis type B3	Rare inborn errors of metabolism (e.g. glucose-6 phosphate dehydrogenase deficiency)
Ketoacidosis	Diabetic ketoacidosis Alcoholic ketoacidosis Starvation ketoacidosis

Table 2.6.7 Causes of normal anion gap metabolic acidosis

Mechanism	*Clinical example*
Renal bicarbonate loss	Tubulo-interstitial renal disease Renal tubular acidosis types 1, 2 and 4
Gastrointestinal bicarbonate loss	Diarrhoea Colostomy Ileostomy Enteric fistulas Use of ion-exchange resins
Drugs	Carbonic anhydrase inhibitors (e.g. acetazolamide)
Endocrine	Hypoaldosteronism Hyperparathyroidism
Excess chloride	Rapid sodium chloride infusion

Table 2.6.8 Delta ratio interpretation

Delta ratio	*Interpretation*
<0.4	Normal anion gap hyperchloraemic metabolic acidosis
<1	Combined high and normal anion gap acidosis
1–2	Isolated high anion gap metabolic acidosis
>2	Mixed high anion gap metabolic acidosis and metabolic alkalosis

a patient with intact renal function will rapidly excrete excess bicarbonate in the urine. Therefore, for a metabolic alkalosis to persist, there must be a reduction in the renal ability to lose excess bicarbonate. In practice, this is usually secondary to hypovolaemia or reduced effective arterial blood volume (including heart failure and cirrhosis), chloride depletion, hypokalaemia, renal impairment or a combination of these factors (Table 2.6.9).

Table 2.6.9 Causes of a metabolic alkalosis

Mechanism	*Clinical example*	*Saline responsive*
Gastrointestinal hydrogen loss	Nasogastric suction Vomiting, chloride-losing diarrhoea, gastrocolic fistula, villous adenoma	Yes
Renal hydrogen loss	Loop or thiazide diuretics, post-chronic hypercapnia, Hypocalcaemia Bartter or Gitelman syndrome	Yes
Transcellular hydrogen shift into cells	Hypokalaemia	Yes
Exogenous alkali	Administration of $NaHCO_3$, gluconate, acetate; citrate load with massive blood transfusion; excess antacids (milk alkali syndrome)	Yes
Contraction alkalosis	Loop or thiazide-type diuretics, sweat losses in cystic fibrosis, gastric losses in achlorhydria, factitious diarrhoea (including laxative abuse)	Yes
Endocrine	Mineralocorticoid excess Primary aldosteronism Cushing syndrome Exogenous steroids	No
Miscellaneous	Bartter syndrome Gitelman syndrome	No

Venous blood gases

In some situations, analysis of venous blood provides sufficiently reliable correlation with arterial blood to assist in clinical decision making.

The peripheral venous pH is approximately 0.02 to 0.04 pH units lower than the arterial pH, the venous serum HCO_3^- concentration is approximately 1 to 2 meq/L higher and the venous PCO_2 is approximately 3 to 8 mm Hg higher.[8] There are currently insufficient data to determine whether these relationships persist in a shocked patient or those with mixed acid–base disorders. In a patient who is not shocked, venous pH, bicarbonate and BE have sufficient agreement to be clinically interchangeable for arterial values.[9] Agreement between arterial and venous PCO_2 is too unpredictable to be clinically reliable.

2.7 Cerebral resuscitation after cardiac arrest

Stephen A. Bernard

ESSENTIALS

1 Neurological injury is common following out-of-hospital cardiac arrest and carries a high rate of morbidity and mortality.

2 Successful resuscitation leads to reperfusion of an ischaemic brain, and this may result in biochemical cascades, largely mediated by calcium influx into cells, promoting cell death.

3 In the early post-arrest period, the appropriate targets for oxygen, carbon dioxide, blood pressure and temperature are all uncertain, but current recommendations are that these be maintained in the normal range.

4 There are no specific pharmacological interventions at this time that have been shown to improve neurological outcome after resuscitation from cardiac arrest.

Introduction

Out-of-hospital cardiac arrest is a common cause of death in developed countries.[1] Prolonged cardiac arrest may lead to neurological injury as a result of global cerebral ischaemia, and most patients who are initially successfully resuscitated from out-of-hospital cardiac arrest and transported to an emergency department (ED) remain comatose and require admission to an intensive care unit (ICU). Subsequently many of these patients die as a consequence of severe anoxic neurological injury.[2] Current international recommendations for care after resuscitation from cardiac arrest outline goals for oxygenation, ventilation, blood pressure control and targeted temperature management (TTM).[3]

This chapter details the pathophysiology of the neurological injury and presents recent data on current treatment strategies that may decrease this injury and improve outcomes after resuscitation from cardiac arrest.

Pathophysiology of cerebral ischaemia and reperfusion injury

The brain is highly dependent on an adequate supply of oxygen and glucose for metabolism. When cerebral oxygen delivery falls below 20 mL/100 g, brain tissue/minute aerobic metabolism changes to anaerobic glycolysis, with a marked decrease in the generation of adenosine triphosphate (ATP).[4] After several minutes of cerebral ischaemia, the supply of ATP is exhausted and cellular metabolism ceases. The failure of the sodium/potassium trans-membrane pump leads to a shift of sodium into the cell, with cell swelling. In addition, hydrogen ions are generated, and the resulting intracellular metabolic acidosis is toxic to intracellular enzyme systems.

Additional injury may occur following return of a spontaneous circulation (ROSC) and reperfusion of the brain with oxygenated blood.[5] The intracellular levels of glutamate, an excitatory neurotransmitter released from pre-synaptic terminals, increase dramatically during reperfusion. Glutamate activates calcium ion channel complexes, and these shift calcium from the extracellular fluid to the intracellular fluid. The calcium influx into cells initiates multiple biochemical cascades, leading to the production of 'free radicals' and the activation of degradative enzymes.

Finally, some neurones that survive the initial anoxic insult proceed to 'programmed cell death', also known as apoptosis.[6] This delayed neuronal death may occur at different rates, varying from 6 hours for neurons in the striatum to 7 days for hippocampal CA1 neurones. Apoptosis is characterized by cellular and nuclear shrinkage, chromatin condensation and DNA fragmentation.

Cerebral haemodynamics after reperfusion

Cerebral perfusion may remain abnormal for some hours after ROSC.[7] In animal models, there is an initial hyperaemia after resuscitation, followed by decreased cerebral blood flow despite normal arterial blood pressure. Due to the inflammatory processes described earlier, the cerebral metabolic rate for oxygen increases slightly. Cerebral oxygen delivery may also be decreased by poor cardiac output, arterial hypotension, hypoxaemia and/or raised intracranial pressure. Cerebral oxygen demand may be increased by fever and/or seizure activity. Thus there may be a mismatch of cerebral oxygen delivery and demand for some hours following resuscitation from cardiac arrest.

Pharmacological interventions

There has been research into pharmacological interventions that might decrease the reperfusion injury. A number of drugs that showed promise in animal models of global cerebral ischaemia have been tested in randomized controlled clinical trials. These include thiopentone,[8] corticosteroids,[9] lidoflazine,[10] nimodipine,[11] magnesium,[12] diazepam[12] and inhaled xenon.[13] However, none of these showed improved neurological or overall outcomes compared with standard care.

Current clinical trials are examining the optimal management of patients with different targets for oxygen, carbon dioxide and temperature.

Oxygenation after resuscitation

In patients who have experienced out-of-hospital cardiac arrest (OHCA) and have initially been successfully resuscitated, achieving ROSC but remaining unconscious, paramedics administer 100% oxygen using a bag-valve oxygen reservoir connected to an endotracheal tube or supraglottic airway during transport to the ED. This 'hyperoxia' therapy usually continues in the ED, during intra-hospital transfer to the cardiac catheterization laboratory and into the ICU. Once the patient has been admitted to the ICU, the oxygen fraction on the ventilator is generally decreased, with a target pO_2 within the normal range (70 to 100 mm Hg).

There are data from laboratory studies[14] and a large observational clinical study[15] indicating that hyperoxia during the initial hours following resuscitation from OHCA may increase neurological injury compared with a lower fraction of inspired oxygen. The most compelling animal study demonstrating possible harm from hyperoxia after resuscitation was done by Balan et al.[16] This study involved cardiac arrest for 10 minutes in anaesthetized animals without any resuscitation attempt followed by 3 minutes of chest compressions and ventilation with 100% oxygen and then defibrillation and adrenaline administration to restore spontaneous circulation. The animals allocated to hyperoxia continued to receive 100%

oxygen for 1 hour after resuscitation, after which time the oxygen was decreased to physiological normal PaO_2 levels. The animals allocated to normoxia received 100% oxygen during resuscitation, but immediately following ROSC the oxygen fraction was reduced to 50%. Thereafter, 5% reductions in the fraction of inspired oxygen (FiO_2) were performed every 2 minutes until an oxygen saturation less than 96% was seen on the pulse oximeter. This oxygen titration strategy resulted in a FiO_2 between 21% and 30% within 12 minutes of ROSC. The neurological performance outcomes in this animal study were assessed 24 hours post ROSC and subsequently histological examination of the brain was undertaken to compare the extent of the neuronal damage in the two groups. The strategy of titration towards normal oxygen levels resulted in both better neurological function in performance testing and reduced hippocampal neuronal injury on histological examination.

In adults, observational clinical studies have compared normoxia with hyperoxia in post–cardiac arrest patients.[15,17,18] One study used data from 120 ICUs in the United States for patients admitted between 2001 and 2005.[15] Patients were divided into three groups based on the PaO_2 on the first arterial blood gas values obtained in the ICU. Hyperoxia was defined as a PaO_2 of 300 mm Hg or greater; hypoxia was defined as a PaO_2 of less than 60 mm Hg and normoxia was defined as an oxygen level between these two levels. Of 6326 patients, 1156 had hyperoxia (18%), 3999 had hypoxia (63%) and 1171 had normoxia (19%). The hyperoxia group had significantly higher in-hospital mortality (63%; 95% CI 60% to 66%) compared with the normoxia group (45%; 95% CI, 43% to 48%), with a proportion difference of 18% [95% CI, 14% to22%]. After adjustment for potential confounders (e.g. age, preadmission functional status, co-morbid conditions, vital signs, and other physiological indices), hyperoxia on initial arterial blood gas analysis on admission to the ICU had an odds ratio (OR) for death at hospital discharge of 1.8 (95% CI, 1.5 to 2.2) compared with normoxia. However, this study did not adjust for several aspects of cardiac arrest that would be expected to have an effect on mortality rate, such as initial cardiac rhythm and cardiac arrest duration.

There have also been several other observational studies examining the relationship between oxygen level in the ICU and outcomes in patients admitted after cardiac arrest. In one study of 12,108 patients admitted to Australian ICUs after resuscitation from in-hospital and out-of-hospital cardiac arrest, 1285 (10.6%) had hyperoxia, 8904 (73.5%) had hypoxia and 1919 (15.9%) had normoxia on the blood gas values entered into the dataset.[17] The hyperoxia group had higher mortality (59%, 95% CI 56% to 61%) compared with the normoxia group (47%, 95% CI, 45% to 50%), with a proportional difference of 11% (95% CI, 8% to 15%). In a multivariable model controlling for some potential confounders, including illness severity, hyperoxia was associated with a higher rate of hospital death (OR 1.2, 95% CI, 1.1 to 1.6).

Whilst the previously mentioned study included both in-hospital and out-of-hospital cardiac arrest patients, a subsequent study identified patients with OHCA by matching patients from the Victorian Ambulance Cardiac Arrest Registry (VACAR) and the Australian and New Zealand Intensive Care Society database (ANZICS-APD).[18] In that study, 957 patients identified on the VACAR database met the inclusion criteria; of these, 584 (61%) were matched to the ANZICS-APD and had both oxygen data from the ICU and outcome at hospital discharge. The unadjusted hospital mortality was 41% in the normoxia patients and 47% in the hyperoxia patients (P = .28). After adjustment for bystander cardiopulmonary resuscitation, patient age and cardiac arrest duration, hyperoxia in the ICU was not significantly associated with a difference in hospital mortality (OR, 1.2; 95% CI, 0.51 to 2.82; P = .83). However, in the ANZICS-APD dataset used for these Australian studies, the lowest/highest arterial oxygen in the first 24 hours was recorded rather than the first arterial blood gas after admission. Thus studies using the ANZICS-APD might not accurately reflect the fraction of oxygen administration early after admission to the ICU.

In newborn babies, clinical trials have shown that neonatal mortality is reduced when room air is used during resuscitation compared with 100% oxygen treatment.[19] It is now routine for newborn babies to be resuscitated with room air rather than supplemental oxygen.

In addition to the possible injury to the brain caused by 100% oxygen after reperfusion, there is evidence of injury to the heart from liberal oxygen administration during reperfusion. The Air versus oxygen in myocardial infarction (AVOID) trial randomized awake patients with chest pain and ST-segment elevation myocardial infarction (STEMI) to either air or supplemental oxygen at 8 L/min during transport to hospital and cardiac catheterization.[20] In 441 patients, there was a significant increase in the area under the curve in the creatinine kinase levels and an increase in the area under the curve in the troponin levels; these approached significance. These data suggest that additional oxygen may increase injury to the myocardium during reperfusion in alert patients with myocardial ischaemia. Given that approximately 40% of comatose post-arrest patients have STEMI on the 12-lead electrocardiogram,[1] it may be that supplemental oxygen increases cardiac injury as well as neurological injury in the post-ROSC patient.

Given that observational studies have suggested that a decrease in oxygen fraction towards normoxia improved outcome in post-arrest patients, preliminary clinical trials have been undertaken to prospectively compare a titrated oxygen approach with a hyperoxia approach. In a Finnish study, patients were randomized to be ventilated either with 30% or 100% oxygen for the first 60 minutes following resuscitation from cardiac arrest.[21] The oxygen saturation was kept above 94% using a mechanical ventilator, which allowed titration of the administered oxygen fraction. In 28 patients, the mean PaO_2 at 10 minutes was 21.1 kPa in the titrated oxygen group compared with 49.7 kPa in the 100% oxygen group. The corresponding values at 60 minutes were 14.6 and 46.5 kPa. No patient in the 100% oxygen group became hypoxic, whereas the inspired oxygen had to be increased in five cases (36%) in the titrated group. This study concluded that during the immediate post-resuscitation period, most patients had acceptable oxygenation when ventilated with 30% oxygen.

However, many ambulance services do not use mechanical ventilators with oxygen blenders during post-ROSC transport to the receiving hospital. Instead, ventilation with supplemental oxygen is delivered using a bag-valve device with oxygen reservoir connected to an endotracheal tube or supra-glottic airway. The titration of oxygen in the pre-hospital setting would therefore require a decrease in the oxygen flow into this type of device. In a laboratory setting, the fraction of administered oxygen has been measured using different oxygen input flows into the bag/reservoir.[22] It was found that a 600-mL breath at 10 breaths per minute and an oxygen flow rate greater than 6 L/min delivered almost 100% oxygen but that a flow rate of 2 L/min oxygen delivered a 46% oxygen fraction.

In a New Zealand study by Young et al., 17 post-arrest patients were randomised to receive either titrated oxygen using this decrease in the oxygen flow into the bag-valve reservoir or 100% oxygen commencing in the pre-hospital setting.[23] The target oxygen saturation in the titrated oxygen group was 90% to 94%. The study found that low measured saturation (SpO_2 < 88%) occurred in 7 of 8 of patients in the titrated oxygen group and 3 of 9 of patients in the group receiving standard care (P = .05). However, the quality of the readings of all pulse oximeters in this study was uncertain, since all readings during the pre-hospital period were uploaded from the patient monitor instead of readings recorded by paramedics with a confirmed adequate trace. Thus many readings may have been included where the finger probe was displaced. Nevertheless, this study suggested that caution is needed during the titration of oxygen using a decrease in oxygen flow rate in patients receiving bag-valve ventilation to avoid hypoxia.

Overall, the data indicate that phase 3 randomized controlled trials comparing a strategy of titrated oxygen to a target of 90% to 94% as soon as possible following resuscitation from OHCA compared with the current practice of maintaining a higher oxygen saturation until ICU arrival should be conducted. Ideally these studies would enrol patients with an oxygen saturation greater than 94% on pulse oximetry immediately or as soon as possible after ROSC to either 100% oxygen or titration of oxygen to a target SpO2 of 90% to 94%. The optimal duration of such a titrated oxygen approach is uncertain, but it should at least be commenced as soon as possible after ROSC and maintained during transport to hospital, initial evaluation in the ED, in the cardiac catheterization laboratory and into the ICU. The major risk in such a study is the development of hypoxia, although this should be able to be rapidly corrected by immediately increasing oxygen administration.

Carbon dioxide titration

Another area of uncertainty in patient management following resuscitation from cardiac arrest is the optimal target for carbon dioxide level.[24] The CO_2 level has an effect on cerebral blood flow, with hypocapnia causing cerebral vasoconstriction leading to decreased cerebral blood flow and hypercapnia causing cerebral vasodilation leading to increased cerebral blood flow.

In patients who remain comatose following resuscitation from cardiac arrest, there is evidence that cerebral hypoperfusion occurs for at least some hours following resuscitation.[25] This hypoperfusion in the early post-arrest period may be due to decreased cerebral perfusion pressure because of hypotension, but there is also evidence of increased cerebral vascular resistance, most likely due to impaired cerebral auto-regulation.[26] Raised intracranial pressure is uncommon in cardiac arrest of cardiac cause but may be present in the case of asphyxia arrest following choking, hanging or drowning. Such raised intracranial pressure would also be expected to decrease cerebral blood flow.

One factor in the regulation of cerebral blood flow that can be monitored and titrated is the arterial pCO_2 level.[27] The pCO_2 may be increased by decreasing the minute ventilation in the unconscious patient who is receiving assisted ventilations. Given the evidence of decreased cerebral blood flow after cardiac arrest, an increase in the arterial pCO_2 would be expected to increase blood flow to ischaemic areas of the brain and possibly improve neuronal recovery. In addition, increasing $PaCO_2$ levels after resuscitation from cardiac arrest may have anti-convulsive, anti-inflammatory and anti-oxidant properties that might lead to a decrease in the inflammatory component of reperfusion injury.[28]

In an observational study using data from the ANZICS-APD, the association of the pCO_2 values during the first 24 hours was compared with survival at hospital discharge in 16,542 post–cardiac arrest patients admitted to 125 Australia and New Zealand ICUs between 2000 and 2011.[29] During the study period, the usual practice in Australian ICUs was to target normocapnia in post-arrest patients. This study found that hypocapnia was associated with a decrease in survival, whereas mild hypercapnia was associated with a 16% increase in survival.

In another observational study conducted in 21 ICUs in Finland, the pCO_2 levels in 409 post–cardiac arrest patients were measured and assessed for the relationship to outcomes using cerebral performance category at 12 months as the primary end point.[30] The mean $PaCO_2$ level during the first 24 hours was an independent predictor of good outcome (OR 1.054; 95% CI, 1.006 to 1.104; $P = .027$). With multivariate regression analysis, a $PaCO_2$ greater than 45 mm Hg was associated with good outcome (OR 1.015; 95% CI, 1.002 to 1.029; $P = .024$) for each percentage point increase in time.

The effect of mild hypercapnia on regional cerebral tissue oxygen saturation ($SctO_2$) has been assessed using near infrared spectroscopy.[31] In a prospective double cross-over study of seven post–cardiac arrest patients, Eastwood et al. measured the $SctO_2$ during normocapnia ($PaCO_2$ 35 to 45 mm Hg) and mild hypercapnia ($PaCO_2$ 45 to 55 mm Hg).[30] During normocapnia, the median left frontal $SctO_2$ was 61% (52% to 65%) and the right frontal $SctO_2$ was 61% (54% to 68%). During mild hypercapnia, the median left frontal $SctO_2$ increased to 69% (59% to 78%) and the right frontal $SctO_2$ increased to 73% (61% to 76%) ($P = .001$). These data suggest that mild hypercapnia improves cerebral oxygenation, presumably due to increased cerebral blood flow.

A phase 2 study randomizing patients after resuscitation from cardiac arrest to either normocapnia or mild hypercapnia has been undertaken.[32] This multi-centre randomized controlled trial allocated 50 mechanically ventilated post–cardiac arrest patients to either 24 hours of normocapnia ($PaCO_2$ 35 to 45 mm Hg) or mild hypercapnia (pCO_2 50 to 55 mm Hg). The primary outcome measure was serum neuron-specific enolase (NSE) concentration over the first 72 hours. The NSE concentrations were increased in both groups over the first 36 hours, with the increase being significantly higher in the normocapnia patients ($P = .04$). These data suggest that mild hypercapnia for the first 24 hours after cardiac arrest might decrease neurological injury.

Given these supportive data, there is a compelling case for phase 3 clinical trials to be conducted comparing a strategy of mild therapeutic hypercapnia (pCO_2 50 to 55 mm Hg) compared with normocapnia (pCO_2 35 to 45 mm Hg) in patients at risk of neurological injury after cardiac arrest. Such a trial would not be feasible in the pre-hospital setting, since that $ETCO_2$ may not correlate accurately with the arterial pCO_2. However, after hospital admission and an initial arterial blood gas analysis to correlate the pCO_2 with the $ETCO_2$, the patient could then be allocated to a lower minute volume on the ventilator using a muscle relaxant and sedation to decrease triggering of the ventilator. In addition, given that TTM is usually undertaken in this patient group, the pCO_2 would need to be measured using alpha-stat for arterial blood gas analysis.[33]

Blood pressure target

The current recommendation for a target optimal systolic blood pressure after resuscitation from cardiac arrest is that the blood pressure be maintained in the normal range.[3] This is based on observational data suggesting that hypotension after resuscitation is associated with worse outcomes.

The largest study to date to ascertain the relationship between blood pressure after resuscitation and outcomes was conducted by Bray et al.[34]; it examined data from the VACAR. In 3620 patients, a systolic blood pressure below 90 mm Hg was associated with lower survival, suggesting that systolic blood pressure should be increased towards 100 mm Hg. However, there are no prospective clinical data that detail whether a lower blood pressure should be increased using intravenous fluid therapy and/or pressor therapy.

Targeted temperature management

TTM between 32°C and 36°C is currently recommended in patients who remain comatose after resuscitation from cardiac arrest.[3] It is thought that a higher temperature increases cerebral oxygen demand without increasing cerebral oxygen supply and thus leads to cerebral ischaemia.

In 2001, two prospective, controlled human studies suggested improved outcome using moderate therapeutic hypothermia (TH) (32°C to 34°C) in comatose survivors of pre-hospital cardiac arrest.[35,36] In one study, 43 patients were randomized to TH (33°C for 12 hours) and 34 were maintained at normothermia.[35] Hypothermia was induced in the ED using surface cooling with ice packs and this was maintained for 12 hours in the ICU. At hospital discharge, 21 of 43 (49%) patients in the TH group had a good outcome compared with 9 of 34 (26%) in the control group ($P = .046$). Following multivariate analysis for differences at baseline, the OR for good outcome in the hypothermic group was 5.25 (95% confidence intervals [CI] of 1.47 to 18.76: $P = .011$). There were no adverse effects of the hypothermia such as sepsis, lactic acidosis or coagulopathy.

A second clinical trial of TH after cardiac arrest was conducted in Europe.[36] This study enrolled 273 comatose survivors of PHCA, with 136 patients undergoing TH (33°C for 24 hours) and 137 patients maintained at normothermia. Hypothermia was induced in the ED and ICU using a refrigerated air mattress. At 6 months post-arrest, 55% of the TH patients had a good outcome compared with 39% of the normothermic controls (OR 1.4, 95% CI 1.08 to 1.81). The complication rate did not differ between the two groups.

In 2013, a larger trial comparing 33°C with 36°C was conducted in Europe and Australia.[37] In total, 939 patients were randomized after admission to the ICU. At the end of the trial, 50% of the patients in the 33°C group had died, compared with 48% of the patients in the 36°C group (hazard ratio with a temperature of 33°C, 1.06; 95% CI, 0.89 to 1.28; $P = .51$). At the 180-day follow-up, 54% of the patients in the 33°C group had died or had poor neurological function compared with 52% of patients in the 36°C group (risk ratio, 1.02; 95% CI, 0.88 to 1.16; $P = .78$). It was concluded that TH at a targeted temperature of 33°C did not confer a benefit as compared with a targeted temperature of 36°C.

Subsequently one before/after study indicated that 36°C was difficult to maintain, presumably due to the more vigorous shivering that occurs at 36°C compared with 33°C.[38] In a study over a 30-month period, 76 patients who were admitted to a single centre after resuscitation from ventricular fibrillation were allocated to 33°C (24 patients) or 36°C (52 patients). Patient demographics, cardiac arrest features and hospital interventions were similar between the two periods. After the change to a target from 33°C to 36°C, fewer patients received active cooling (100% vs. 70%, $P < .001$), patients spent less time at target temperature (87% vs. 50%, $P < .001$), and fever rates increased (0% vs. 19%, $P = .03$). During the 36°C period, there was also a decrease in the proportion of patients who were discharged alive (71% vs. 58%, $P = .31$), discharged to home (58% vs. 40%, $P = .08$); or with a favourable neurological outcome (cerebral performance category score 1 to 2: 71% vs. 56%, $P = .22$).

These data suggest that a target temperature of 36°C is more difficult to maintain than a target temperature of 33°C. However, it remains unclear whether 36°C is significantly better for recovery compared with a more normal temperature (36.5°C to 37.5°C); thus further larger studies are needed to compare a target of 33°C with normal temperature in this patient group.

Summary

Neurological injury is common in patients resuscitated from prolonged cardiac arrest. In addition to the usual supportive measures, such as endotracheal intubation and blood pressure correction, patients who remain comatose after ROSC should receive oxygen, ventilation, blood pressure and temperature management that targets the normal range.

2.8 Anaphylaxis

Anthony F.T. Brown

ESSENTIALS

1 **The term *anaphylaxis* describes both immunoglobulin E (IgE) immune–mediated reactions and non-allergic, non-immunologically triggered events. Co-morbidities—such as asthma, infection, exercise, alcohol and stress or concurrent medications such as β-blockers, angiotensin converting enzyme inhibitors and aspirin—increase the risk ('summation anaphylaxis').**

2 **Deaths occur by hypoxia from upper airway asphyxia or severe bronchospasm or by profound shock from vasodilatation and extravascular fluid shift.**

3 **Parenteral penicillin, Hymenoptera stings and foods are the most common causes of IgE immune–mediated fatalities. Radiocontrast media, aspirin and other non-steroidal anti-inflammatory drugs are the most common causes of non-allergic fatalities. The asthmatic patient and the older patient with ischaemic heart disease or on treatment with a β-blocker are at highest risk of death.**

4 **Oxygen, adrenaline (epinephrine) and fluids are first-line treatment.**

5 **The role of H_1 and H_2 antihistamines, steroids, glucagon and salbutamol is unclear and unproven. They should be considered only once cardiovascular stability has been achieved with first-line agents.**

6 **Discharge follows a period of observation from 4 to 6 hours after full recovery. A written discharge plan—with adrenaline autoinjector and referral to an allergist for all significant, recurrent, unavoidable or unknown stimulus reactions—is essential. Patient education is important to successful long-term care.**

7 **Two comprehensive practice guidelines recently released include those of the Joint Task Force on Practice Parameters (2015) in the United States and the European Academy of Allergy and Clinical Immunology (2014).**

Introduction

Anaphylaxis represents the most catastrophic of the immediate-type generalized hypersensitivity reactions and remains the quintessential medical emergency. It usually occurs unheralded in otherwise healthy people following exposure to a trigger. It presents as a dynamic continuum from mild to severe, gradual in onset to fulminant; it may involve multiple organ systems or cause isolated shock or wheeze. Prompt clinical recognition and treatment with adrenaline, oxygen and fluids to restore cardiorespiratory stability is essential to ensure a favourable outcome. Careful discharge planning, including allergy referral where appropriate, protects against further attacks of anaphylaxis.

Definition

The term 'anaphylaxis' was introduced by Richet and Portier in 1902, literally meaning 'against protection'. It is currently used to describe the rapid, generalized and often unheralded immunologically mediated events in previously sensitized persons that follow exposure to certain foreign substances. This is known as antigen-induced or immune-mediated allergic anaphylaxis.

An identical clinical syndrome known as non-allergic anaphylaxis follows non-immunological mechanisms, with the release of identical inflammatory mediators. Non-allergic anaphylaxis may occur on first exposure to an agent and does not require a period of sensitization. The term 'non-allergic anaphylaxis' is preferred by the World Allergy Organization (WAO) to the older 'anaphylactoid reaction'.[1] In this chapter the clinical term 'anaphylaxis' is used to describe *both* of these syndromes despite their important aetiological differences.

Classification of anaphylaxis

Surprisingly there is still no international agreement on the classification, diagnosis or severity grading of anaphylaxis.[2] One simple definition is that anaphylaxis is 'a serious, life-threatening generalized or systemic hypersensitivity reaction'.[1] Similarly, the National Institute of Allergy and Infectious Disease (NIAID) and the Food Allergy and Anaphylaxis Network (FAAN) recommend an equally brief, broad definition: 'Anaphylaxis is a serious allergic reaction that is rapid in onset and may cause death'.

The NIAID/FAAN full definition is considerably longer yet more complete, aiming to capture over 95% of clinical cases within the three diagnostic criteria.[3] Criterion 1 should identify at least 80% of anaphylaxis cases even if the allergic status of the patient and potential cause of the reaction may be unknown, as the majority of anaphylactic reactions include skin symptoms. Criterion 2 is to identify anaphylaxis in the absence of cutaneous features, as in children with food allergy or insect sting allergy, but it requires a known allergic history and possible exposure. Gastrointestinal symptoms are included. Criterion 3 captures the rare patient with an acute hypotensive episode after exposure to a known allergen (Box 2.8.1).[3] Until they are refined by future prospective data, these inclusive definitions for anaphylaxis should be used by researchers.[4]

Severity grading

There is no validated grading system that prospectively links the clinical features of anaphylaxis with severity, urgency, treatment or outcome. One system based on a retrospective multivariate analysis of over 1000 clinically diagnosed generalized hypersensitivity reactions defined three grades (Table 2.8.1).[5] Generalized allergic reactions confined to the skin and subcutaneous tissues were considered as mild grade, but the moderate and severe grades with multisystem involvement that correlated with the need for adrenaline represent true anaphylaxis according to the NIAID/FAAN criteria. Again, this grading system should be used as a starting point by researchers for descriptive purposes until prospective data in the future refine the criteria.

Aetiology

Important clinical categories of anaphylaxis include anaphylaxis related to medications, biologics and vaccines as well as to insect stings, foods, anaesthesia, natural rubber latex (NRL) exposure, exercise and idiopathic anaphylaxis (Box 2.8.2).[1,6] Geographic variations are reported,

Box 2.8.1 Definition of anaphylaxis: clinical criteria for diagnosis

Anaphylaxis is highly likely when any one of the following three criteria are fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue or both (e.g. generalized hives, pruritus or flushing, swollen lips-tongue-uvula) and at least one of the following:
   - Respiratory compromise (e.g. dyspnoea, wheeze-bronchospasm, stridor, reduced PEF, hypoxaemia)
   - Reduced BP or associated symptoms of end-organ dysfunction (e.g. hypotonia [collapse], syncope, incontinence)
2. Two or more of the following that occur rapidly after exposure to a *likely allergen for that patient* (minutes to several hours):
   - Involvement of the skin-mucosal tissue (e.g. generalized hives, itch-flush, swollen lips-tongue-uvula)
   - Respiratory compromise (e.g. dyspnoea, wheeze-bronchospasm, stridor, reduced PEF, hypoxaemia)
   - Reduced BP or associated symptoms (e.g. hypotonia [collapse], syncope, incontinence)
   - Persistent gastrointestinal symptoms (e.g. crampy abdominal pain, vomiting)
3. Reduced BP after exposure to *known allergen for that patient* (minutes to several hours):
   - Infants and children: low systolic BP (age-specific) or greater than 30% decrease in systolic BP[a]
   - Adults: systolic BP of less than 90 mm Hg or greater than 30% decrease from that person's baseline

[a]Low systolic blood pressure for children is defined as less than 70 mm Hg from 1 month to 1 year; less than 70 mm Hg + 2 × age from 1 to 10 years; and less than 90 mm Hg from 11 to 17 years. (Reproduced with permission from Sampson HA, Munoz-Furlong A, Campbell RL, et al. Second symposium on the definition and management of anaphylaxis: summary report—Second National Institute of Allergy and Infectious Disease/Food Allergy and Anaphylaxis Network symposium. *J Allergy Clin Immunol.* 2006;117:391–397).
BP, Blood pressure; *PEF*, peak expiratory flow.

Table 2.8.1 Severity grading system for generalized hypersensitivity reactions

Grade	*Defined by*
1: Mild[a] (skin and subcutaneous tissues only)	Generalized erythema, urticaria, periorbital oedema or angio-oedema
2: Moderate[b] (features suggesting respiratory, cardiovascular or gastrointestinal involvement)	Dyspnoea, stridor, wheeze, nausea, vomiting, dizziness (presyncope), diaphoresis, chest or throat tightness or abdominal pain
3: Severe[b] (hypoxia, hypotension or neurological compromise)	Cyanosis or $SpO_2 \leq 92\%$ at any stage, hypotension (SBP < 90 mm Hg in adults), confusion, collapse, LOC or incontinence

[a]Mild reactions can be further subclassified into those with and those without angio-oedema.
[b]Only grades 2 and 3 constitute true anaphylaxis. (Reproduced with permission from Brown SGA. Clinical features and severity grading of anaphylaxis. *J Allergy Clin Immunol.* 2004;114:371–376).
LOC, Loss of consciousness; *SBP*, systolic blood pressure; *SpO_2*, oxygen saturation on pulse oximetry.

such as sesame anaphylaxis in the Middle East and chickpea and rice reactions in Asia.

Drug-induced anaphylaxis

Penicillin is the most common cause of drug-induced anaphylaxis. Around 1:500 patient courses have an apparent allergic reaction, mostly urticaria alone.[7] True allergic cross-reactivity to cephalosporins occurs in only around 1% to 2% and occurs largely with the first-generation cephalosporins.

Aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) are the next most common cause of drug-induced anaphylaxis. Reactions appear to be medication-specific, as there is no clinical cross-reactivity with structurally unrelated NSAIDs.[6] Finally, reactions to chemotherapy drugs such as cis-/carboplatinum and doxorubicin are becoming increasingly common as their use increases, as are reactions to monoclonal antibodies including omalizumab, cetuximab and rituximab. Reactions to these biological modifiers may be delayed up to 12 to 24 hours, which in the case of cetuximab may relate to IgE directed against galactose-α-1,3-galactose (α-gal).

Valid tests for IgE-mediated reactions are unavailable for most drugs or biologics with the exception of the penicillins. Supervised by an allergy/immunology specialist, short-term desensitization may be possible.

Insect sting anaphylaxis

Reactions to stings from bees, wasps and ants of the order Hymenoptera are second only to drug-induced anaphylaxis and occur in up to 3% of the population (<1% of children). Fatalities are more common in adults, often from shock. Non-anaphylactic toxic, large local or late serum sickness–like reactions also occur following a sting.

Food-induced anaphylaxis

This is most common in the young, particularly after the ingestion of peanuts, tree nuts (such as walnuts and pecans), shellfish, fin fish, cow's milk, wheat, soy and egg—the eight most common ingredients that trigger 90% of all food allergies. They are referred to as 'The Big-8' and are included among the food products that require mandatory labelling. Cross-reactivity with other foods is unpredictable or reactions may occur to additives, such as carmine, metabisulphite and tartrazine. Mislabelling and contamination during manufacturing or at home causes inadvertent exposure, and associated factors such as exercise after food must be recognized (see later).

Although fatalities are rare and usually associated with pre-existing asthma, biphasic reactions are seen; similar to all the other causes, this means that the symptoms subside only to recur several hours later. Patient and carer education is paramount, with schools in particular prepared to respond with auto-injector adrenaline (epinephrine)—as with the EpiPen or EpiPen Jr or the Anapen or Anapen Jr—in an emergency.

Anaesthesia-related anaphylaxis

Perioperative anaphylaxis

Neuromuscular blocking agents and latex cause most cases, followed by antibiotics and induction drugs; but opioids, NSAIDs, colloids, blood products, radiocontrast dye, isosulphan or methylene blue, methylmethacrylate, chlorhexidine and protamine may be responsible for 'perioperative anaphylaxis'. One published report of median annual incidence from France was gave a figure of 100:1,000,000 anaesthetics, of which 73% were IgE-mediated.[8] Other estimates range from 1:4000 to 1:25,000 anaesthetics, with up to 4% of reactions fatal.

General anaesthesia reactions are due to muscle relaxants in 60% of cases, with suxamethonium and rocuronium in the highest-risk group. Reactions to suxamethonium and other relaxants can occur in the absence of prior use, suggesting cross-reactivity and rendering large-scale preoperative testing unfeasible.

Latex-induced anaphylaxis

Health care workers, children with spina bifida and those with genitourinary abnormalities who undergo multiple surgical procedures as well as individuals subjected to occupational exposure are the highest-risk groups for NRL allergy. Atopy and cross-reacting fruit allergy are also associated with an increased risk. Reactions may follow direct contact, parenteral contamination or aerosol transmission.

Patients at known high risk require treatment in a latex-free environment with special syringes and non-latex–containing gloves, stethoscopes, breathing-systems, blood pressure cuffs, intravenous tubing and administration ports. Every emergency department (ED) must have the capacity to support an unexpected case of latex allergy, perhaps by sharing with the anaesthesia

Box 2.8.2 Causes of anaphylaxis

IgE-dependent mechanisms

Drugs, chemicals and biological agents

Penicillins, cephalosporins, sulphonamides, muscle relaxants, vaccines, insulin, thiamine, protamine, gamma globulin, cis-/carboplatinum and doxorubicin, monoclonal antibodies cetuximab/rituximab, antivenoms, formaldehyde, ethylene oxide, chlorhexidine, semen

Foods

Peanuts, tree nuts, shellfish, fin fish, milk, egg, fruits, vegetables, sesame, flour

Hymenoptera sting venom, insect saliva, other venoms

Bees, wasps, ants, hornets, ticks, triatomid 'kissing bugs', snakes, scorpions, jellyfish

Natural rubber latex

Environmental

Pollen, horse dander, hydatid cyst rupture

Non-IgE–dependent mechanisms

Physical factors

Exercise, cold, heat, sunlight

Medications and biological agents

Opiates, aspirin and NSAIDs, ACEIs, vancomycin, radiocontrast media, N-acetylcysteine, fluorescein

Food additives

Metabisulphite, tartrazine

Idiopathic

Exclusion of all known causes including mastocytosis

Several mechanisms may coexist, such as exercise-induced following food.
Non-IgE–dependent mechanisms include complement activation, kinin production or potentiation and direct mediator release.
ACEI use is an important cause of unexplained angioedema, occurring in up to 1:200 patients on these drugs; it may develop at any interval after starting (most commonly early on).
Note: Cross-reactivity is seen; both IgE-dependent and non-IgE-dependent reactions may occur with the same agent.
ACEIs, Angiotensin converting enzyme inhibitors; *NSAIDs*, non-steroidal, anti-inflammatory drugs.

department access to a 'latex allergy resuscitation cart' containing relevant latex-free equipment. A clear patient warning should be posted in the ED at the time and staff access should be limited.

Exercise-induced anaphylaxis

Anaphylaxis occurs with a variety of physical activities, although up to 50% of exercise-induced reactions occur following the ingestion of a food or are associated with prior aspirin or NSAID use or high pollen levels. Mast cell degranulation appears to be triggered by cross-linking of allergen-specific IgE combined with neuropeptide release by adjacent nerve endings.

The severity of symptoms is generally influenced by the amount of food ingested, the vigour of the exercise and the lapse of time between the two, with more severe reactions occurring with exercise soon after food ingestion. Prophylactic medication is ineffective, unlike prophylactic salbutamol or sodium cromoglycate that prevent exercise-induced asthma.

Idiopathic anaphylaxis

This is defined as anaphylaxis in which no discernible causative allergen, inciting physical factor or disease state can be identified. The diagnosis is by exclusion, with the majority of cases seen in adults, of whom 50% are atopic, although it does also occur in children. Among other conditions, indolent systemic mastocytosis and hereditary or acquired angio-oedema require exclusion.

Co-factors 'summation anaphylaxis'

Many co-factors and co-morbidities or concurrent medications increase the risk of anaphylaxis, giving rise to the concept of 'summation anaphylaxis'.[9] These include asthma, severe atopy (which predisposes to some types of anaphylaxis, such as latex or exercise-induced), intercurrent infection, cardiac disease, exercise, alcohol, psychological stress, premenstrual status and drugs (see later).[1]

Summation anaphylaxis may also explain the unpredictable response of some individuals to recurrent antigen exposure.

Predisposing drugs

Drugs that predispose to or worsen anaphylactic reactions include β-adrenergic blockers, NSAIDs and the angiotensin converting enzyme inhibitors (ACEIs). ACEIs and to a much lesser extent angiotensin II receptor blockers (ARBs) together with the gliptins are associated in particular with non-histaminergic, bradykinin-related angioedema.

Epidemiology

The true incidence of anaphylaxis is unknown. With the lack of a standard definition, data are unreliable and are mostly derived from retrospective case collections from sources as diverse as the ED, perioperative reports or the allergist/immunologist's office. Under-reporting is common, as the diagnosis may have been missed or there may have been spontaneous recovery, pre-hospital treatment or a fatality. However, despite this, all anaphylaxis data from Western countries show that the incidence is increasing.[1,10]

Emergency department anaphylaxis

ED anaphylaxis presentations in adults have an annual incidence from 1:439 to 1:1100 ED cases, representing up to one adult presentation per 3400 population per year.[11] The annual incidence of paediatric anaphylaxis is around 1:1000 ED presentations, although generalized allergic reactions in children (that is, without multisystem involvement) are nearly 10 times more common than this.[12]

The causative agent is suspected in 75% of ED anaphylaxis cases, being recognized from a previous reaction or by close temporal association with symptom onset. The most frequent causes in adults are drug-related and due to Hymenoptera stings, whereas food-induced or drug-related causes predominate in children. Respiratory features appear more commonly in paediatric anaphylaxis, as do cardiovascular features in adults.[12]

Fatal anaphylaxis

Deaths follow hypoxia from upper airway swelling with asphyxia, bronchospasm and mucus plugging and from shock related to vasodilatation, extravascular fluid shift and direct myocardial depression. Tachycardia is usual in shock, but bradycardia related to a neurocardiogenic vagally mediated mechanism (Bezold-Jarisch reflex) has occasionally been observed. This may respond to atropine if adrenaline fails (see second-line agents under 'Management').

Fatalities are rare at less than one (0.33 to 0.64) per million population per year.[10,13] When they do happen, fatal reactions are rapid, with a median time to cardiorespiratory arrest of just 5 minutes if iatrogenic, 15 minutes for venom and 30 minutes following foods, with no death occurring greater than 6 hours after contact with a trigger. Adrenaline was given in only 14% of cases prior to arrest and not at all in 38% of fatalities.[13]

Fatal food-induced anaphylaxis in the United Kingdom included 43 of 48 patients having associated asthma, usually with suboptimal daily inhaled steroid use, of which over half had only ever had a mild previous food reaction. This suggests that the severity of subsequent reactions cannot be predicted from the reaction history and that sound professional advice was often inadequate or absent.[14]

Pathophysiology

Triggering events

Most cases of immune-mediated, allergic anaphylaxis are IgE- or occasionally IgG_4-mediated. Reaginic antibodies are released into the circulation by plasma cells derived from B lymphocytes under the influence of helper T cells following previous exposure to an antigen (exactly why this happens is unclear). These antibodies then bind to glycoprotein receptors on blood-borne basophils or tissue mast cells, sensitizing them. A huge variety of substances induce IgE antibody formation, ranging from drugs, chemicals and biological agents, foods, Hymenoptera sting venom, insect saliva and other venoms, to latex and environmental allergens (see Box 2.8.2).

Non-IgE–dependent, non-allergic anaphylaxis

Non-IgE–dependent, non-allergic anaphylactic reactions are caused by mediator release triggered independently of reaginic antibodies, leading to complement activation, the direct pharmacological release of mediators or activation of the clotting/fibrinolysis system. Physical factors, medications, biological agents and food additives may trigger these non-IgE reactions (see Box 2.8.2).

Cellular events

Tissue-based mast cells and circulating basophils release inflammatory mediators following the binding of multivalent allergen cross-linking the surface, high-affinity IgE Fc receptors (FcεRI) or from cell membrane perturbation. This, coupled with the mobilization of Ca^{2+} in the endoplasmic reticulum, leads to release of preformed granule-associated mediators by exocytosis or to the de novo synthesis of eicosanoid lipid mediators from endogenous membrane arachidonic acid stores and the activation of genes for various cytokines and chemokines.[15,16]

Mast cell and basophil inflammatory mediators

The preformed mediators include histamine, serine proteases (such as tryptase, chymase and carboxypeptidase A) and proteoglycans (such as heparin and chondroitin sulphate E). Newly synthesized lipid mediators include prostaglandin D_2 and thromboxane A_2 via the cyclo-oxygenase pathway and the leukotrienes LTC_4, LTD_4 and LTE_4 via the 5-lipoxygenase pathway. The cytokines released include tumour necrosis factor alpha (TNF-α), various interleukins (such as IL-3, IL-5, IL-6, IL-10, IL-13 and IL-16) and granulocyte-macrophage-colony stimulating factor (GM-CSF). Finally, chemokines include platelet activating factor (PAF), neutrophil chemotactic factor (IL-8) and eosinophil chemotactic factor, plus macrophage inflammatory protein 1α.[16]

Modulation of mediator release

At the cellular level, mediator release is modulated by the steady-state resting intracellular cyclic adenosine monophosphate (cAMP) levels. Substances that elevate cAMP, such as adrenaline, inhibit mediator release, partly explaining adrenaline's essential role in treatment. Also, from knowledge of the complex array of mediators involved, it is self-evident why antihistamines cannot form the first line of therapy.

Mediator pharmacology

Mediators act to induce vasodilatation, increase capillary permeability and glandular secretion, cause smooth muscle spasm, particularly bronchoconstriction; they also act to attract new cells such as eosinophils, leucocytes and platelets. Positive feedback mechanisms amplify and perpetuate reactions recruiting further effector cells to release increasing amounts of mediators in a 'mast cell–leucocyte cytokine cascade' effect.[17] In addition, it appears that severe and/or fatal reactions also relate not only to the amount of mediators released but also to the speed of their degradation—for instance in the case of reduced PAF catabolism from lower levels of PAF acetylhydrolase.[1,6]

Conversely, other anaphylactic reactions self-limit, with spontaneous recovery related to endogenous compensatory mechanisms including increased adrenaline, angiotensin II or endothelin 1 secretion.[18]

Box 2.8.3 Clinical features of anaphylaxis

Cutaneous
- Tingling or warmth, erythema (flushing), urticaria, pruritus (itch), angioedema
- Rhinorrhoea, conjunctival injection, lacrimation

Respiratory
- Throat tightness, cough, dyspnoea, hoarseness, stridor, aphonia
- Tachypnoea, wheeze, SpO_2 < 92%,[a] cyanosis[a]

Cardiovascular/neurological
- Tachycardia (rarely bradycardia), hypotension,[a] chest pain,[b] arrhythmia,[b] cardiac arrest[a]
- Light-headedness, sweating, incontinence,[a] syncope,[a] confusion,[a] coma[a]

Gastrointestinal
- Odynophagia (difficult or painful swallowing), abdominal cramps, nausea, vomiting, diarrhoea

Miscellaneous
- Premonitory aura, anxiety, feeling of impending doom
- Pelvic cramps

[a]Indicative of a severe reaction (see Table 2.8.1 for grading system).
[b]From cardiac mast cell-mediated coronary artery spasm (*or* adrenaline-related following treatment).
SpO_2, Oxygen saturation on pulse oximetry.

Clinical features

Anaphylaxis is characteristically a disease of fit patients and is rarely seen or described in critically ill or shocked patients other than asthmatics. The speed of onset relates to the mechanism of exposure and the severity of the reaction. Parenteral antigen exposure may cause life-threatening anaphylaxis within minutes, whereas symptoms can be delayed for some hours following oral or topical exposure.

Cutaneous and generalized allergic reactions

A premonitory aura, tingling or warm sensation, anxiety and feeling of impending doom precede generalized erythema, urticaria with pruritus and angioedema of the neck, face, lips and tongue. Rhinorrhoea, conjunctival injection and tearing are seen.

Eighty to 90% or more of patients with anaphylaxis have cutaneous features that assist in prompt early diagnosis.[11,12,18] However, alerting cutaneous features may be absent because of pre-hospital treatment or their spontaneous resolution, be subtle clinically and missed or the onset of other life-threatening systemic complications, such as laryngeal oedema or shock, may precede them.

Systemic reactions

The hallmark of anaphylaxis is the precipitate onset of multisystem involvement with respiratory, cardiovascular, gastrointestinal and/or neurological system dysfunction (Box 2.8.3).

Respiratory manifestations

Throat tightness and cough precede mild to critical respiratory distress due to oropharyngeal or laryngeal oedema with dyspnoea, hoarseness, stridor and even aphonia, or such manifestations may be related to bronchospasm with tachypnoea and wheeze. Hypoxia with an oxygen saturation less than 92% on pulse oximetry and central cyanosis indicate severe anaphylaxis and the need for immediate treatment (see severity grading in Table 2.8.1).

Cardiovascular and neurological manifestations

Light-headedness, sweating, incontinence, syncope or coma may precede or accompany cardiovascular collapse with tachycardia, hypotension and cardiac arrhythmias, which again herald severe anaphylaxis. These arrhythmias can appear seemingly benign supraventricular rhythms, particularly in children, but can progress to an impalpable pulse requiring external cardiac massage (see severity grading in Table 2.8.1).

Cardiac chest pain Chest pain may occur due to coronary artery spasm from cardiac mast cell release of histamine, leukotrienes and PAF even in the absence of coronary artery disease, or these may be exacerbated when present or subclinical in the older patient.[1,6,18]

Gastrointestinal manifestations

Difficult or painful swallowing, nausea, vomiting, diarrhoea and abdominal cramps occur in up to one-third of cases but are usually overshadowed by the more immediately life-threatening features.

Differential diagnosis

The protean manifestations of anaphylaxis have a potentially vast differential diagnosis, although the rapidity of onset, accompanying cutaneous features and their relationship to a likely or known trigger suggest the true diagnosis in most cases. The following differential diagnoses should be considered.

Wheeze and difficulty breathing

Bronchial asthma, cardiogenic pulmonary oedema, foreign body inhalation, irritant chemical exposure and tension pneumothorax are distinguished by the history, co-morbidity and associated presenting features.

Light-headedness and syncope

An anxiety or vasovagal reaction should be considered where there is a history of exaggerated fear of an impending reaction or in the context of a painful procedure, such as an injection or local anaesthetic infiltration with collapse. Bradycardia, sweating and pallor without urticaria, erythema or itch associated with a brief prodrome and rapid response to the recumbent position favour a vasovagal reaction over anaphylactic shock.

Other forms of shock

Other types of distributive shock, such as septicaemia, spinal denervation, epidural or spinal block; hypovolaemic shock from haemorrhage or fluid loss; cardiogenic shock from primary myocardial dysfunction; and obstructive shock from cardiac tamponade or tension pneumothorax should all be apparent from the history and examination. Cutaneous and respiratory features other than tachypnoea are absent in these non-anaphylactic causes of shock.

Flushing

Scombroid poisoning following spoiled-fish ingestion, carcinoid syndrome, alcohol and systemic mastocytosis all produce flushing and require a careful history and investigation to differentiate.

Facial swelling or angioedema

Bacterial or viral infections usually cause fever and/or pain and traumatic or anticoagulant-related bleeding causes recognizable bruising.

Bradykinin-mediated angioedema in the absence of urticaria or itch can be drug-related such as with ACEIs, or they may be caused by actual or functional C1 esterase inhibitor deficiency (hereditary angioedema). See later.

Use of angiotensin converting enzyme inhibitors

ACEIs are the single most common cause of drug-related angioedema, usually within weeks of commencing the drug; but angioedema may also occur months or years later and even after recently stopping them. The angioedema is non-histaminergic and related to localized bradykinin effects without associated pruritus or urticaria. A similar reaction is also seen with the gliptins.

There is no effective or approved treatment for this type of angioedema, nor does it respond to conventional management with adrenaline or antihistamines, which should not be persisted with.

C1 esterase inhibitor deficiency

This may be hereditary autosomal dominant, with a positive family history, the *absence* of pruritus or urticaria, prominent abdominal symptoms and a history of recurrent attacks related to minor stress. Alternatively, a deficiency of C1 esterase inhibitor may be acquired in lymphoproliferative and some connective tissue disorders. A rapid, inexpensive screening test for serum C4 should be performed and, if low, may be followed by the more specific C1 esterase inhibitor assay to confirm the diagnosis. Management of an attack is with 20 U/kg C1 esterase inhibitor concentrate given intravenously or with 30 mg of icatibant, a bradykinin 2 receptor (B2R) antagonist, given subcutaneously.

Clinical investigations

The diagnosis of anaphylaxis is clinical. No immediate laboratory or radiological test confirms the process and testing must never delay immediate management. The measurement of electrolytes and renal function, blood glucose, chest x-ray and an electrocardiogram (ECG) are indicated only if there is a slow response to treatment or when there is doubt about the diagnosis.

Disease progression may be monitored by pulse oximetry, haematocrit level (which may rise with fluid extravasation), and arterial or venous blood gases to look for a respiratory or metabolic acidosis.

Laboratory testing

This is rarely performed or of immediate clinical relevance and should never delay management.

Mast cell tryptase

Ideally, three samples should be taken for mast cell tryptase (MCT) in liaison with the hospital laboratory—the first as soon as possible after resuscitation has commenced and the next at 1 to 2 hours after the start of symptoms (but no longer than 6 hours) and one at 24 hours or in convalescence (for baseline tryptase levels).[19]

Despite initial promise, a serum MCT taken from 1 to 6 hours after a suspected episode cannot solely be relied upon to diagnose anaphylaxis as it is not consistently elevated above the reference range of 1 to 11.4 ng/mL, particularly following food allergy. Conversely, an MCT assay may be elevated post-mortem in a non-anaphylactic death.[6,19]

However, measuring change in levels 'delta tryptase', specific allelic subtypes such as mature *b* tryptase or using a multimarker approach to include PAF may improve the value of laboratory testing, providing this does not interfere with acute management.

Histamine

Histamine levels are impractical to measure as they are unstable and evanescent, remaining elevated for only 30 to 60 minutes maximum.

Box 2.8.4 Treatment of anaphylaxis

Initial treatment

- Stop delivery of any potential causative agent
- Call for senior help
- Give adrenaline (epinephrine) 0.01 mg/kg IM into upper lateral thigh, to maximum 0.5 mg (e.g. 0.3–0.5 mL of 1:1000 adrenaline [epinephrine] IM).
- May be repeated every 5–15 min.
- Or use patient's EpiPen or Anapen if readily available—may be given through clothing.
- Lay patient supine (or elevate legs) for shock.
- Give high-flow oxygen.
- Insert a large-bore IV cannula (14 or 16 g) and give crystalloid fluid bolus of 10–20 mL/kg for shock.

Deteriorating rapidly or failure to respond

- Start 1:100,000 adrenaline (epinephrine) infusion with 1 mL (1 mg) of 1:1000 adrenaline in 100 mL normal saline at 60–120 mL/h (10–20 µg/min) titrated to response as follows:
- *Must* be on ECG monitor.
- Give faster in cardiopulmonary collapse/arrest.
- Consider assisted ventilation and endotracheal intubation by a skilled emergency doctor (may be technically challenging).

Management

Initial approach

Immediately stop any potential causative agent, such as an intravenous drug or infusion. Manage the patient in a monitored resuscitation area, including at least a pulse oximeter, non-invasive blood pressure device and ECG unit. Call for immediate senior help.

Obtain a brief history of possible allergen exposure and perform a rapid assessment of the extent and severity of the reaction. Look particularly for signs of upper airway swelling, bronchospasm or circulatory shock.

The primary objective is to achieve stabilization of cardiorespiratory status by administering adrenaline (epinephrine), oxygen and fluids to the supine/recumbent patient. Antihistamines and steroids play no role until after this has been achieved; even then, their value is debatable (Box 2.8.4).[3,6]

Oxygen and airway patency

Give oxygen by face mask to all patients, aiming for an oxygen saturation above 92%. Place the patient supine, preferably with the legs elevated to optimize venous return. Elevate the head and torso if respiratory distress is prominent or worsened. Prepare for active airway intervention, including opening the difficult airway kit if there are signs of impending airway obstruction or rapidly progressive respiratory failure.

Cyanosis and exhaustion indicate imminent respiratory arrest. Never give a sedative or muscle relaxant drug unless you are well trained in the management of the difficult airway, as endotracheal intubation and mechanical ventilation can be extremely challenging. Perform a surgical airway via the cricothyroid membrane as a last resort before hypoxic cardiac arrest occurs.

Adrenaline (epinephrine)

Adrenaline is the drug of choice for acute anaphylaxis, whether allergic IgE-mediated or non-allergic. Give adrenaline in all but the most trivial cases and certainly if there is progressive airway swelling, bronchospasm or hypotension. Adrenaline has α-, β_1- and β_2-adrenergic effects to counteract profound vasodilatation, mucosal oedema and bronchospasm. Equally important is that adrenaline triggers a rise in intracellular cyclic AMP, thus inhibiting further mast cell and basophil mediator release.[1,6]

Adrenaline (epinephrine) dose

The dose of adrenaline is 0.01 mg/kg up to a maximum of 0.5 mg intramuscularly (IM), repeated every 5 to 15 minutes as necessary. Give this as 0.01 mL/kg of 1:1000 aqueous adrenaline or 0.3 to 0.5 mL (0.3 to 0.5 mg) into the upper outer thigh.

The adrenaline may be injected through clothing in an emergency, including when self-administered pre-hospital, using an EpiPen or EpiPen Jr containing 300 and 150 µg, respectively, or Anapen or Anapen Jr (same respective adrenaline doses).

Adrenaline (epinephrine) route

Intramuscular adrenaline Intramuscular adrenaline is recommended when anaphylaxis is treated early, progressing slowly, venous access is difficult or delayed or in the unmonitored patient. The intramuscular route is superior to the subcutaneous and the vastus lateralis muscle in the thigh is preferred to the deltoid muscle in the arm. Adrenaline given IM is successful in the large majority of cases, particularly if given promptly.[1]

Intravenous adrenaline Intravenous adrenaline is necessary only if there is rapidly progressive vascular collapse with shock, imminent airway obstruction or critical bronchospasm and/or impending cardiac arrest. The patient must have ECG monitoring and an experienced emergency physician in charge. Administer the intravenous adrenaline slowly with extreme care, suitably diluted and titrated to response to avoid potentially lethal complications, such as myocardial ischaemia, cardiac arrhythmias and cerebrovascular accident.[13,20,21]

Adrenaline (epinephrine) infusion

Although 1:10,000 adrenaline containing 100 µg/mL is readily available—for instance, as 10-mL prefilled syringes—it is impossible to give this slowly enough at 10 µg/min in the small initial quantities of 0.75 to 1.5 µg/kg (i.e. 50 to 100 µg) necessary.

Therefore make up an infusion of adrenaline by putting 1 mg in 100 mL normal saline (that is, 1:100,000 adrenaline with 10 µg/mL) and start at 60 to 120 mL/h via an infusion device to deliver 10 to 20 µg/min and titrate to response. Be prepared to continue the infusion for anything up to 60 minutes after resolution of all the symptoms and signs of anaphylaxis and then wean over the next 30 minutes and stop, watching closely for any recurrence.[22] Patients with persistent symptoms (protracted anaphylaxis) require a maintenance infusion of 5 to 10 µg/min and admission to a monitored intensive care area.

Adrenaline (epinephrine) nebulizer

Nebulized adrenaline 5 mg, as 5 mL of undiluted 1:1000 adrenaline, may be given particularly for upper airway oedema and bronchospasm while parenteral adrenaline is being prepared as described earlier.

Fluid replacement

Insert a large-bore intravenous cannula as soon as possible in patients showing signs of shock. Rapidly administer an initial fluid bolus of 10 to 20 mL/kg normal saline to counter the massive intravascular fluid shifts and peripheral vasodilation that occur within minutes with anaphylactic shock. There are no outcome data favouring colloids over crystalloids.

Second-line agents

Once adrenaline, oxygen and fluids have been given to optimize cardiorespiratory status and tissue oxygenation, the following drugs may be considered in a support role only, although evidence for their efficacy is lacking, being extrapolated from their use in urticaria or acute asthma.[1]

H_1 and H_2 antihistamines

Reserve antihistamines for the symptomatic relief of skin symptoms, such as urticaria, mild angioedema and pruritus. There are no outcome data to support their use in anaphylaxis.[23]

Antihistamines must never be relied on as sole therapy in significant anaphylaxis. Side effects of sedation, confusion and vasodilatation with the H_1 antihistamines can be troublesome, particularly when given parenterally.

The combination of an H_2 antihistamine with an H_1 antihistamine is better at attenuating the cutaneous manifestations of a generalized allergic reaction than an H_1 antagonist given alone. Choose a non-sedating H_1-antihistamine, such as loratadine 10 mg daily, especially on discharge, if the patient wishes to continue working or driving a vehicle (see 'Discharge oral medication', later).

Corticosteroids

As with the antihistamines, there are no placebo-controlled trials to confirm the effectiveness of steroids in significant anaphylaxis despite their many theoretical benefits on mediator release and tissue responsiveness, such as the downregulation of the late-phase eosinophilic inflammatory response.[24]

However, in view of the safety of corticosteroids, most clinicians give prednisone 1 mg/kg up to 50 mg orally or hydrocortisone 1.5 to 3 mg/kg intravenously, particularly in patients with airway involvement and bronchospasm, based on the important early role of corticosteroids in asthma. Side effects including changes in sodium and potassium ion flux and the anaphylaxis itself are more likely with the intravenous route of delivery.

It is also possible that steroids can prevent a biphasic reaction with recrudescence of symptoms following recovery; but, again, supporting data are unconvincing (see 'Disposition', later). Steroids are, however, essential in the management of recurrent idiopathic anaphylaxis.

Glucagon, atropine and salbutamol

Patients taking β-blockers have more severe and/or treatment-refractory anaphylaxis. Give glucagon from 1 to 5 mg intravenously, followed by an infusion at 5 to 15 μg/min titrated to response if adrenaline has been ineffective. Glucagon raises cyclic AMP by a non-adrenergic mechanism but may cause nausea and vomiting.

As mentioned earlier, some patients with anaphylactic shock develop a bradycardia that is resistant to adrenaline, possibly mediated by a neurocardiogenic vagal reflex. Atropine 0.6 mg intravenously up to 0.02 mg/kg has been successful in this situation.[20]

Finally, give nebulized salbutamol in addition to adrenaline for resistant bronchospasm, which has the advantage of familiarity.

Other vasopressors

Vasopressors such as noradrenaline, metaraminol, phenylephrine and vasopressin anecdotally have treated hypotension resistant to initial adrenaline and fluid therapy.

Methylene blue

Methylene blue, a competitive inhibitor of guanylate cyclase at a dose of 1.5 to 2.0 mg/kg, may counteract resistant nitric oxide–mediated vasodilatation particularly related to PAF but, in turn, it has caused anaphylaxis itself.[6]

Pretreatment

There is no convincing justification for pretreatment. In particular, the practice of routine prophylactic corticosteroids and/or antihistamines to reduce the risk of serious reactions to iodinated contrast media during radiological procedures is neither reliable nor supported by the literature and should be abandoned.[25]

Disposition

Patients with systemic anaphylactic reactions, including all those who receive adrenaline, should be kept under observation for at least 4 to 6 hours after apparent full recovery. Those with a more prolonged reaction, oral allergen exposure, reactive airways disease or cardiac disease should be watched a little longer (8 to 10 hours) because deaths from anaphylaxis occur in this group.[4] Observation is safely performed in the ED if a suitable holding area exists, and ECG monitoring is unnecessary.[11,12]

Most anaphylactic reactions are uniphasic and respond rapidly and completely to treatment. Some patients develop protracted reactions with an incomplete response to adrenaline or may deteriorate on attempted adrenaline weaning. Keep these patients with unstable vital signs monitored and admit them to an intensive care area.

Biphasic anaphylaxis

Relapse after apparent complete resolution of all initial symptoms and signs is known as *biphasic anaphylaxis*, which is reported in 1% to 5% of cases. It is unclear if more severe presenting features, delayed or inadequate doses of adrenaline or the non-use of steroids predispose to or predict this biphasic response.[26]

ED observation times of 4 to 6 hours are acceptable or, in an asthmatic patient or one with oral allergen exposure or known cardiac disease up to 8 to 10 hours to exclude this type of reaction (see 'Disposition', earlier).

Discharge policy

Discharge the patient following observation and consider the need for take-home medication, self-injectable adrenaline and allergist/immunologist referral.

Discharge oral medication

There are no data to support the common practice of prescribing a 2- or 3-day discharge supply of combined H_1 and H_2 antihistamines plus oral steroids to prevent early relapse. However, consider loratadine 10 mg once daily, ranitidine 150 mg q12h and prednisolone 50 mg/day in adults with predominant cutaneous features following a generalized allergic reaction or bronchospasm.

Self-injectable adrenaline (epinephrine)

As a guide, self-injectable adrenaline is prescribed for the patient with anaphylaxis after known allergen exposure outside of a medical setting; for patients with food allergy, particularly to nuts or peanuts; and for those in whom the reaction was severe and/or the cause unknown. The decision whether the emergency physician or general practitioner should initiate self-injectable adrenaline use or wait for specialist allergist/immunologist review with formulation of an individualized anaphylaxis action plan will depend on individual factors such as local facilities and patient access to emergency services.

EpiPen and Anapen

The EpiPen and Anapen with 0.3 mg (300 μg) of adrenaline and the EpiPen Jr and Anapen Jr containing 0.15 mg (150 μg) are approved for self-administered intramuscular use. Up to two injectors are available at a time on the Pharmaceutical Benefits Scheme (PBS) schedule on an Authority script for a patient after hospital or ED discharge for acute allergic anaphylaxis treated with adrenaline or as a continuing supply for patients who have previously been issued with an Authority prescription.[27]

When an EpiPen or an Anapen is dispensed in the ED, it is essential to explain and demonstrate exactly how to use the device and to educate both the patient and another caregiver, particularly with children. Teach the patient and carer how to recognize the symptoms and signs of anaphylaxis and encourage the actual use of the device, particularly if distant from a health care facility. As these devices differ in their administration technique, they should not be prescribed interchangeably. Tell recipients that self-injectable adrenaline has a relatively short shelf-life of around 1 to 2 years and explain how to look after it.[28]

Allergist/immunologist referral

Disappointingly, few patients who suffer an episode of anaphylaxis are referred from the ED for specialist allergist/immunologist follow-up. Refer anyone prescribed a self-injectable adrenaline (epinephrine) device, including patients following a wasp or bee sting suitable for immunotherapy; suspected food- drug- or exercise-induced anaphylaxis; and patients with severe reactions without an obvious trigger.[29]

Give the patient a letter detailing the nature and circumstances of the anaphylactic reaction, the treatment given and the suspected causative

agent or agents. Ask the patient also to write a brief diary of the events in the 6 to 12 hours preceding the reaction, particularly when the cause is unclear. Ask him or her to include all foods ingested, drugs taken including non-proprietary, cosmetics used and activities performed outside as well as indoors. Later recall of these events at a specialist allergist/immunologist review will be flawed unless these facts are documented contemporaneously.

Drug and allergen avoidance

Patients at risk of recurrent anaphylaxis with hypertension or ischaemic heart disease should ideally be taken off β-blockers and care should be taken not to substitute an ACE inhibitor. Discuss this with the patient's other specialists to be certain the overall risk-benefit favours medication change.

Advise patients to reduce allergen exposure risk by destroying nearby wasp nests and removing allergenic foods in the house, plus avoiding insect stings with appropriate clothing as well as certain foods by checking the manufacturer's label.[18]

IgE skin testing, in vitro testing and challenge testing

Skin or blood tests for specific IgE antibodies should be done only by those trained in their performance and interpretation, usually 3 to 4 weeks after the acute episode. Skin prick testing is the more sensitive and, when possible, standardized extracts should be used with correct technique. In addition, an experienced physician, such as a specialist allergist/immunologist, should supervise, as occasional severe reactions occur. These tests are not appropriately performed by an emergency physician.

In vitro testing for allergen-specific IgE is less sensitive and depends on clinical correlation and the availability of specific assays. Over 500 different allergens are available for testing with the ImmunoCAP system (Thermo Fisher Scientific Inc, Waltham, MA), or clinicians may use a radioallergosorbent test (RAST).

Finally, challenge testing may help diagnose non-allergic anaphylaxis. False-positive and false-negative reactions do occur but are much less likely than with skin prick or in vitro testing. In any event, experienced specialist allergist/immunologist supervision is essential.[18]

CONTROVERSIES

- The exact mechanisms that underlie initial IgE antibody formation in response to a myriad of different substances and why this happens in one individual but not another are not known.
- A single internationally agreed definition or grading system for anaphylaxis is as yet unavailable.
- Symptoms or signs that most reliably predict the risk of severe anaphylaxis are yet to be defined.
- The utility of laboratory testing in confirming and quantifying the severity of an anaphylactic reaction is debated.
- The most effective drug doses in acute treatment, particularly adrenaline, have not been defined.
- Predictors of biphasic reactions are as yet unavailable.
- The utility of discharge medications is a controversial issue.

SECTION 3

TRAUMA

Edited by *Peter Cameron*

3.1 Trauma overview

Peter Cameron • Gerard O'Reilly

ESSENTIALS

1 **Injuries cause 9% of all deaths.**

2 **Trauma remains the leading cause of death in those aged from 1 to 44 years in the most highly developed countries. The burden of injury is especially high in developing countries.**

3 **Improvements in trauma care systems have resulted in fewer patients dying from avoidable factors and less disability.**

4 **The key objective of a mature trauma system is to transfer 'the right patient to the right level of care in the shortest time'.**

5 **The initial management of trauma patients involves a team approach. A primary survey of airway, breathing, circulation, disability and exposure, where the identification and treatment of immediately-life threatening injuries occur concurrently, is followed by a secondary survey involving a head-to-toe examination.**

6 **Audit and feedback of trauma systems are essential to improve outcomes.**

Epidemiology

Trauma causes 9% of all deaths; motor vehicle trauma alone ranks fifth amongst the leading causes of death and tenth among the leading causes of disability-adjusted life years (DALYs) lost.[1,2] Trauma is the leading cause of death for those aged from 1 to 44 years in developed countries.[3,4] The burden of injury is especially high in developing countries, where systems of trauma care are generally non-existent or in their infancy. Deaths from unintentional injury are generally much more common than suicide or homicide in most countries including the United States.[3] But in some countries (e.g. Australia), suicide now causes more deaths than motor vehicle collisions (MVCs) for some age groups (15 to 44 years).[4] The economic and social costs of the deaths and disability from trauma are great, as most victims are young and are major contributors to society through their work, family and organizational involvement.

The trauma system—background

In most developed countries, there have been significant reductions in mortality and morbidity from injury as a result of a systematic approach to trauma care.[5,6] The majority of these reductions have resulted from prevention strategies, including seatbelt legislation, drink-driving legislation, improved road engineering, motorcycle and bicycle helmet use and road safety and workplace injury awareness campaigns. Changes in both trauma system configuration and individual patient management have brought about improvements in the survival rate of those who are seriously injured, although the impact has not been as great as that of injury prevention.

Civilian interest in injury morbidity and mortality was initially most evident in the United States because of the high incidence of urban violence and road trauma and owing to lessons learnt from the wars of the 20th century. Research into systems of trauma care began with epidemiological work by Trunkey and others in examining trauma deaths.[7] These researchers developed the concept of a trimodal distribution of trauma deaths. Trunkey proposed that about 50% of deaths occurred within the first hour as a result of major blood vessel disruption or massive brain and/or spinal cord injury. This could be improved only by prevention strategies. A second more important group (from the therapy perspective) accounted for about 30% of deaths and included patients with major truncal injury causing respiratory and circulatory compromise. The remaining 20% of patients were said to die much later from acute respiratory distress syndrome (ARDS), multiple organ failure (MOF), sepsis and diffuse brain injury.[7] Trunkey initially identified the second group as most likely to benefit from

improvements in trauma system organization, and it is a tribute to the effectiveness of such schemes that the number of patients dying from avoidable factors within the first few hours of injury has generally declined.[5,6] Such improvements in trauma system provision have resulted in a redistribution of the three groups proposed by Trunkey, and it is now generally accepted that far fewer than 30% are included in the second group. Furthermore, with improved initial management, complications such as MOF and ARDS have decreased to such an extent that, in mature trauma systems, even the third peak is now minimal, with the vast majority of deaths occurring from major head injury and massive organ disruption in the first 1 to 2 hours.[8]

Trauma care systems have been developed to ensure a multidisciplinary approach and a continuum of care from the roadside or scene of injury through hospital care to rehabilitation. Identifying weakness in such a system is always difficult because of the delay between cause and effect. Suboptimal management does not usually lead to immediate death: for example, a period of hypoxia may result in organ failure many hours later. Another difficulty is the relatively low incidence of death. Although this is of course to be welcomed, it does make statistical analysis more difficult when the 'adverse event' occurs uncommonly. Careful audit of the entire trauma process and accurate measurement of 'input' (i.e. injury severity) and 'output' (i.e. death or quality of survival) is essential if the process of trauma care is to be further improved.

The trauma system—pre-hospital

Whereas the initial work on trauma system development focused on the need for centres of expertise and trauma management, it is now accepted that the pre-hospital phase is of critical importance. The linchpin of a mature trauma system is a highly skilled and resourced pre-hospital service following the key principle of: *the right patient to the right level of care in the shortest time*.[9] Timely access to the care of an effective pre-hospital service followed by the triage of the injured patient to the closest most appropriate facility are essential. Specifically, high-risk patients should be taken to a hospital capable of managing critically ill trauma patients.[9] A diagrammatic representation of one integrated trauma system, at its inception in 1999, is provided in Fig. 3.1.1,[10] as it remains relevant today.

Criteria for identifying those patients who may require resuscitation at a tertiary level trauma centre or 'major trauma service (MTS)' will depend on resources. In the most developed trauma systems, 'mechanism of injury' criteria are usually included in the pre-hospital triage tool. This ensures high sensitivity of the tool but leads to considerable overtriage. In less resourced settings, it may be appropriate to identify high-risk patients on the basis of abnormal vital signs and obvious major injury. The elements of a trauma system's triage tool may include most or all of the predictors of life-threatening injury listed in Table 3.1.1.

The appropriate application of pre-hospital triage guidelines relies on adequate resourcing. In regions with developed trauma systems, pre-hospital staff are expected to provide a range of advanced life support interventions including patient intubation and chest decompression, thereby ensuring that further organ injury is limited during the pre-hospital phase. The pre-hospital care providers armed with these skills may be doctors (as in some European countries, for example) or highly trained paramedics (as in the United States, Australia and the United Kingdom).

The trauma system—intra-hospital

Preparation

Effective pre-hospital communication, usually by phone and/or radio, allows timely preparation for the arrival of a trauma patient. Proper communication includes trauma team notification, staff and trauma bay identification and the adoption of universal precautions (gloves, gowns, etc.).

Trauma team notification might occur by phone or paging system and ensures the gathering of the trauma team *prior* to the patient's arrival. Members of the trauma team may vary. An example of trauma team composition and roles in a level 1 trauma centre is provided in Box 3.1.1. Variations to this list may occur in different settings depending upon the availability of skilled staff and the nature of specific injuries or physiological status prior to the patient's arrival.

Table 3.1.1 Predictors of life-threatening injury appropriate for use in pre-hospital trauma triage

Mechanism	Ejection from vehicle
	High-speed collision (>60 kph)
	Motorcycle/cyclist impact >30 kph
	Fall >5 m
	Vehicle rollover
	Fatality in same vehicle
	Explosion
	Pedestrian impact >30 kph
	Extrication >30 min
Injuries (any of the following)	Serious or suspected serious penetrating injuries: head, neck, chest, abdomen, pelvis, axilla, groin
	All significant blunt injuries as assessed by ambulance
	All injuries involving: evisceration, explosion, severe crush injury, any amputation, suspected spinal injury, serious burns, pelvic fracture
Vital signs	Respiratory rate <10 or >30 per minute
	Systolic blood pressure <100 mmHg (<75 mmHg for child)
	Glasgow Coma Scale <15
	Oxygen saturation <90%
Treatment	Intubation
Patients who have undergone any of the following pre-hospital interventions	Any airway manoeuvre at any time
	Assisted ventilation
	Chest decompression
	Failure to control external bleeding
	>500 mL fluid
	Sedatives
Other criteria	All inter-hospital trauma transfers
	Significant co-morbidity
	Pregnancy

Trauma team call-out criteria reflect the pre-hospital trauma triage criteria (see Table 3.1.1) and should be applied rigorously. Trauma team skill, functioning and leadership are essential to achieve the best patient outcome. The appropriate skill mix is reflected by the team membership listed in Box 3.1.1. Trauma team performance, including leadership and communication, will have an impact on patient outcome.[11]

Initial management

The application of a consistent systematic approach to trauma resuscitation has been widely promulgated by training programmes, such as the Advanced Trauma Life Support (ATLS) course.[12] The patient is brought directly to a prepared bay, the layout of which is illustrated in Fig. 3.1.2. The principles of the initial identification and management of immediately life-threatening injuries, with prioritization accorded to airway (including protection of cervical spine), breathing, circulation, (neurological) disability and exposure (ABCDE) are applied to all injured patients. The primary survey is followed by a secondary survey involving a head-to-toe examination. In the best-resourced departments, parallel processing of the patient will occur with the simultaneous management of ABCDE problems.[12]

Airway

It should be assumed that hypoxia is present in all patients who have sustained multiple injuries. Early expert airway intervention is essential.

Box 3.1.1 Team roles

Team leader (emergency physician or trauma surgeon)
Overview
Resuscitation
Assessment
Communication
Ambulance handover
Referrals
Investigations
Task allocation
Primary survey
Secondary survey

Airway doctor (anaesthetist)
Control of airway
Inline immobilization of cervical spine
Ventilation
Gastric tube

Procedure doctor (emergency registrar/trauma registrar)
Intravenous access/bloods
Intercostal catheter
Urinary catheter
Arterial blood gas (ABG)/art line

Nurses
Trauma nurse leader/scribe
Airway nurse
Circulation nurse

Radiographer
Orderly

Supplemental oxygen, via a well-fitting face mask, should be considered for every patient. If the airway is clear and protected, the neck should be immobilized, usually with a semi-rigid collar; however, if airway manoeuvres are necessary, it is often better to use manual inline immobilization without a collar, ensuring minimal neck movement with constant vigilance. The management of an obstructed airway in a trauma patient should be undertaken by an experienced senior clinician with significant airway experience. The first priority is to clear the upper airway by direct visualization, suction and removal of any foreign bodies. Insertion of an oropharyngeal airway and the jaw-thrust manoeuvre are usually successful in clearing an upper airway obstruction. Insertion of a nasopharyngeal airway can be hazardous in patients with a fracture of the cribriform plate. The direction of insertion (backwards, not upwards) is important. Chin lift is not recommended because it may cause additional movement of the cervical spine.

Early endotracheal intubation should be undertaken if the patient is apnoeic, has an unrelieved upper airway obstruction, has persistent internal bleeding from facial injuries, has respiratory insufficiency due to chest or head injuries or the

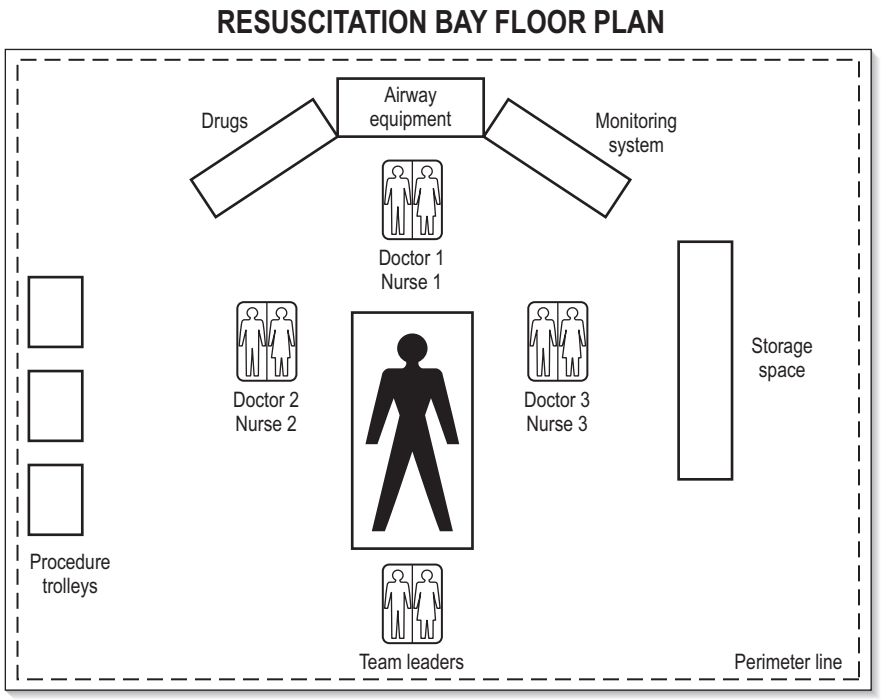

FIG. 3.1.2 The layout of a typical trauma resuscitation bay. (Reproduced with permission from Myers CT, Brown AF, Dunjey SJ, et al. Trauma teams: order from chaos. *Emerg Med*. 1993;5:34.)

potential for airway compromise (airway burns, facial instability, coma or seizures). Endotracheal intubation may also be necessary for procedures such as computed tomography (CT) scanning or for the management of confused or disturbed patients. Any operator undertaking the emergency intubation of major trauma victims should be skilled in rapid sequence intubation and prepared for a difficult airway. He or she must be equipped with the skills for dealing with a 'failed' intubation (see Section 2.1) with a variety of interventions, including surgical cricothyroidotomy.

Breathing

Once the airway is secure, the patient's breathing must be assessed. Particular attention is paid to optimizing oxygenation and maintaining normocapnia. During the primary survey, immediately life-threatening risks to breathing must be identified and dealt with. These injuries include tension pneumothorax, open pneumothorax, massive haemothorax, flail chest and pulmonary contusion. The specific features and management of these injuries is covered in Section 3.6.

Circulation

Shock is a clinical syndrome in which the perfusion of vital organs is inadequate to maintain function. Blood loss is the major cause of shock in the patient with major trauma. Other less common causes of shock must also be considered:

- Tension pneumothorax. This will cause rapid circulatory compromise.
- Cardiogenic shock. This may be pre-existing (e.g. acute myocardial infarction [AMI] leading to a road traffic collision or other injury, drugs causing reduced cardiac compensation and hypovolaemia) or secondary to direct cardiac injury (i.e. myocardial contusion, valvular/septal injury or pericardial tamponade).
- Neurogenic shock. This results from the loss of sympathetic tone. It may be caused by central brain stem injury and vasomotor instability or spinal cord injury and the interruption of descending sympathetic tracts. It is characterized by bradycardia but may also occur in profound hypovolaemic states.
- Anaphylactic shock and septic shock may coexist with hypovolaemic shock.

The initial stages of hypovolaemia can be difficult to detect. Reliance on systolic blood pressure to identify shock is dangerous. All patients who have sustained an injury that could be associated with significant blood loss, however remote the possibility, must be carefully monitored. In the initial phase, measurement of the clinical parameters will give some information about the perfusion of vital organs. However, more invasive monitoring will be required if hypovolaemia is severe or sustained.

Where the patient has obvious catastrophic external haemorrhage, this needs immediate attention. Interventions may include direct pressure, wound closure with sutures or staples or the temporizing application of a tourniquet.

It is essential to gain good venous access at the earliest phase in resuscitation. This is usually via two large-bore peripheral cannulae. In the absence of accessible arm veins, central venous access may be indicated. The recommended site (subclavian, jugular or femoral) depends on a number of factors. The subclavian vein is reliable in terms of patency, whereas the ease of access to the femoral vein is offset by its potential futility in major truncal haemorrhage. The internal jugular veins can be difficult to access in the immobilized trauma patient. Cut-downs of the saphenous veins and cubital fossa may also be used.

At the initial stages, where the blood pressure is unchanged, patients with potential blood loss can usually be managed without blood transfusion, namely with crystalloid. No benefit has been demonstrated in using non-blood colloids over crystalloids in traumatic haemorrhage.[13] Similarly, for hypertonic crystalloid the available data are inconclusive at best.[14]

Where there is hypotension and tachycardia, blood transfusion should commence immediately, initially using O-negative blood and changing to group-specific or cross-matched blood as it becomes available. Section 3.12 covers the role and details of massive transfusion therapy in the trauma patient. Until the source of haemorrhage has been identified and haemostasis achieved, vigorous over-resuscitation with fluid may actually result in a worse outcome.[15] Tranexamic acid (TXA) also has a role in the injured patient with haemorrhagic shock and is discussed further in Chapter 3.12.[16]

The essential point is that after securing the airway and optimizing oxygenation and ventilation, the most important determinant of outcome in the major trauma patient with haemorrhagic shock is the time to definitive haemostasis. There is certainly no point in delaying surgery 'to normalize the intravascular volume'. The major source of haemorrhage in the trauma patient must be identified early. The usual suspects are chest, abdomen, pelvis, long bone and/or external (e.g. scalp, major limb artery).

Disability

As the purpose of the primary survey is to identify immediate threats to life, the assessment for a head injury and its severity entails an examination of conscious state (using the Glasgow Coma Scale) and neurological signs (pupils, limb weakness). If there is any risk of intracranial injury, a CT scan of the brain will be indicated immediately upon completion of the primary survey. Section 3.2 deals with the assessment and management of traumatic brain injury.

Exposure

Hypothermia is associated with worse outcomes in the patient with major trauma.[17] Temperature control is now considered to be of critical

importance in reducing the sequelae of major trauma (metabolic derangement, coagulopathy). The role of therapeutic hypothermia in isolated head injury remains controversial and is a subject of ongoing research. While maintaining normothermia, it is important to have exposed the patient fully, including a log roll with spinal immobilization, to enable a complete examination.

Next steps

By this stage, the trauma patient will have been received into a well-organized resuscitation area and the first life-saving procedures will have been initiated by an integrated and skilled team of doctors and nurses. At this point any immediately life-threatening conditions can be expected to have been identified and dealt with. Constant vigilance and reassessment are essential. Other occult injuries may be present in patients identified with serious injuries.

While the trauma team leader continues to review the situation in the light of a constantly changing clinical scenario and, potentially, the provision of more biomechanical data from the site of the incident, he or she should also be beginning to consider the next steps. The first of these is the calling in of other experts. Whereas it will have been clear that an airway doctor will be an essential part of the initial resuscitation team, it may be some minutes before it is known which other skills are required. Orthopaedic surgeons and neurosurgeons are often required. With the increase in non-operative management and angiographic embolization of intra-abdominal injury, general surgery is not required as often, although general surgeons are often important in coordinating ongoing care. Whichever specialty is required, the patient's emergency problems demand experience; therefore 'if in doubt, refer'.

Radiographs are required at this stage. The initial films should be limited to those that will have a direct bearing on immediate management, including antero-posterior (AP) views of the chest and the pelvis. Ideally the resuscitation room should have an integrated x-ray facility but, if this is not available, portable films should be obtained. It is not appropriate to transfer a multiply injured unstable patient to a separate x-ray facility. Ultrasound is increasingly being used in the identification and management of immediate life threats in major trauma patients during the primary survey, including localizing the source of shock (haemorrhagic or pericardial tamponade).

Following the primary survey and investigations deemed necessary, the patient requires a secondary survey. This entails a focused history and a complete head-to-toe examination for injuries not classified as immediately life-threatening.

Subsequent chapters deal with individual trauma problems, but it is essential that throughout the patient's stay in hospital a single clinician has overriding responsibility for his or her care. In the resuscitation area, this is the 'team leader', who may be from any trauma-related discipline. Handover to the clinician responsible for ongoing care must be comprehensive, timely and well documented.

Quality improvement in trauma care

Trauma kills people in a variety of ways; hence no one department in a hospital will see a large number of deaths. Many trauma victims die before they reach hospital, some in the ED and others scattered through the inpatient specialties and in intensive care. Hence from any one clinician's perspective, trauma is not an outstanding problem. However, when looked at from a public health perspective, it is clearly a major issue, not least because some of the deaths are avoidable. Identifying these and the much more difficult-to-define group of patients who survive but whose outcome is not as good as expected is an important component of a mature trauma care system. Once opportunities to improve care have been identified, corrective actions (e.g. protocols, targeted education, etc.) can be implemented; whether the problem with care is fixed should then be monitored (i.e. closing the loop). This is a Trauma Quality Improvement (TQI) program.[18]

To inform a TQI program, a mature trauma care system needs a trauma registry, measuring the relevant variables. Important variables to measure are the extent of the anatomical injury, the degree of physiological derangement that results, age and the previous well-being of the patient. All these have a direct effect on outcome and must therefore be measured before any comment can be made about the process of care. Patient outcome itself must also of course be measured. This is relatively easy in terms of risk adjusted mortality. However, disability is a much more difficult issue and, currently, there are no universally accepted measurement tools. The Glasgow Outcome Scale (GOSE), the Short Form–36 (SF36) questions and the WHODAS are available tools that have been used.[19–22] As 90% of major trauma patients survive their injury in a mature trauma system, it is important to measure disability and quality of life following major trauma when comparing outcomes.[23]

Trauma in developing countries

Globally, national governments are beginning to recognize the burgeoning human and economic cost of trauma, particularly road trauma. The public health achievements of the developed countries (seatbelts, helmets, alcohol and speed restrictions) are being implemented and, similarly, governments of developing countries are looking to implement trauma systems.[24]

Research in developing countries reinforces the benefits of trauma systems previously described in countries with established emergency medical systems. For example, evidence indicates that people with life-threatening but potentially treatable injuries are up to six times more likely to die in a country with no organized trauma system than in one with an organized, resourced trauma system.[25] Trauma system development requires trauma outcome measurement.[18,26] As such, developing countries are likely to adopt trauma registries over the next several decades in an attempt to track the burden of trauma and the impact of system-wide interventions.

As developing countries embark upon trauma system development, it is becoming increasingly important to access standardized trauma care education through intensive short-courses. ATLS has been widely used. Other courses (such as Primary Trauma Care [PTC]) have also become popular in less-resourced settings. Such courses are often less expensive and more flexible than ATLS.

CONTROVERSIES

- The number of major trauma patients necessary for a hospital to maintain high-quality trauma care is uncertain.
- The degree to which potential major trauma patients should be over-triaged to ensure that patients with major trauma are received at major trauma centres is also a subject of debate. There may be a greater risk in bypassing hospitals to take patients to a trauma centre, depending on distance and injury type. There is also the issue of de-skilling personnel from non-trauma centres and what effect this has on overall system outcomes.
- The degree to which major trauma patients should be managed by protocol rather than clinical judgement is again controversial. Clinicians are increasingly being asked to follow protocols in these critical situations. This prevents some adverse outcomes but may cause over-investigation and treatment.
- The role of hypotensive resuscitation in blunt trauma has not been defined. Where victims have prolonged delays to theatre or the bleeding is not surgically correctable, hypotensive resuscitation may cause more complications.
- The role of controlled hypothermia in head-injured patients remains to be defined.
- The role of tranexamic acid in mature trauma care systems is also a subject of continued discussion.

3.2 Neurotrauma

Gerard O'Reilly • Peter Cameron

ESSENTIALS

1 **Neurotrauma is the most common cause of death in trauma.**

2 **A detailed history of the mechanics of the trauma experienced is invaluable.**

3 **Secondary brain injury is a major and potentially preventable cause of mortality and long-term morbidity.**

4 **Cerebral cellular dysfunction secondary to trauma is a result of both primary and secondary mechanisms and involves sodium, calcium and potassium shifts across the cell membrane; the development of oxygen free radicals; and lipid peroxidation.**

5 **There are two features of prime importance to resuscitation in patients suffering neurotrauma: maintenance of airway/ventilation and maintenance of cerebral perfusion pressure.**

6 **Rapid sequence orotracheal intubation, with in-line immobilization of the cervical spine is the preferred method for gaining definitive airway control in the head-injured patient.**

7 **Current adult emergency department and neurosurgical practice involves the use of computed tomography (CT) to investigate head injury.**

Introduction

Neurotrauma is a common feature in the presentation of multisystem trauma, particularly when it is associated with motor vehicle accidents and falls. Head injuries contribute to between 30% and 50% of all trauma deaths.[1,2] The implications for the health system are enormous, with an annual rate of admission to hospital wards associated with head trauma approaching 300 per 100,000 population[3] and twice this in the elderly.[4] The long-term sequelae of moderate and severe neurotrauma constitute a major drain on health resources, and the morbidities associated with mild brain injury are becoming clearer.

Advances in preventative strategies, trauma systems, resuscitative therapies and rehabilitation management have improved outcomes. However, neurotrauma remains a serious health issue, with a huge impact from long-term disability on the quality of life and the productivity of society's youth.

Pathogenesis

Primary brain injury occurs as a result of the forces and disruptive mechanics of the original incident: this can be avoided only through preventative measures such as the use of bicycle and motorcycle helmets.

Secondary brain injury is due to the complex interaction of factors and typically occurs within 2 to 24 hours of injury.[5] A principal mechanism of secondary injury is cerebral hypoxia due to impaired oxygenation or impaired cerebral blood flow. Cerebral blood flow is dependent on cerebral perfusion pressure (CPP), mean arterial systemic blood pressure (MAP) and intracranial pressure (ICP).

$$CPP = MAP - ICP$$

ICP may be raised as a result of the mass effect of the haemorrhage or by generalized cerebral oedema. Cerebral vasospasm further reduces cerebral blood flow in patients in whom significant subarachnoid haemorrhage has occurred.

Cellular dysfunction is a result of both primary and secondary mechanisms and involves sodium, calcium, magnesium and potassium shifts across the cell membrane; the development of oxygen free radicals; lipid peroxidation; and glutamate hyperactivity. Excessive release of excitatory neurotransmitters and magnesium depletion also occur.

Classification of primary injury in neurotrauma

Primary injuries are classified as follows:

- Skull fracture
- Concussion
- Contusion
- Intracranial haematoma
- Diffuse axonal injury
- Penetrating injury

Skull fracture

The significance of skull fracture is not related to the specific bony injury but rather the associated neurotrauma. Fractures in the region of the middle meningeal artery in particular may be associated with acute extradural haemorrhage. Fractures involving the skull base and cribriform plate may be associated with cerebrospinal fluid (CSF) leak and the risk of secondary infection. Depressed skull fractures may compress underlying structures, cause secondary brain injury and require surgical elevation. Injury to underlying structures may result in secondary epilepsy.

Concussion

Concussion is a transient alteration in cerebral function, usually associated with loss of consciousness (LOC) and often followed by a rapid recovery. The proposed mechanism is a disturbance in the function of the reticular activating system. Post-concussive syndromes, including headache and mild cognitive disturbance, are common.[6] Symptoms, particularly headache, are usually short-lived but may persist. 'Second-impact syndrome' describes a greater risk of significant re-injury following an initial injury causing a simple concussion. It is likely to be due to diffuse cerebral swelling.[7] In animal models, concussion may be associated with modest short-term increases in ICP and disturbances in cerebral cellular function.[8]

Contusion

Cerebral contusion is bruising of the brain substance associated with head trauma. Forces involved are less than those required to cause major shearing injuries and often occur in the absence of skull fracture. Morbidity is related to the size and site of the contusion and coexistent injury. Larger contusions may be associated with haematoma formation, secondary oedema or seizure activity. The most common sites for contusions are the frontal and temporal lobes.[9]

Intracranial haematoma

Extradural Extradural haematoma (EDH) is uncommon but classically associated with a fracture of the temporal bone and injury to the underlying middle meningeal artery.

Haemorrhage subsequently occurs, stripping the dura from the skull and expanding to cause a rise in ICP and eventually uncal herniation and death. Haemorrhage may be from vessels other than the middle meningeal artery (e.g. brisk arteriolar or venous bleeding). Signs will depend on the site of the haematoma.

Subdural Subdural haematomata (SDH) may have an acute, subacute or chronic course. They generally follow moderate head trauma with LOC. In the elderly, SDH may be associated with trivial injury and in children with shaking (abuse) injury. Haemorrhage occurs into the subdural space, slowly enlarging to cause a space-occupying collection whose functional implications will vary according to location. The mortality from acute SDH is high (approximately 30%) but this represents a decrease over recent decades.[10] Subacute and chronic SDH may be associated with a degree of cerebral dysfunction, headache or other symptomatology and with a significantly lower mortality compared with acute SDH.

Intracerebral haemorrhage As with cerebral contusion, the most common sites of intracerebral haemorrhage (ICH) associated with trauma are the temporal and posterior frontal lobes. Effects on function are variable depending on the site. ICH may progress from an initial contusion or be secondary to altered vascular characteristics. Symptom development and complications may be delayed as the size of the haemorrhage increases over time.

Subarachnoid and intraventricular haemorrhage Subarachnoid blood is relatively common after major head injury. Intraventricular haemorrhage may also be evident. As in non-traumatic settings, the presence of subarachnoid blood may lead to cerebral vasospasm and secondary ischaemic brain injury.

Diffuse axonal injury

Diffuse axonal injury (DAI) is the predominant mechanism of injury in neurotrauma, occurring in up to 50% of patients.[11] Shearing and rotational forces on the axonal network may result in major structural and functional disturbance at a microscopic level. Disturbance to important communicative pathways sometimes results in significant long-term morbidity despite non-specific or minimal changes on computed tomography (CT) scanning. The exact pathogenesis of DAI is incompletely understood. Specific injury in the regions of the corpus callosum and midbrain has been proposed; however, DAI is believed to be the mechanism for persistent neurological deficits seen in head-traumatized individuals with normal CT scans.

Penetrating injury

Penetrating neurotrauma is characterized by high levels of morbidity and mortality. This is especially true of gunshot wounds. Exposure of cerebral tissue through large compound wounds or through basilar skull structures is associated with a dismal outlook. Penetrating injury in the periorbital and perinasal regions is associated with a high risk of infection.

Epidemiology

Neurotrauma is surprisingly common. In some settings more than 30% of the population have suffered from a traumatic brain injury (TBI). In addition to being a major cause of death in trauma, neurotrauma leads to significant morbidity. More than 40% of those who have sustained a TBI will have residual disability a year later.[12]

Common causes of a TBI include motor vehicle collisions (including vehicle versus pedestrian and bicycle collisions), falls, assault and firearms. In young males, alcohol is often involved.

Prevention

Primary prevention of neurotrauma depends on the cause. Most preventative strategies are directed at vehicular traffic and include speed-reduction measures, in-car safety devices and bicycle helmets. Improvements in roadside lighting and enhanced pedestrian visibility contribute to the reduction of injury in this group.

Prevention of secondary injury involves maintenance of cerebral perfusion and oxygenation and is addressed under 'Clinical management'.

Clinical features

Definition

For decades, the clinical classification of TBI (as mild, moderate or severe) that has been used to direct emergency investigations (i.e. CT head) and emergency management has been based on the Glasgow Coma Scale (GCS) (Table 3.2.1).[13] Other classification systems have emerged that more specifically inform the identification and management of TBI at both ends of the severity spectrum, including concussion and coma.[14–17] Most current classification systems of TBI severity still define three groups, but for the 'milder' end of the spectrum they are not based on GCS alone.[14–17] The key headings of contemporary classifications of TBI severity are consistent with the situations described in the following paragraphs.

Definite moderate-severe traumatic brain injury

One or more of death from TBI, worst valid GCS <13, LOC >30 minutes, post-traumatic amnesia (PTA) >24 hours, evidence of brain injury on imaging

Table 3.2.1 Glasgow Coma Scale

Best motor response	
Obeys command	6
Localizes to pain	5
Withdraw to pain	4
Abnormal flexion to pain	3
Abnormal extension to pain	2
Nil	1
Best verbal response	
Oriented	5
Confused	4
Uses inappropriate words	3
Makes incomprehensible sounds	2
Nil	1
Eye opening	
Spontaneously	4
To verbal command	3
To pain	2
Nil	1

Probable mild traumatic brain injury

Worst valid GCS >12 *and* LOC <30 minutes *and* PTA <24 hours

Possible mild traumatic brain injury

One or more of blurred vision, confusion, dizziness, headache, or nausea[14]

History

A detailed history of the mechanics of the trauma is essential. In the setting of moderate/severe TBI (i.e. major trauma), this may occur immediately following the primary survey. The focused history will ascertain time courses, pre-hospital care, pre-sedative and pre-relaxant neuromuscular function and episodes and duration of hypotension or other decompensation. A history of previous health problems, allergies, medications and social setting is desirable.

Primary survey

As with all trauma patients, the initial assessment and therapy must be directed at the maintenance of airway, ventilation and circulatory (CPP) adequacy along standard Advanced Trauma Life Support (ATLS) principles.[18] The greatest risks to the patient with a moderate to severe head injury are hypoxic injury and deficient cerebral perfusion due to systemic hypotension.

Indications for intubation and ventilation of the neurotrauma patient are inadequate ventilation or gas exchange (hypercarbia, hypoxia, apnoea); inability to maintain airway integrity (protective reflexes); a combative or agitated patient; and the need for transport where the status of the airway is potentially unstable (between hospitals, to CT, to angiography, etc.).

With elevation of ICP and loss of autoregulation of cerebral circulation, relatively higher systemic blood pressures are required. The practice of minimal-volume resuscitation has no place in treating the patient with serious neurotrauma.

Early assessment of neurological disturbance using the GCS or AVPU scale (Alert: GCS 14–15; response to Verbal stimuli: GCS 9–13; response to Painful stimuli: GCS 6–8; or Unresponsive: GCS 3–5) is important. Simultaneous protection of the cervical spine by immobilization is recommended. This management should commence in the pre-hospital setting and the level of care should be maintained.

Secondary survey

A full secondary survey, including log-roll, should follow.

Clinical assessment of the neurological status of head-injured patients commences with formal documentation of the GCS (see Table 3.2.1). The maximum score is 15 and the minimum 3. Coma may be defined in terms of the GCS where patients have a total score of 8 or less:

- Failure to show eye opening in response to pain (eye-opening response = 1)
- Failure to obey commands (best motor response = 5)
- Making at best only incomprehensible sounds (best verbal response = 2)

Examination of pupillary responses, particularly in the unconscious patient, is important as an indicator of increasing ICP; a non-responsive dilated pupil indicates ipsilateral herniation. However, a more common cause of abnormal pupil reactions in head injury is the presence of direct ocular trauma.

A general neurological examination, including reflexes, should be performed; the degree to which co-operation is possible and the presence of lateralization of signs are particularly important to document. Consideration of the pre-injury mental state is important, particularly where drug or alcohol intoxication is possible.

Investigations

Mild traumatic brain injury

The emergency department (ED) investigation plan of *probable* mild TBI (MTBI) in an adult should adopt a low threshold for a CT scan of the brain in any such patient.[17,19,20] Specifically, indications for ED CT of the brain following head injury are one or more of the following:

- GCS less than 13 (moderate/severe TBI) in the ED
- GCS less than 15 or PTA at 2 hours after the injury (*probable* mild TBI)
- Suspected skull fracture
- Post-traumatic seizure
- Focal neurological deficit
- More than one episode of vomiting
- Prolonged LOC
- Anticoagulant medication[14,17]

Very brief LOC alone in young adults and children is not an indication for a CT of the brain.

Moderate/severe traumatic brain injury

Urgent CT scanning is the investigation of choice in moderate/severe TBI. However, other investigations and therapy (i.e. the primary survey) may take priority in the patient with multisystem trauma, particularly in the presence of unresponsive haemorrhagic shock.

In the absence of emergency access to a CT unit, urgent consultation with a neurosurgeon and/or early transfer to an appropriate facility is essential.

Treatment

Mild traumatic brain injury

Patients with mild TBI but with no indication for CT of the brain or a normal CT scan can be safely discharged after a period of observation (e.g. 2 hours). The exception to this approach is the patient taking anticoagulant medication, who should be observed for a longer period before discharge. For this group, there should be consideration of an 'interval' CT after 24 hours.

It is essential to assess for ongoing PTA, as this is frequently overlooked in the ED. A simple screen to use is the modified Westmead PTA scale.[6] In the presence of these criteria (for PTA), the persistence of mild symptoms (e.g. mild headache, nausea, occasional vomiting) is common and patients should be advised accordingly. In adults, such symptoms may be treated with mild analgesics (paracetamol, aspirin) and antiemetics (metoclopramide, prochlorperazine) and the patient discharged when comfortable. Advising patients that there may be problems with post-concussive symptoms (including short-term memory and information processing) and providing them with written material has been shown to improve outcomes at 3 months.[6,21]

On discharge, patients must be counselled appropriately and discharged with written advice in the care of a responsible adult. Specific advice must be provided regarding expected duration of symptoms, possible risks or delayed complications and reasons for re-presentation to the ED (Box 3.2.1). Information should also be given about the second-impact syndrome and exclusions from sporting activity.

Follow-up by a local medical officer should be arranged and neuropsychological assessment may be warranted for high-risk groups. Patients should be cautioned about making major life, occupational and financial decisions until they are free of post-concussive symptoms. Currently there is no drug to treat the primary pathology in minor head injury,[22] nor does a biomarker for severity of brain injury exist.

Moderate/severe traumatic brain injury

Priority in the management of moderate to severe neurotrauma is given to maintenance of the airway and an adequate CPP. Hypotension systolic blood pressure (SBP) (<90 mmHg) and

Box 3.2.1 Patient advice

General advice following head injury

The patient should read and understand these instructions:

- Rest comfortably at home in the company of a responsible adult for the next 12–24 hours.
- Resume normal activity after feeling recovered.
- Drink clear fluids and consume a light diet only for the first 6–12 hours (a normal diet may be commenced as desired after that).
- Mild pain killers (such as paracetamol) may be taken for headache as directed by the doctor.
- Following head injury, a small number of patients develop ongoing symptoms, such as recurrent mild headache, concentration difficulties, difficulty with complex tasks, mood disturbance, etc. If you notice such problems, consult your local doctor for appropriate referral.
- Within the next 2 weeks, avoid exposure to activities that may create a risk of further head injury.
- If you do not understand these instructions and advice, check with emergency department staff before your discharge or consult your local doctor.
- If you require a certificate for work, please make this clear to emergency department staff.

Report immediately the following problems:

- Persistent vomiting (more than twice)
- Persistent drowsiness—unable to be woken up completely
- Confusion or disorientation or slurred speech
- Increased headache (not relieved by standard doses of paracetamol)
- Localized weakness or altered sensation or inco-ordination
- Blurred or double vision
- Seizures, fits or convulsions
- Neck stiffness

hypoxia (PaO_2 <60 [8 kPa]) should be corrected immediately.[23] Control or modification of ICP has a place in the emergency management of neurotrauma. Avoidance of secondary brain injury and associated cerebral swelling is the goal of such therapy.

ICP monitoring is generally indicated in patients with severe head injury (GCS <9) who remain comatose. Institutional variability exists in methods of measurement, as do specific indications for monitoring. Use of CSF drainage to lower ICP in patients with an initial GCS less than 6 during the first 12 hours after injury may be considered.[24] Elevation of the head of the bed to 30 degrees will reduce ICP modestly without altering CPP.

Mannitol (0.25–1.0 g/kg IV) may produce a short-term reduction in ICP, but there is no evidence that it improves patient outcomes.[24] Mannitol causes an osmotic dehydration which is non-selective. Complications of mannitol therapy include fluid overload, hyperosmolality, hypovolaemia and rebound cerebral oedema. Mannitol may be used as a temporizing measure to enable a patient with a surgically remediable lesion to get to the operating theatre.

Routine use of hyperventilation in head injury is contraindicated. Hypocarbia reduces cerebral blood flow (and ICP) through vasoconstriction, which, if extreme, may reduce CPP to the point of exacerbation of secondary brain injury.[25]

Anticonvulsant prophylaxis (phenytoin, with a loading dose of 15–18 mg/kg IV over 30–60 minutes) is indicated for the prevention of seizures within the first week after injury[26]; there is not yet sufficient evidence to administer levetiracetam in preference to phenytoin.[24] Seizures are managed acutely using standard therapies and guidelines (including benzodiazepines). Endotracheal intubation and mechanical ventilation may be indicated for status epilepticus or when seizures are refractory to therapy.

Antibiotic prophylaxis is indicated for compound fractures. Tetanus immunoprophylaxis is given as part of routine wound care. There continues to be considerable interest and research with regard to cerebral protection and salvage therapies. To date, no benefit has been demonstrated in the administration of steroids in patients with head injury, and they are not recommended.[24] Bifrontal decompressive craniectomy is not recommended to improve outcomes in patients with severe diffuse TBI; however, this procedure has been demonstrated to reduce ICP and to minimize days in the intensive care unit (ICU).[24] The role of hypothermia is controversial; although animal studies have shown a benefit, the results of prospective human studies have been variable and/or inconclusive; currently prophylactic hypothermia is not recommended.[24] High-dose barbiturate administration is recommended to control elevated ICP refractory to maximum standard medical and surgical treatment.[24] In summary, general supportive therapy—including the maintenance of thermoregulation, hydration, pressure care and nutrition—are the mainstays of therapy.

Disposition

In patients with mild TBI, recommendations with regard to a 'safe' period of observation, need for hospital admission or the predictive value of injury mechanism are not consistent. Rural and isolated settings present logistic difficulties in the management of this group. Careful observation for a prolonged period is a reasonable alternative and early neurosurgical consultation, together with a low threshold to transfer to a neurosurgical centre, is prudent.

Patients with moderate to severe neurotrauma require hospital admission, preferably under the care of a neurosurgeon in a specialized neurosurgical unit or ICU. Rehabilitation and social readjustment is a focus of therapy from early in the clinical course.

Inter-hospital transfer of patients with significant neurotrauma requires the attendance of skilled transfer staff and the maintenance of level of care during transfer. Airway management must anticipate the potential for the patient to deteriorate en route. The presence of pneumocephalus precludes unpressurized (high-altitude) flight. The use of teleradiology and neurosurgical consultation will be of value in the management of the remote head-injured patient.

CONTROVERSIES

- Intracranial pressure monitoring has not been shown to improve outcome from major head injury.
- The use of CT scanning in mild head injury has become more widespread. Although it is increasingly accepted that CT is indicated, the timing or urgency of the investigation is controversial. Further studies are required to define discriminators and high-risk markers as guides to the most rational application of this investigation.
- Consideration should be given to referral of patients with mild or worse head injury with persistent post-concussive symptoms for neuropsychological assessment in order to facilitate recovery and resumption of normal activities. Nevertheless a demonstrated improvement through any intervention other than reassurance is lacking in controlled trials.

Acknowledgements

The chapter's authors for this edition would like to acknowledge the important contribution of authors for previous editions, including Professor Lee Wallis and Dr. Marcus Kennedy.

3.3 Spinal trauma

Pieter van Driel

ESSENTIALS

1 **Clinically significant cervical spine injury can be confidently eliminated in conscious, clear-headed patients below 65 years of age using clinical examination criteria (as described in National Emergency X-Radiography Utilization Study (NEXUS) and Canadian C-spine rules) alone.**

2 **Physical examination alone does not assist in the diagnosis of unstable vertebral injury unless the deformity is gross.**

3 **A lack of neurological symptoms and signs does not eliminate spinal column injury or spinal cord at risk.**

4 **A patient can be ambulant and still have a major vertebral injury, even a potentially unstable one.**

5 **The natural history of spinal cord injury may lead to progressively increasing symptoms commencing some hours after the incident.**

6 **Magnetic resonance imaging is evolving as the imaging modality of choice in patients with neurological signs.**

7 **The likelihood of significant vertebral injury in unconscious trauma victims is 10%; 2% of all trauma victims with significant altered conscious state have a spinal cord injury.**

8 **Although spinal immobilization is a standard of care for protecting the spine, the use of these devices can have adverse clinical effects.**

9 **Methylprednisolone is not recommended in most Australian and international centres if given, however, it should be within 8 hours after spinal cord injury in order to improve both motor function and functional outcome.**

Introduction

Spinal cord injury is one of the most disabling traumas, causing major and irreversible physical and psychological disability to the patient and permanently affecting his or her lifestyle. The emotional, social and economic consequences affect the individual, family, friends and society in general.

Approximately 2% of adult victims of blunt trauma suffer a spinal injury, and this risk is tripled in patients with craniofacial injury.[1]

Motor vehicle collisions, falls and sporting injuries—notably diving and water sports—are the major causes of acute spinal cord injury in Australia.[2] Road traffic accidents account for about half of all spinal injuries. Despite the work to minimize spinal injuries in contact sports, such as rugby, serious spinal cord injuries still occur.[2] Young people are most often affected, but minor falls in the elderly or low-impact injuries in people with pre-existing bony pathology can also cause spinal cord damage. Spinal cord injury due to pathological vertebral fractures may be the first presentation of malignancy.

Observations from two studies[3,4] suggest that possibly preventable neurological deterioration may be due to one or more of the following:

- The injury not being recognized initially (e.g. not being specifically examined for, being occult or masked by other injuries)
- The onset of the secondary effects of the spinal cord injury involving oedema and/or ischaemia
- Aggravation of the initial spinal cord lesion by inadequate oxygenation and/or hypotension
- Aggravation of the initial spinal cord lesion by inadequate vertebral immobilization

Pathophysiology

Level of vertebral injury

The level of neurological injury in patients who sustain spinal injuries is variously reported. In studies from Victoria and New South Wales,[4,5] the distribution of the level of injuries was cervical 60%, thoracic 30%, lumbar 4% and sacral 2%.

Spinal cord injuries occur most commonly at the level of the 5th, 6th and 7th cervical vertebrae, largely because of the greater mobility of these regions. The C5–C6 and C6–C7 levels account for almost 50% of all subluxation injury patterns in blunt cervical spinal trauma.[6]

Associated injuries

There are three noteworthy observations[3,5] from associated injuries in patients with spinal injury:

- Approximately 8% to 10% of patients with a vertebral fracture have a second fracture of another vertebra, often at a distant site. These second fractures are usually associated with the more violent mechanisms of injury, such as ejection or rollover. Secondary injuries are usually relatively minor and stable (e.g. fractures of the vertebral processes), but occasionally they may be major and may also be associated with neurological damage. Therefore when 'thinking spine', it is important to 'think whole spine' and, in particular, to attempt to avoid rotation of the vertebral column.
- Owing to the mechanism of injury, many patients with spinal injuries have other

associated injuries, including head, intrathoracic or intra-abdominal injuries, which may modify management priorities.[5]
- Patients may complain of pain from other injuries; hence a back or neck injury may go unnoticed. Pain may often not be a significant feature despite severe vertebral column damage. Furthermore, spinal pain may take some time to become apparent because of other pathological processes modifying the pain, such as swelling and inflammation.

Spinal trauma may result in several injuries directly related to the spinal cord. Specific injuries—such as vertebral injuries, spinal shock, spinal cord injuries and their neurological symptoms—are described later in this chapter.

Effects of spinal cord damage on the autonomic nervous system

Autonomic nervous system effects are mentioned here because important pathophysiological mechanisms must be understood to deliver optimum care and treatment to patients with spinal cord injuries.

The entire sympathetic nervous system and pelvic parasympathetic outflow is transmitted via the spinal cord. In an injury higher than the upper thoracic vertebrae, there is significant impairment of total body sympathetic and pelvic parasympathetic functions. The extent and severity of autonomic dysfunction is dependent on the segmental level or levels affected and the extent or completeness of the neurological insult.

Direct effects

Direct effects include manifestations related to the cardiovascular, gastrointestinal, urogenital and thermoregulatory systems.

Cardiovascular effects

In complete quadriplegia, sympathetic denervation causes relaxation of resting vasomotor tone, resulting in generalized systemic vasodilatation. It is recognized during initial assessment by dry extremities with variable warmth and colour. In males there may be penile engorgement or priapism. Owing to the peripheral vasodilatation, there is a drop in total peripheral resistance with consequent hypotension (neurogenic shock). Under normal circumstances, this would result in a baroreceptor response in order to achieve compensation. However, as the effector arm of the sympathetic nervous system is paralysed, the normal compensatory effects of tachycardia and vasoconstriction do not occur. The vagus nerve carrying parasympathetic supply to the heart is unopposed, with resultant bradycardia. The higher and more complete the spinal cord injury, the more extensive the autonomic dysfunction.

The usual symptoms and signs of the shock process in response to hypovolaemia cannot occur, as tachycardia and vasoconstriction are mediated by the sympathetic nervous system, which has been interrupted by the high spinal cord lesion.

Gastrointestinal effects

Following spinal cord injury, a paralytic ileus develops. This is usually self-limiting and recovers over 3 to 10 days. Paralysis of sphincters occurs at the lower end of the oesophagus and at the pylorus; as a consequence, passive aspiration of the stomach contents, especially of fluid, is a potential problem. Furthermore, owing to paralysis of the thoracic and abdominal wall musculature, the capacity to cough and hence clear the airway is diminished. In quadriplegia and high paraplegia, occult fluid aspiration due to passive regurgitation of retained gastric contents may not be recognized. The airway therefore requires close observation and active protection. A nasogastric tube must be inserted and gastric contents drained.

Urinary effects

Urinary retention is partly the consequence of acute bladder denervation and, in the early post-injury phase, due to spinal shock. Catheter insertion is required to prevent over-distension of the bladder in order to optimize recovery. This also permits measurement of urinary output.

Thermoregulatory effects

Following cervical or upper thoracic spinal cord injury, the patient effectively becomes poikilothermic. In a cold environment, he or she is unable to vasoconstrict to conserve heat or shiver to generate heat. The patient is already peripherally vasodilated, which promotes loss of heat and lowers body temperature. In the warm environment, although the patient is already peripherally vasodilated, the capacity to sweat is sympathetically controlled and therefore lost.

Pre-hospital issues

Extrication and immobilization

Emergency medical services (EMS) personnel are sent to see trauma patients in difficult circumstances. For instance, a patient may be stuck in a vehicle, partially submerged in water or found in a small and inconvenient place. These circumstances often make it hard to carefully handle and immobilize the cervical spine initially. Several devices have been developed to extricate a trauma patient from a crashed vehicle with maximum in-line protection of the spinal column.

A restless patient—due to hypotension, hypoxia, drug abuse, anxiety or other causes—makes it even harder to immobilize the spine. Depending on local protocols, training and skills, EMS personnel should either be able to treat the cause of the restlessness or sedate such a patient in order to protect the cervical spine.

Next to resuscitation interventions following the ABCDE (airway, breathing, circulation, disability and exposure) approach, in-line protection of the total spine should become the focus of attention. Trauma patients should remain in immobilization devices until spinal trauma has been excluded and splinting of specific injuries can be effected. However, they do not need to be left in the devices applied by pre-hospital care providers: these are often structured to provide rigid immobilization for initial stabilization and transport. Nor should they be left tied to spine boards or wrapped in extrication devices, as these are uncomfortable and can cause unwanted cutaneous pressure injuries. Moreover, tight webbing and wraps can interfere with respiratory excursion. In general the pre-hospital devices are removed and replaced with others that are more appropriate for the emergency department (ED) environment.

In-line protection of the spine

In case of suspected injury, in-line protection of the spine is important, although more than 90% of suspected patients do not have an unstable C-spine injury. Recommendations for techniques of immobilisation are evolving. The International Liaison Committee On Resuscitation (ILCOR) 2015 consensus on science and treatment recommendations (CoSTR) regarding immobilization of victims with suspected spinal injury recommend against the use of semi-rigid cervical collars by first aid providers. The Australian and New Zealand Council on Resuscitation (ANZCOR) has formulated the following recommendations:
- Immediate recognition of the potential for spinal injury
- Minimal movement and handling of victim
- Immediate assessment of the victim
- Immediate spinal care with manual techniques
- Early transfer for definitive assessment and care

The effectiveness of common immobilization techniques is largely unproven and there are side effects from unnecessary immobilization. There is even evidence that immobilizing the cervical spine does not significantly reduce neurological injury.[7]

Several types of devices exist and are used either alone or in combination. In Australia different approaches are used following different regional protocols. The common combination in out-of-hospital spine care comprises a spine board and associated padding to ensure a normal

curvature of the spine. Nevertheless there is a decline in the use of the spine board because of its side effects. Other devices, such as extrication devices—not primarily designed as spinal immobilizers—have been used to splint the spine in special circumstances.

The various devices and techniques are variably effective and do not completely immobilize. However, they have generally been tested on uninjured subjects with normal muscular tone and posture.

As mentioned previously, spinal immobilization can be harmful. Standard spinal immobilization applied to otherwise healthy subjects has resulted in significant spinal pain in all of the subjects.[8] Spinal immobilization can mask life-threatening injuries. Cervical collars have been shown to increase intracranial pressure. Spinal immobilization restricts pulmonary function in healthy adults and children. Prolonged immobilization of the cervical spine with rigid pre-hospital rescue collars and other immobilization devices may unnecessarily add to patient discomfort and the need for ongoing spinal nursing. Tissue perfusion in the sacral area is adversely affected within 30 minutes on a rigid spinal board.[9] This predisposes to pressure area problems and problematic decubitus ulceration.

Therefore the pre-hospital devices should be removed as soon as possible after the patient's arrival in the ED, usually immediately after the primary survey, and replaced with more appropriate ones for the ED environment.

First treatment options

Primary survey

Patients presenting with a potential spinal cord injury are managed in keeping with the approach for any patient who has experienced a major trauma. Therefore a standard approach of primary survey, resuscitation, secondary survey and definitive management is adopted.

Specific attention should be paid to the following important issues in the assessment and treatment of patients with (potential) spinal injury.

Airway

Assessment of the airway is vital in the management of suspected spinal cord injury, especially when the cervical spine is involved. Passive regurgitation and aspiration of fluid stomach contents may occur as a result of blunting or absence of cough, gag and vomiting responses. This is especially the case with higher cervical injuries. Therefore the insertion of a nasogastric tube is of vital importance in minimizing the likelihood of aspiration. In quadriplegia and high paraplegia, unopposed vagal action owing to functional total or near-complete sympathectomy predisposes the patient to bradycardia on vagal stimulation of the pharynx. It is important that such patients have electrocardiographic (ECG) monitoring and that atropine be immediately available to block these effects. Pretreatment with atropine prior to manipulation of the upper airway is a consideration.

Advanced airway management Early endotracheal intubation and assisted ventilation should be considered in patients with quadriplegia and high paraplegia. Regular assessment of respiratory status is undertaken and includes continuous pulse oximetry and frequent measurement of vital capacity in order to detect fatigue.

Blind nasal or endoscopic-assisted intubation under local anaesthesia is the preferred mode of non-emergency intubation. Additionally, every manipulation of the head and neck of the patient should be done with extreme caution to minimize further damage to the vulnerable spine.

The literature suggests that video-laryngoscopy results in less overall movement during intubation, and it does not seem to have an impact on cord injury.

Since the rocuronium antagonist sugammadex has become widely available, rocuronium has become the muscle relaxant of first choice in many settings because of the beneficial side-effect profile. Suxamethonium is therefore used less often but still acceptable for a rapid-sequence intubation in the emergency setting. The hyperkalaemia associated with denervation is a concern in injuries more than 10 to 12 hours old (see Chapter 2.1).

Breathing

Ventilation in patients with spinal cord injury may be affected by the level of cord injury, aspiration and primary lung injury. In the absence of major airway obstruction and flail chest, the presence of paradoxical breathing is considered highly suggestive of cervical spine injury. Paradoxical breathing occurs because of loss of motor tone and paralysis of thoracic muscles innervated by thoracic spinal segments. Diaphragmatic action results in a negative intrapleural pressure. As a consequence of chest wall paralysis, the tendency is for the soft tissues of the thorax to 'cave in', producing paradoxical chest wall movement. The diaphragm must then undertake the full work of breathing, including overcoming added resistance to ventilation caused by paradoxical chest wall movement. In addition to standard assessment of respiratory status, continuous pulse oximetry and assessment of vital capacity is necessary. Early intubation should be considered if vital capacity is inadequate or falling.

Ventilation may be reduced for several reasons:

- The diaphragm may simply fatigue and require assisted ventilation.
- A progressively ascending spinal cord injury owing to either further primary damage or secondary ascending spinal cord oedema may encroach upon the third to fifth cervical segments.
- The same segments may be involved with the initial injury and thus the diaphragm may itself be partially paralysed.
- The consequences of coexisting chest trauma must also be taken into consideration, as respiration may be embarrassed by the natural progression of thoracic cage, pulmonary or intrapleural injuries.

Circulation

Volume resuscitation in the resuscitative phase of the primary survey is undertaken in keeping with usual practices. With the exception of perhaps diving injuries, victims of hypotensive trauma should be considered as suffering from intravascular volume depletion and bleeding until proved otherwise. Standard initial volumes of resuscitation fluid will not adversely affect haemodynamic status. Owing to peripheral vasodilatation, the spinal cord trauma patient's intravascular volume is relatively depleted; therefore volume preloading is appropriate. However, unnecessary volume overloading in an attempt to raise systolic blood pressure substantially will lead to acute pulmonary oedema.

After resuscitation fluids have been administered, haemorrhage controlled, ongoing losses replaced and fluid required for oedema responses to injury considered, routine maintenance fluids are all that is needed.

Paralysis of the sympathetic nervous system and hence the compensatory mechanisms for intravascular volume depletion necessitates a heightened suspicion of ongoing bleeding, the signs of which may be dramatic or subtle. Progressive hypotension is a key sign. Paradoxically, the heart rate may rise progressively from a bradycardia of 50 to 60 beats/min to more normally acceptable rates. It is uncertain by which mechanism this pseudo- or relative tachycardia of quadriplegia occurs. One thought is that with progressive hypotension and brain stem hypoperfusion, the vagal effects are switched off by the brain stem, thus allowing the heart rate to rise towards a more normal or denervated range. In addition, the skin may develop patchy or blotchy cyanosis. This is due to a sluggish peripheral circulation and hence locally elevated levels of deoxygenated or desaturated haemoglobin.

In cases of spinal cord injury, the impact of functional sympathectomy will depend upon the level and completeness of the neurological injury. Complete injuries above T1 and perhaps T4 can be expected to have clinically significant manifestations of neurogenic shock. The clinical signs are bradycardia due to unopposed vagal

action, peripheral vasodilatation and cessation of sweating. Peripheral vasodilatation is responsible for variable cutaneous manifestations. Initially, flushing can be expected; however, the skin may be pale or cyanosed and its temperature elevated, reduced or within normal limits. The state of these signs is dependent on perfusion pressure, adequacy of oxygenation and the ambient temperature.

Priapism in a trauma patient is due to penile vasodilatation and is regarded as a highly suggestive sign of spinal cord injury.

Circulatory status is best assessed by conscious state, urine output and venous pressure monitoring. In the early phases of management, close urine output monitoring is of major importance. Early insertion of the urinary catheter allows measurement of urine output, may assist in identifying occult renal tract injury and also prevents undesirable bladder overdistension.

Inotropic support is often unnecessary.[5] However, satisfactory cerebral perfusion is essential. In order to maintain cerebral perfusion, a mean arterial pressure (MAP) of at least 60 mmHg is recommended. In the patient with a previously normal Mini Mental State Examination, deterioration may suggest intracranial hypoperfusion due to either intracranial trauma or the neurogenic shock process. Chronotropic and vasoconstrictor agents are occasionally required. These are more likely to be necessary in older patients or those suffering from hypertension who are now relatively hypotensive despite volume loading. Chronotropic agents are occasionally required for patients prescribed β-blocker and/or peripheral and central vasodilator drugs. Likewise patients with established cerebrovascular disease may require higher perfusion pressures than the resting pressure of the quadriplegic.

The degree of the physiological effects on the circulation will depend on the site and completeness of the injury. Spinal cord injury below the sympathetic outflow will have little effect on the circulation; complete spinal cord injury above the thoracic outflow will produce a total body sympathectomy. A complete spinal cord injury in the mid-thoracic segments should result in preserved vasomotor function in the head, neck and upper limbs. Cardiac reflexes should also be relatively well preserved. Vasomotor tone to the abdominal cavity, pelvis and lower limbs will be paralysed. Likewise, incomplete lesions will have a varying effect depending on the site and completeness of the injury. Careful establishment of the segmental level and degree of spinal cord injury on secondary survey will assist in anticipating the likely extent of autonomic dysfunction.

The denervated lung is intolerant of volume overload. Therefore careful monitoring of fluid balance, including urine output and, in circumstances of low urine flow, central venous pressure, is required.

Disability

Spinal cord injury has an association with significant head trauma. In patients with an altered conscious state due to head trauma, early brief assessment of mental state and pupillary reflexes is important. All trauma victims with altered conscious state require spinal immobilization until spinal cord or unstable vertebral injury is excluded on physical examination and investigation.

In patients with injuries at or above T4, bilateral Horner syndrome may be present with relative pupillary constriction.

Exposure

As a spinal cord injury may be one of several injuries, the patient should be fully exposed and then wrapped in a warming blanket in keeping with a routine approach to patients with multisystem trauma.

General management issues

The general management is in keeping with the approach to any victim of major trauma.

Analgesia and medications

Owing to the variable physiology of the peripheral circulation due to vascular tone denervation and sympathetic efferent interruption, the absorption of subcutaneous and intramuscular medications is unreliable. It is recommended that analgesia be provided by continuous intravenous infusion, with careful monitoring of vital signs. For similar reasons and where possible, all other medications are administered by the intravenous route.

Temperature

In complete quadriplegia, the patient has been rendered poikilothermic by the interruption of efferent sympathetic activity. Attention is directed to ensuring that the core temperature remains within the normal range. Such patients will demonstrate a core body temperature in keeping with changes in ambient temperature.

Clearing the spine

Clearing the cervical spine

Prolonged immobilization of the spine with rigid pre-hospital rescue collars and other rigid immobilization devices may unnecessarily add to patient discomfort, complications from the immobilization devices and the need for ongoing spinal nursing.

Although various algorithms exist for clearing the spine of significant injuries and compliance with such clearing algorithms is high, none have been validated for clinical effectiveness. Most incorporate the elements of either the US National Emergency X-Radiography Utilization Study (NEXUS) or the Canadian C-Spine Rules (CCR), thus restricting evidence-based decision rules to the cervical spine (see Tables 3.8.6 and 3.8.7).[10]

It is still the emergency physician's responsibility to minimize exposure to radiation. The need for imaging of the cervical spine can be safely determined by applying the criteria of NEXUS or the CCR. The application of one of these two clinical tests essentially clears the c-spine in a number of patients. Although not studied as a combination, many clinicians use NEXUS and CCR in combination.

The fundamental differences between the two tests are that the CCR incorporates the mechanism of injury, circumstances and examination findings of active movement of the cervical spine.[11-13]

Following the (radiological) algorithm in Fig. 3.3.1 is a safe way to approach the patient with cervical spine trauma.

Thoracic, lumbar and sacral spine clearance

Little information is available to provide evidence-based guidelines for clearing the thoracic, lumbar and sacral spine. The investigation and injury exclusion strategy is based on appropriate clinical reasoning (read the mechanism!) and an understanding of the effectiveness and limitations of medical imaging options in both logistics and effectiveness. All patients with significant mechanisms of injury and pain or tenderness along the thoracic, lumbar and sacral spine should be imaged. Additionally, patients with multiple injuries and high-risk mechanisms should be imaged routinely.

Secondary survey, referral-disposition and definitive treatment

The secondary survey of spinal cord damage

The definitive diagnosis of a spinal cord injury is made from the findings on secondary survey. Two specific injury entities need to be considered: skeletal and neurological.

A head-to-toe clinical examination is conducted in keeping with the standard conventions used in examining any victim of major trauma. The following paragraphs outline the specific points of clinical examination pertinent to spinal injury.

Head and neck

An examination of the cervical spine is conducted while maintaining immobilization. Palpation of the spine posteriorly may demonstrate

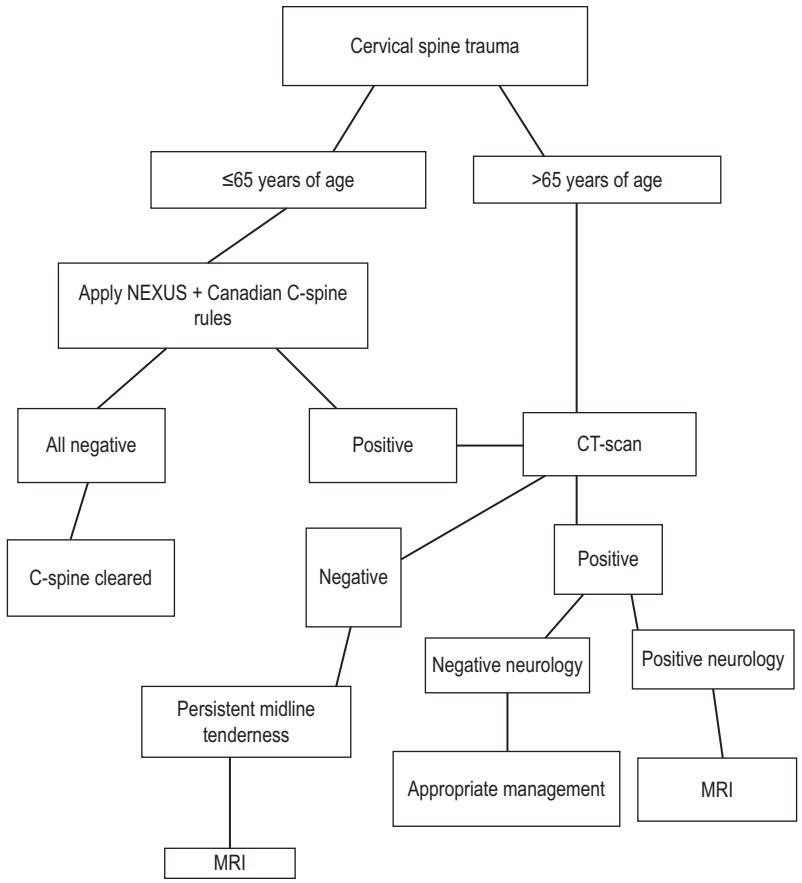

FIG. 3.3.1 Suggested radiological algorithm for cervical spine trauma. *CT*, Computed tomography; *MRI*, magnetic resonance imaging.

generalized tenderness owing to diffuse muscular spasm. However, the point of maximal tenderness should be determined. In hyperextension injuries, the prevertebral and paravertebral muscles are often contused. This is a helpful sign when evaluating hyperextension–hyperflexion injuries in patients who were in stationary vehicles hit from behind. Longitudinal pressure to the head increases cervical pain. Such patients should be considered to have a higher likelihood of a significant vertebral injury.

The neck should be examined for swelling and bruising. Deformity will be noted if there is a dislocation with significant displacement. It should be remembered that significant bony and soft tissue injury frequently occurs without any major findings on external examination.

As prolonged immobilization of the cervical spine with rigid pre-hospital rescue collars and other rigid immobilization devices may unnecessarily add to patient discomfort, complications from the application of splinting devices and the need for ongoing spinal nursing, it is important to determine whether immobilization devices can be removed early during the assessment and treatment phases of management. Reasons for lengthy periods of immobilization include times to definitive radiological assessment and waiting for windows of opportunity to ensure vertebral stability (see also earlier in this chapter/section- 'In-line protection of the spine' and 'Clearing the spine').

A re-examination of the upper airway is required. A prevertebral haematoma can cause obstruction; the gag reflex may be blunted; moreover, airway protection may be embarrassed owing to paralysis of muscles below the neck, resulting in inefficient gag and cough. The patient will have gastric stasis and be at considerable risk of fluid aspiration.

The torso

The patient should be either lifted or rolled onto his or her side using a formal spinal lifting technique so that the back can be examined. The spine is examined for alignment, swelling, bruising and abrasion. Deformity is generally not a feature, except in the presence of major dislocation or disruption.

The rise and fall of the chest is noted. Paradoxical movement is a sign of thoracic cage muscular paralysis and will be more pronounced the higher the segmental level of injury. Careful examination of the thorax, abdomen and pelvis is required. In both quadriplegia and high paraplegia, serious injury may be masked by the use of analgesia and anaesthesia. Significant vertebral injury to the thoracic and lumbar spines is associated with major injuries to the thoracic, abdominal and pelvic organs.

The abdomen is specifically assessed for an evolving paralytic ileus.

Neurological assessment

A thorough examination of the peripheral nervous system is required. It is strongly recommended that both motor and sensory examinations be undertaken in accordance with the following convention. Examine motor, sensory and reflex components independently. Examination begins at the head and then progresses across the shoulders. The upper limbs are then examined. The torso evaluation begins from just below the clavicles, extending inferiorly to the groin; each lower limb is then assessed. Finally, the saddle area and pelvic floor are assessed.

This approach reduces the likelihood of an incorrect diagnosis of paraplegia by finding a 'pseudo' neurological level of injury just below the clavicles when upper limbs have not been examined. It is therefore important that the upper limbs be assessed before examining the torso.

Motor function

Muscle power is assessed in terms of neurological segments and not muscle groups. Muscle power in each segment is graded from 0 to 5, as shown in Table 3.3.1.

It is often impossible to assess power grades in certain segments owing to the patient's injuries. The upper limbs are the most easily examined. The strength of a cough provides some information as to the state of the thoracic and abdominal musculature.

In the emergency setting, the state of the pelvic muscles is determined through a rectal examination by assessing rectal tone and requesting the patient to tighten the sphincter on the examiner's gloved finger.

Sensory function

Dorsal column sensation is assessed using a piece of cotton wool and testing for light touch. Spinothalamic sensation is assessed using a pin or sharp object. Although proprioception, vibration and temperature can be assessed, this is not essential and adds little to the emergency examination. When testing with a sharp object, a hypodermic injection needle or a trocar stylet must not be used: these are engineered to stab the skin as painlessly as possible, therefore they cause trauma and are unreliable.

The general convention described here should be followed. Sensory examination begins on the face, which, as it is supplied by the trigeminal nerve and bypasses the spinal cord, acts as a reference point. It is an important axiom based on anatomy that 'in the absence of head injury or local facial injury, sensation to the face is always normal in pure spinal cord injury' (the trigeminal

nerve comes from above the spinal cord). It is recommended that examination of the head, neck and upper torso be performed as follows. Start by examining the C2 dermatome laterally on the neck, behind the mandible and beneath the ear. Extend examination onto the top of the shoulder, thus assessing the C3, C4 and C5 dermatomes. In the upper limbs, examine the dermatomes in segmental order. This should include T2 on the upper medial aspect of the arm. Then carry on examining the torso in the mid-clavicular plane or at the outer border of the surface marking of the rectus sheath.

Reflexes

Reflexes are examined in keeping with usual examination practices. Superficial abdominal reflexes should be noted. The anal and bulbocavernosus reflexes are important in assessing sacral segments.

Corticosteroids—methylprednisolone

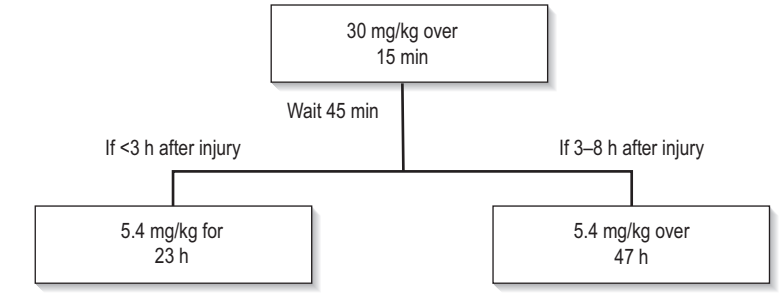
A Cochrane review from 2012 found that administration of methylprednisolone (MPS) within 8 hours after injury gave a significant recovery of motor function.[14] A systematic review and meta-analysis done in 2016 failed to show long-term benefit but limited data suggested short-term improvements in motor score if MPS was administered within 8 hours of injury.[15]

Administration for an additional 24 hours (totalling 48 hours) may give an additional improvement of motor neurological function and functional outcome. On the other hand, the use of MPS is not without complications. It is contraindicated in patients with heavily contaminated open injuries and other heavily contaminated situations, such as perforated bowel and established sepsis. It poses the risk of developing acute adrenal insufficiency in these patients, which needs recognition and prompt treatment to prevent further complications. It is relatively contraindicated in diabetes mellitus. Prophylactic measures, such as for acute peptic ulceration and monitoring of blood glucose, should be instituted.

The benefit of steroids in spinal cord injury is therefore considered questionable. Despite this, steroids remain a treatment option and several centres prefer to use high-dose MPS in the early management of patients with neurological injury. In Australia, spinal cord injury is not listed as an indication for high-dose MPS. Therefore the decision to use high-dose corticosteroids should be made in conjunction with the specialist services, either the major trauma service or spinal injuries service that will be managing continuing care. If corticosteroids are used, treatment must commence within 8 hours from the time of injury. The total treatment period should be for 24 hours if treatment commences within 3 hours of injury and 48 hours if it commences between 3 and 8 hours of injury.[16]

Table 3.3.1 Muscle power grading

Power grade	*Clinical finding*
Grade 0/5	No movement
Grade 1/5	Flicker
Grade 2/5	Movement present but not a full range against gravity
Grade 3/5	Full range of movement against gravity with no added resistance
Grade 4/5	Full range of movement against gravity with added resistance but with reduced power
Grade 5/5	Normal power



These doses may be approximated to the nearest 0.5 g. For example, a 70 kg patient requiring 24 h of treatment would need:

Calculation	Actual Dose
30 (mg/kg) x 70 (kg) = 2100 mg followed by: 5.4 mg/kg/h x 70 (kg) = 8694 mg	2g (1 x 2 g or 2 x 1 g or 4 x 500 mg vials) followed by: 8.5g (4 x 2 g + 1 x 500 mg or 8.5 x 1 g or 17 x 500 mg vials) over 23 h

FIG. 3.3.2 Methylprednisolone for acute spinal cord injury.

A guideline for the use of MPS in acute spinal cord injury is presented in Fig. 3.3.2.

Referral—disposition

As soon as practicable, patients with a spinal cord injury should be referred to a centre with facilities for optimal management. Specific treatments such as immobilization, specific therapy and transport considerations should be discussed with the continuing care provider or spinal injuries unit prior to transfer. If transport is delayed, it is appropriate that the spinal injuries unit be involved and contribute to the patient's initial management, especially in areas of specific management, as soon as possible, even if transfer is to be delayed by several days.

Specific conditions

Vertebral injury[2]

Cervical spine fractures

Cervical spine injuries may result from one or more combinations of the following mechanisms:

- Hyperflexion
- Hyperextension
- Flexion—rotation
- Vertebral compression
- Lateral flexion
- Distraction

Hyperflexion Hyperflexion produces the following injuries:

- A simple, stable wedge fracture
- A fracture with an anterior teardrop
- Bilateral anterior subluxation
- Clay shoveller's fracture
- Bilateral facet dislocation

Flexion injuries can cause a vertebral body fracture with an antero-inferior extrusion teardrop fracture. This is often associated with retropulsion of a vertebral body fracture fragment or fragments in the spinal canal.

The clay shoveller's fracture is a particular spinous process fracture produced by a sudden load on a flexed spine with resulting avulsion of the C6, C7 or T1 spinous processes.

Hyperextension Anterior widening of disc spaces, prevertebral swelling, avulsion of a vertebral body by the anterior longitudinal ligament, subluxation and crowding of the spinous processes are features of the hyperextension injury. Encroachment on the canal by an extruded disc

or a posterior osteophyte may occur in patients with osteoarthritis of the cervical spine.

Flexion—rotation This is responsible for unilateral facet dislocation or forward subluxation of the cervical spine.

Vertebral compression This is the mechanism responsible for burst fractures. The intervertebral disc is disrupted and driven into the vertebral body below. In addition, disc material may be extruded anteriorly into prevertebral tissues and posteriorly into the spinal canal. The vertebral body may be comminuted to varying degrees, with fragments being extruded anteriorly and posteriorly into the spinal canal.

Lateral flexion This may produce uncinate fractures, isolated pillar fractures, transverse process injuries and lateral vertebral compression.

Distraction These injuries may result in gross ligamentous and intervertebral disc disruption. The hangman's fracture may also occur by combined distraction and hyperextension mechanisms.

C1—the atlas

Fractures of the atlas comprise 4% of cervical spine injuries. Mechanisms of injury generally involve hyperextension or compression. Around 15% to 20% of fractures may be associated with a C2 injury and 25% may be associated with a lower cervical injury. The Jefferson fracture is a blowout fracture of the ring. Other fractures include isolated injuries of the posterior arch, the anterior arch and the lateral mass.

C2—the axis

Axis fractures comprise 6% of cervical spine injuries, in the majority of cases with an association with concurrent C1 injury.

Computed tomography (CT) scan images are examined for odontoid subluxation. Three types of odontoid fracture are described:

- Type 1 is an avulsion of the odontoid tip. It is generally a stable injury and accounts for 5% to 8% of odontoid fractures.
- Type 2 injury is a fracture through the base of the dens and is generally unstable. It comprises 55% to 70% of odontoid injuries. In younger children, the epiphysis may be present and thus the injury may be confused with a type 2 fracture.
- Type 3 is a subdental fracture of the odontoid extending into the vertebral body. It comprises 30% to 35% of odontoid fractures.

Other fractures of the odontoid include avulsion fractures of the lower anterior margin of the body due to a hyperextension injury. A hangman's fracture is a bilateral neural arch fracture of C2. It is a hyperextension injury and is associated with prevertebral soft tissue swelling, anterior subluxation of C2 on C3 and avulsion of the antero-inferior corner of C2.

C3—C7

Fractures in this segment of the cervical spine are clearly picked up with CT scanning. Such fractures are defined as unstable when

- the anterior and all of the posterior elements are disrupted.
- there is more than 3 mm overriding of the vertebral body above over the vertebral body below.
- the angle between two adjoining vertebrae is greater than 11 degrees.
- the height of the anterior border of a vertebral body is less than two-thirds of the posterior border.

Fractures of the thoracic spine

Hyperflexion is the principal mechanism of injury to the thoracic spine, with resultant wedging of vertebral bodies. Owing to the rigidity of the thoracic cage and the associated costovertebral articulations, most injuries of the thoracic spine are stable. However, internal stabilization may be necessary where kyphosis is pronounced.

Thoracolumbar spine

Fractures of the thoracolumbar spine comprise 40% of all vertebral fractures responsible for neurological deficit. Most are flexion or hyperflexion-rotation injuries. Plain films may demonstrate facet joint disruption, evidence of interspinal ligament disruption, posterior bony fragments protruding into the spinal canal and burst fragments at the superior surface of the vertebral body. These fractures are generally unstable.

Lumbar spine

Injuries similar to those previously described do occur in the lumbar spine. Three specific injuries of the lumbar spine merit further discussion and are broadly considered posterior distraction injuries of the vertebral arch. They constitute a group known as seatbelt injuries, produced when a hyperflexion force is applied to a person wearing a lap-only type seatbelt. In unrestrained persons, a flexion injury generally flexes the spine around a point through the anterior spinal column, typically causing a wedge compression fracture of the body. In the restrained person, the point of flexion is moved forward to the anterior abdominal wall. This change in momentum forces converts the hyperflexion mechanism to one of distraction. These injuries are caused by deceleration from high speed, as seen in head-on road traffic accidents or aircraft crashes.

Plain film radiology remains the first-line imaging study. Suggestive findings include the following:

- A vacant or empty appearance of the vertebral body on the AP film
- Discontinuity in the cortex of the pedicles or spinous processes on the antero-posterior (AP) view
- Fracture with or without dislocation in the lateral view, which may be subtle

CT and magnetic resonance imaging (MRI) are of value in further delineating architectural disruption. However, the exact nature of the fracture complex may be difficult to delineate on axial images, as the fractures are often orientated parallel to the scanning plane. Three-dimensional reconstruction of multislice CT images has greatly improved spinal injury imaging.

These injuries are often associated with concurrent intra-abdominal visceral injuries.

Chance fractures

These are characterized by an oblique or horizontal splitting of the spinous process and neural arch, extending the superior posterior aspect of the vertebral body into the intervertebral disc and damaging it.

Horizontal fissure fracture

This fracture is very similar to the chance fracture with the exception of the fracture line, which extends horizontally through the vertebral body to its anterior aspect.

Smith fracture

This fracture spares the posterior spinous process. The fracture line involves the superior articular processes, the arch and a small posterior fragment of the superior posterior aspect of the vertebral body. Although the spinous process is intact, the posterior ligaments are disrupted.

Spinal shock

Spinal shock is often confused with the neurogenic shock of sympathetic interruption. These, however, are different entities. Complete separation of the spinal cord from the brain abolishes voluntary movement and sensory perception and causes changes in cord physiology and reflex activity. Acute cord confusion is a simple explanation of the resulting pathophysiology. Spinal shock is manifested by the transient cessation of cord activity in the normal cord below the injury. The cord distal to the injury is unable to function, as one would expect from a newly created upper motor neuron lesion. Spinal shock may last for a few hours to several weeks, depending on the segmental level and extent of the cord injury. During this period both somatic and autonomic reflexes below the injured segments disappear. Spinal shock has been attributed to the sudden

loss of descending facilitatory impulses from higher centres. Recovery from spinal shock is heralded by the return of the Babinski response, followed by the perineal reflexes. In quadriplegia and high paraplegia, as the cord recovers from spinal shock, either recovery of function (depending on the degree of injury resolution at the injury site) occurs or, more commonly, spasticity develops. If the cord injury is at the conus medullaris or the cauda equina, unless recovery occurs, a lower motor neuron pattern with areflexia remains.

Spinal cord injuries

Spinal cord injuries should be divided into primary and secondary injuries, as the causes affect the choice of treatment. Primary spinal cord injuries involve injuries directly caused by the trauma mechanism and its damaging energy affecting the spinal cord. Secondary spinal cord injuries are caused by other mechanisms often related to the initial trauma (i.e. hypotension, hypoxia, etc.).

Primary spinal cord damage (Fig. 3.3.3)

Transverse spinal cord syndrome

The spinal cord is completely damaged transversely across one or more adjacent spinal segments. No motor or autonomic information can be transmitted below the damaged area and ascending sensory stimuli from below the damaged spinal segments are blocked. The manifestations are: total flaccid paralysis, total anaesthesia, total analgesia and usually areflexia below the injured segment.

The transverse cord syndrome can be incomplete, with partial paralysis, reduced sensation and pain sensibility below the injured part.

The term 'sacral sparing' implies that some sensibility with or without motor activity in the areas supplied by the sacral segments is preserved in an otherwise complete transverse cord syndrome. The presence of sacral sparing implies an incomplete injury, as some neurological transmission through the injured segments is preserved. It will be recalled that spinothalamic and corticospinal transmission to and from sacral segments is located in the outermost parts of the spinal cord and is, therefore, immediately adjacent to the origin of the spinal cord's blood supply.

Acute central cervical cord syndrome

The central part or grey matter of the spinal cord is injured. Transmission in the outer rim of the spinal cord is essentially intact but impaired. The signs of this injury are as follows:

- Motor function: there will be weakness in both upper and lower limbs, with weakness marked in the upper limbs
- Sensation: there is sensory loss in both the upper and lower limbs; it is more severe in the upper limbs
- Reflexes are variable.

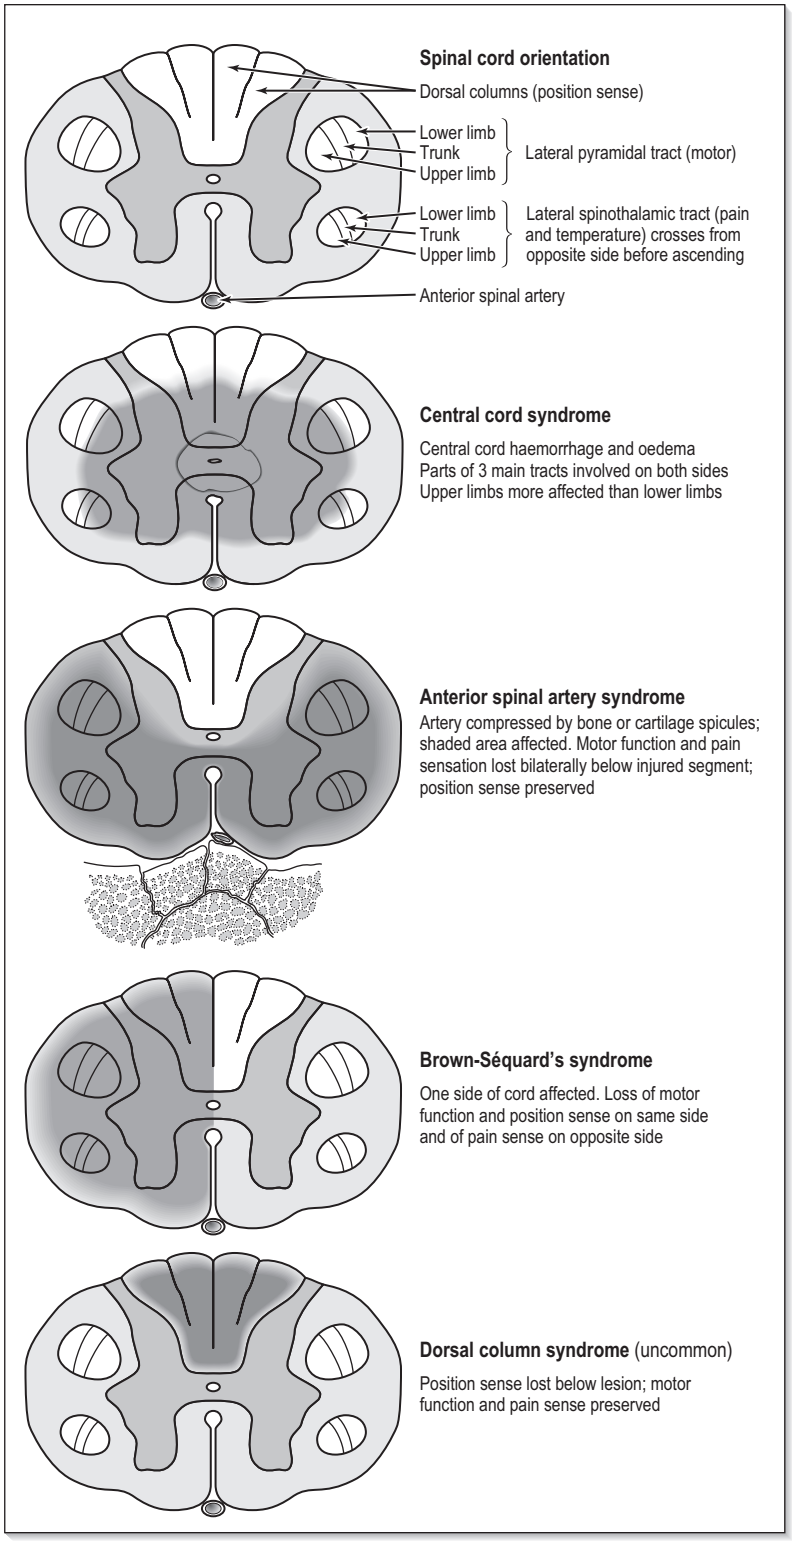


FIG. 3.3.3 Spinal cord and syndromes. (From *Clinical Symposia* 1998;34[2]:17. Comprehensive Management of Spinal Cord Injury, Plate 11. Redrawn with permission of Novartis Pharmaceuticals Corporation.)

This is frequently caused by a hyperextension injury and is typically seen in older patients with cervical spondylosis. In this situation, the cord is compressed between posterior osteophytes and the intervertebral disc in front and the ligamentum flavum behind.

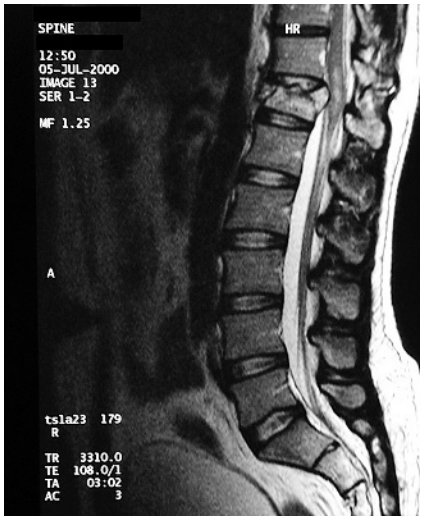

FIG. 3.3.4 Magnetic resonance imaging scan of acute central cord syndrome.

Acute anterior cervical cord syndrome

The anterior half of the spinal cord—the region supplied by the anterior spinal artery—is damaged (see Figs 3.3.3 and 3.3.4). There is motor loss or paralysis below the level of the injured segment or segments. Spinothalamic transmission is impaired; thus there is analgesia with loss of temperature sensation and coarse touch. As the dorsal columns are relatively intact, there is some preservation of joint position, vibration sense and fine touch. In the context of an acute cord injury, the patient may not interpret dorsal column preservation in terms of joint position sense or light touch. Dorsal column function may be manifested as preservation of vague and poorly localized sensation in the extremities.

These injuries are frequently the result of flexion–rotation or vertical compression injuries.

Brown-Séquard's syndrome

This syndrome is a functional cord hemisection with dissociated sensory loss. One-half of the cord is damaged. In a pure Brown-Séquard lesion, ipsilateral motor function is impaired, as are light touch, joint position sense and vibration. Contralateral spinothalamic sensation—that is, pain and temperature—is impaired, whereas ipsilateral sensation is relatively preserved. Reflexes are variable.

Posterior cord syndrome

This is an uncommon injury that causes contusion or disruption to the dorsal columns, leading to impaired or disrupted proprioception, vibration and fine touch sensation.

This syndrome is usually the result of penetrating trauma to the back or a hyperextension injury in association with fractures of the vertebral arch.

Spinal cord concussion

This diagnosis implies a temporary cessation of spinal cord neurological function. In this instance, there is a near full recovery of cord function within 48 hours. The patient will be first assessed as suffering from either a complete or an incomplete spinal cord injury and will then recover within days. The patient has suffered an injury to the spinal cord, such as haemorrhage or contusion, that has been enough temporarily to stop electrical activity in the injured spinal segment; however, there has been no or very little, mechanical or anatomic injury to the cord. It is the pattern of recovery over a day or two that allows the diagnosis to be made. Unfortunately spinal cord concussion constitutes less than 1% of all spinal cord injuries.

In all the incomplete spinal cord syndromes, the location of cord pressure or damage varies in terms of incompleteness and segmental level(s) of cord injury and so will the range of symptoms and signs.

Secondary spinal cord damage

It is often believed that most spinal cord damage occurs at the time of injury, but it may occur subsequent to the initial injury.[6] Such secondary damage may be caused by the following:

- Inappropriate manual handling.[4,5] Subsequent mishandling causes significant movement at the site of the primary vertebral injury, leading to spinal cord damage. This can be prevented by careful handling of the patient. It is important to be aware of the possibility of a spinal cord injury and to protect the spine until the diagnosis has been excluded. This involves standard cervical in-line immobilization, whole-spine immobilization using a spine board or a Jordan frame and 'log roll' for moving the patient.
- Hypoxia and hypotension. These aggravate the primary injury, causing progressive neurological deterioration by mechanisms similar to those that cause secondary brain damage in head injury.
- Acute response to injury. Intrinsic metabolic changes in the previously undamaged spinal cord at the region of the initial vertebral injury may also cause secondary deterioration due to oedema, haemorrhage and the release of metabolically active substances from damaged neurons. The culmination of the pathophysiological processes leads to cord ischaemia and oedema, thereby promoting further neurological damage. The oedema and haemorrhage tend to resolve within 10 to 14 days, with some improvement in neurological function. Resolving oedema results in local segmental recovery. However, residual ischaemic change in secondarily affected spinal cord adjacent to the primarily injured segments does occur, producing a permanent neurological deficit.

Unconscious patients

As previously mentioned, the definitive diagnosis of spinal cord injury is a secondary survey consideration and hence identified primarily from symptoms and physical findings. There is no pathognomonic sign of a spinal cord injury in an unconscious patient. The following should alert the examiner to the possibility of a coexisting spinal cord injury in an unconscious trauma victim:

- Paradoxical breathing or chest wall movement (diaphragmatic breathing) in the absence of a major airway obstruction; stove-in or large flail chest suggests a cervical cord injury.
- Priapism in the unconscious trauma victim suggests quadriplegia or high- to mid-thoracic paraplegia.
- Preserved facial grimace in the absence of a response to painful stimuli in the limbs suggests tetraplegia.
- Lower limb flaccidity in the presence of normal upper limb tone suggests paraplegia.
- Observed upper limb movement in the absence of lower limb movement suggests paraplegia.
- The combination of persistent bradycardia and hypotension despite volume challenge suggests spinal cord laesion.
- Where this is accompanied by a flaccid rectal sphincter, there is an increased likelihood of spinal cord injury.

Special attention, again, should go to protection of the cervical spine in this category of patients. As the gold standard of imaging, the cervical spine CT is highly sensitive and may reliably exclude unstable injuries in patients with obtunded or intubated blunt trauma.[17]

Documentation conventions

Two of the pitfalls in the management of any neurological injury are terminology and documentation. The following convention is recommended:

Motor function is recorded either using segmental terminology in written format or on a muscle chart (Fig. 3.3.5). It will be impossible to chart every segment accurately, but it should be possible to record motor power in the upper and lower limbs confidently. Power should be graded using the 0 to 5/5 system.

Sensation is recorded more descriptively. *Normaesthesia, hyperaesthesia, hypoaesthesia* and *anaesthesia* are the descriptors for dorsal column function and testing for light touch. *Normalgesia, hyperalgesia, hypoalgesia* and *analgesia* are used

in describing pain perception. These are recorded on sensory charts or described according to the following examples.

In a patient with a transverse spinal cord syndrome, incomplete below C6 and complete below T1, the sensation is described as

- normaesthesia and normalgesia to C5
- hypoalgesia and hypoaesthesia below C5
- anaesthesia and analgesia below T1.

In a patient with an acute central cervical cord syndrome below C6, with total segmental paralysis in the C6 to C8 segments and with some involvement of C5, the sensation might be described as

- normaesthesia and normalgesia to C4
- hypoalgesia and hypoaesthesia below C4
- anaesthesia and analgesia below C5
- hypoalgesia and hypoaesthesia below T1

CONTROVERSIES/EMERGING ISSUES

- Recent research has shown that patients with persistent midline cervical tenderness incur considerable health care costs.[18] With more understanding of the financial, social and psychological impact of spinal trauma, it is expected that more and more emphasis will be put on prevention, early detection and therapy in cases of (potential) spinal injury.
- Clinical decision rules for cervical spinal clearance will need further testing with CT scanning as the new standard diagnostic modality of first choice. It is therefore expected that these rules will change according to the results of future research.
- With the technical developments expected in the coming years, it is expected that MRI scanners will become more widely available, will be faster and have higher diagnostic accuracy while becoming less costly. Also, since CT scanning has the disadvantage of the patient being exposed to radiation, it is expected that indications for MRI scanning of the spine will be broadened.
- Treatment options are under investigation: the focus is shifting to early decompression and the possible roles of hypothermia and neuroprotective and regenerative therapeutic agents are being considered.

3.4 Facial trauma

Mark Putland • Kiran Veera

ESSENTIALS

1 **Facial trauma occurs as isolated injury with assault, sporting mishaps, falls and as part of complex multisystem injury.**

2 **Immediate threat to life may relate to airway obstruction or local haemorrhage; however, threat to life is mostly due to associated injuries. Therefore assessment of facial trauma usually takes place in the secondary survey.**

3 **It is vitally important to understand the relationship between structure and function in managing facial trauma. Functions of the face include vital activities, sensation, and important social functions. Cosmetic outcome cannot be separated from functional outcome in facial trauma.**

4 **Plain radiographs are rarely used and have been replaced by computed tomography (CT) scanning; however, the orthopantomogram is still valued by some dental surgeons, who may provide definitive care for some facial trauma.**

5 **Although difficult, some assessment of vision must be made after facial trauma, as simple procedures may be sight-saving.**

Introduction

This chapter covers the assessment and emergency department (ED) management of facial injuries. Eye injuries, dental trauma and radiology of dental trauma are covered in detail elsewhere in this book.

Facial trauma is most common in young males; drug and/or alcohol intoxication is frequently involved.[1] Aetiology varies around the world. The main causes in adults are road trauma, interpersonal violence, falls and sporting injuries. Most of the developing world is seeing an increasing frequency of road trauma as a cause, whereas parts of the developed world have witnessed reductions in such injuries due to legislative and technological changes. Falls in elderly people are becoming a more common cause in developed countries as populations age. Intimate partner violence is often associated with facial injury, especially affecting female patients .

Anatomically, the face is supported on a bony scaffold that is suspended beneath the base of the anterior and middle cranial fossae. Muscles are grouped into the superficial layer of muscles of facial expression, the deep muscles of mastication and the tongue and the musculature of the oropharynx. Viscera include the eyes, the salivary and lacrimal glands and ducts and the upper parts of the hollow viscera or the gastrointestinal and respiratory tracts.

Vital functions include eating and drinking (mastication, salivation and swallowing) and breathing (the upper airway). Sensory function is performed by the organs for sight, hearing, smell and taste as well as a finely mapped area of touch and proprioceptive sensation. Activities critical to human social functions include facial expression and speech, gestures of affection and sexuality and identification.

The intimate relationship between form and function is demonstrated extremely clearly in the face. After immediate threats to life are excluded or managed, the goal of management of facial trauma is to return the face to as close to its normal form as possible, although association between facial trauma and psychological difficulties may be less clear than previously assumed.[2,3]

Association with other injury

Estimates of the rate of associated life-threatening injury depend on the population surveyed; however, it is reported as high as 20% in some series.[4,5]

Risk of associated injuries is proportional to the force transmitted, and the severity of facial injury correlates with the likelihood of associated injury.[6] High-energy facial injuries include fractures of the frontal bone and symphysis mandible, whereas isolated fractures of the zygoma, nasal bones and angle of the mandible occur with relatively low levels of energy transfer.[7,8] As well as occurring as part of complex multi-system trauma, facial injuries may be directly associated with injury to the brain, cervical spine and cerebrovascular system.

Mandibular and displaced mid-face fractures occurring in high-energy mechanisms (e.g. motor vehicle crashes) are associated with blunt cerebrovascular injury; however, this is not the case with low-energy mechanisms (e.g. a punch to the face).[9]

Simple assaults resulting in facial fracture are unlikely to cause cervical spine injury unless there is an associated fall.[10,11]

Increased age, a lower score on the Glasgow Coma Scale (GCS), another injury below the face and high-energy mechanisms are all associated with injury to the cervical spine and blunt cerebrovascular and/or brain injury.[12–15]

Patient frailty, medical co-morbidities and the effects of polypharmacy are important to consider in the case of elderly patients with low falls; such individuals are at risk of complex multisystem trauma from relatively minor mechanisms.[16]

History

As with all trauma, it is essential to determine the mechanism of injury for risk stratification and to guide further assessment. Sensitive enquiry about intimate partner violence should also be made. The use of anticoagulants and anti-platelet agents should be documented.

Primary survey

The primary survey should be completed as usual regardless of the apparent severity of the facial injury, ensuring that associated life-threatening injury is excluded or managed before non–life threatening facial injury.

When facial trauma itself is life-threatening, it will be due to either airway obstruction or uncontrolled haemorrhage.

Airway

Airway management in facial trauma presents a challenge of competing priorities. Simple, isolated facial trauma that can be assessed and managed in a position of comfort for the patient is unlikely to involve airway challenges. More severe facial trauma—in which the airway may be threatened by blood, deformity, oedema or loose bodies like teeth, bone fragments and projectiles—is more commonly associated with other injury, including spinal injury. This mandates initial assessment and management in the supine position, which impedes the patient's ability to manage his or her own airway.

When a sophisticated trauma team response is possible, these competing demands are dealt with by expert and prompt management of the airway by a dedicated provider supported by assistants as required. Thus prompt exclusion or

stabilization of other injuries will allow for better patient positioning as soon as practicable. In austere settings it may be necessary to accept a position other than supine, allowing the patient to manage his or her own airway until more resources can be deployed.

Signs of partial airway obstruction include restlessness, agitation, inability to lie flat, gurgling, snoring and stridor as well as signs of increased respiratory effort. It is important to remember that airway obstruction can be a dynamic process, developing as oedema or bleeding increase or as conscious state decreases.[17]

Usual airway management skills should be employed. Jaw thrust and suction may significantly improve the airway function of an injured face. An assistant can provide continuous suction. Unstable fractures of the mandible or mid-face may need to have anterior traction applied to open the airway and reduce haemorrhage.

In a badly injured face the main barriers to laryngoscopy are blood, loose bodies and altered anatomy rather than geometry and patient resistance. Rapid sequence induction may be modified to allow for attempted laryngoscopy after the induction of anaesthesia but before muscle relaxation has been administered, allowing the airway reflexes to keep the airway open until it can be secured or until the cords are visualized. Easy recourse to a surgical airway must be available and should be explicitly planned for. In occasional cases a primary surgical airway will be the safest option.[18]

Breathing

The assessment and management of breathing generally focuses on other injuries or lung injury due to aspirated blood or teeth. A two-person bag-valve-mask technique may be required owing to the effects of facial deformity.

Circulation

Some 5% of mid-face fractures may be associated with life-threatening haemorrhage.[19] Reducing mobile mid-face fractures, anterior and posterior nasal packing and direct pressure can manage most bleeding. Topical tranexamic acid or procoagulant dressing materials may be helpful. More severe cases may require the airway to be secured so the entire pharynx can be packed. Be aware that patients with multiple facial fractures have a high rate of base-of-skull fracture. Instrumentation and packing of the nose, if required, must be undertaken with great care to avoid inadvertent instrumentation of the cranial cavity.

As with all trauma, the principles of haemostatic resuscitation should be applied.

Secondary survey

Inspect for asymmetry or loss of normal contours; palpate all bony prominences for steps, crepitus and tenderness; where possible, have the patient assess his or her own dental integrity by running the tongue over the teeth and checking occlusion. By keeping in mind common injuries, these may be sought specifically (Table 3.4.1).The most important nerves of the face are the three branches of the trigeminal (motor to muscles of mastication and sensory to the skin of the face) and five main branches of the facial nerve (motor to the muscles of facial expression); these should be assessed specifically.

Imaging

CT has replaced plain x-ray in the assessment of facial injury, as the ease of image acquisition and reformatting has increased. The orthopantomogram (OPG) remains helpful for dental surgeons in planning their operative management, but it is not universally available.

Point-of-care ultrasound has a developing role in assessing the globe when retraction of swollen lids is impossible due to oedema. It is generally avoided if an open globe is possible. However, by applying the probe to a well of gel overlying

Table 3.4.1 Physical examination for specific injuries

Eye	• Enophthalmos • Exophthalmos • Visual acuity • Visual fields • Extraocular movements • Inquiry for diplopia Blowout fracture with extraocular muscle entrapment • Uniocular upgaze palsy • Binocular diplopia on upward gaze • Paraesthesia over infraorbital nerve distribution[21] Globe injury • Monocular diplopia (lens dislocation) • 'Teardrop'-shaped pupil • Dark protruding uveal tissue • Hyphaema • Positive Seidel test for open globe Orbital compartment syndrome (retrobulbar haemorrhage) • Proptosis • Raised intraocular pressure • Progressive ophthalmoplegia • Loss of vision or relative afferent pupillary defect (RAPD) (in the unconscious)[22,23]
Nose	• Deformity • Septal haematoma • Cerebrospinal fluid rhinorrhoea
Base-of-skull fracture	• Battle sign (post-auricular ecchymosis) • 'Raccoon eyes' (bilateral periorbital bruising) • Haemotympanum • Cerebrospinal fluid oto-/rhinorrhoea
Ear	Haematoma over the pinna
Oral cavity	Mandibular fracture • Malocclusion • Pain on biting • Loss of bite strength • Trismus • 'Tongue blade test'—patient forcefully bites down enough on a wooden tongue depressor to allow the physician to snap the blade with a twisting motion—85%–95% sensitive for mandibular fracture[24] • Sublingual haematoma • Sensory change on the lower lip and lower alveolar margin (inferior alveolar nerve injury) Dental injury • Subluxed, missing teeth, broken or chipped teeth Parotid duct injury • Exclude in cases of penetrating trauma to the cheek • Palpate duct as it crosses the border of the masseter • Look for saliva leakage onto the cheek[20]
Other facial bone fracture	Le Forte fractures • Dish face on lateral inspection • Mobile mid-face (grasp upper teeth and pull forward, stabilizing the head) Zygomatic arch and tripod fractures • Loss of cheek contour • Trismus (temporalis muscle entrapment) • Subconjunctival haemorrhage without posterior limit • Asymmetrical eye position or diplopia[20] Nasal-orbital-ethmoid complex fracture • Widening of the intercanthal distance[20] • Cerebrospinal fluid rhinorrhoea

a closed eye that is protected by an occlusive adhesive dressing, images may be obtained without pressure on the eye.

Disposition

Most facial wounds can be closed carefully in the ED, providing attention is paid to close approximation of key anatomical landmarks (e.g. the vermillion border when closing lip lacerations). Careful assessment should be made for involvement of underlying structures, such as the parotid duct in cheek lacerations or the tarsal plates and lacrimal apparatus in eyelid lacerations. Surgical debridement is avoided for the sake of cosmesis and antibiotics are generally not indicated. However, fastidious cleaning is required, particularly in the case of dirty injuries or injuries caused by bites.[20]

Facial fractures are generally managed after swelling has reduced and once more serious injuries have been stabilized. Patients with isolated facial fractures can usually be discharged from the ED with an early surgical outpatient review arranged unless pain, bleeding or risk related to swelling mandate admission.

Careful documentation of examination findings and management will assist with the provision of forensic evidence in assault cases later on.

Specific injuries

See Table 3.4.1.

Soft tissue injuries

Soft tissue injuries include abrasions, contusions, lacerations, avulsions and burns. The aim of treatment is to preserve appearance and function. The management of soft tissue facial injuries involves consideration of how the wound should be repaired and whether it should be repaired in the ED. Possible reasons for delayed wound closure are more urgent coexisting injuries, severe crush injuries, the presence of a foreign body, severely contaminated wounds and an underlying fracture. In these cases, the wound should be irrigated, haemostasis achieved, the wound covered with normal saline-soaked gauze and the patient referred to the appropriate specialty team.

Soft-tissue injuries that usually require repair in the operating theatre include ocular or significant eyelid injury; parotid gland or duct injury; facial nerve injury (injuries to the cheek between the tragus of the ear and a line drawn vertically through the pupil may be associated with damage to the facial nerve, parotid gland or duct); nasolacrimal apparatus injury; alveolar process wounds and significant tooth injuries; lacerations with significant tissue loss or contamination or requiring exact anatomical closure; or where difficulties with patient co-operation are expected. Careful consideration is required before areas of special concern are repaired in the ED (e.g. the lips and perioral area; tongue and oral cavity; nose; ears; periorbital structures; and eyebrows). The eyebrow should not be shaved. Subperichondrial haematomas of the ear require drainage within 7 to 10 days to avoid permanent injury to the cartilage (cauliflower ear) and to achieve best cosmetic results. For all wounds closed in the ED, careful attention must be given to thorough cleansing. This can be effectively achieved with pulsatile wound irrigation using normal saline; abrasions containing dirt or other foreign bodies must be scrubbed to prevent traumatic tattooing of the dermis.[20] If the wound is gaping or if structures deeper than the skin and the subcutaneous layer are involved, multiple-layer repair is usually advisable. This helps to prevent deep tissue space collections and may produce a better cosmetic result, with less scar depression or widening.

Visual assessment after facial trauma can be difficult, especially in the unconscious patient. Loss of vision after blunt facial trauma may be due to direct injury to the globe, direct injury to the optic nerve (usually bony impingement) or indirect injury to the optic nerve (deceleration injury). It may also be caused by raised local intraocular pressure (orbital compartment syndrome [OCS]).[25] OCS is an uncommon ophthalmic emergency, but the diagnosis is clinical. Relief of the intraocular hypertension is time-critical and usually requires a lateral canthotomy and inferior cantholysis.[26] In the patient with a decreased level of consciousness, a relative afferent pupillary defect (Marcus Gunn pupil) is an indication for this procedure.

Facial fractures

The structure of the facial skeleton allows for the dispersion of applied force via a series of small bone fractures, thereby protecting the skull and intracranial contents. The maxilla and mandible require three times the amount of applied force to cause a fracture as do the nasal bones.[7] Diagnosis of a facial fracture involves a combination of inspection, palpation and radiographic examination. Fractures other than undisplaced fractures of the nose, zygomatic arch or maxilla will usually require acute maxillofacial surgical review. If associated injuries allow it, all facial fractures should be managed initially with elevation of the patient's head and the application of ice.

Mandible

The horseshoe shape of the mandible disperses applied force, which leads to fractures occurring at vulnerable sites regardless of the point of impact and a high incidence of multiple fractures. Common sites of fracture are the condylar neck and angle and the body at the level of the first or second molar.[27] Most fractures will require some form of internal fixation. Complications of mandibular fractures include chin paraesthesia or hypoaesthesia, delayed union, non-union, infection and malocclusion.[28] All mandibular fractures through tooth-bearing bone are considered open; in fact, some authorities consider all mandibular fractures to be open. Evidence for prophylactic antibiotic use is poor; however, antibiotics are still generally used preoperatively.

Zygomatic arch

Isolated fractures of the zygomatic arch are uncommon and are more often part of a more extensive zygomatic complex fracture. Surgical reduction is required for cosmetic reasons or to correct restricted mandibular range of motion.

Zygomatic complex (tripod fractures)

Blunt trauma to the zygoma more commonly results in fractures at the articulations of the zygomatic bones with the frontal bone, maxilla and zygomatic process of the temporal bone. Separation at the zygomaticofrontal suture, the zygomaticotemporal suture and at the zygomaticomaxillary suture or infraorbital rim produces the tripod or tripartite fracture. Frequently the lateral wall of the maxillary sinus and the lateral and central portions of the orbital floor (not to be confused with the orbital blowout fracture) will also fracture as part of the zygomaticomaxillary complex fracture. Ten percent to 20% of these fractures are accompanied by an ocular injury.[29]

Orbital fractures

Fracture of the orbital floor may occur as part of a zygomaticomaxillary fracture or as an isolated injury—the less common orbital blowout fracture. This is a fracture of the orbital floor without fracture of the orbital margin. An increase in intraorbital pressure, as delivered by a fist or a small ball, is transmitted to within the orbit and the relatively weak orbital floor is disrupted, with possible herniation of the contents into the maxillary sinus. Very rarely, a supraorbital rim fracture may be part of a frontal sinus fracture; a lateral orbital wall fracture may be associated with a fracture of the zygoma; or a medial orbital wall fracture may occur with a nasoethmoidal fracture. CT scanning is necessary to define these fractures fully. Orbital apex fractures are uncommon, but clinical or radiological signs of optic nerve compression (e.g. retro-bulbar haematoma or bone fragment impingement) necessitate urgent surgical referral.[30] All patients with fractures of the orbital margin or floor require referral. Complications of surgical treatment of orbital floor fractures

include persistent diplopia, hypo-/hyperaesthesia or paraesthesia, ectropion and epiphora.[31]

Maxillary fractures

Fractures of the maxilla include fractures of the alveolar ridge of the maxilla, fracture of the anterolateral wall of the maxillary sinus and the Le Fort fractures. Isolated maxillary fractures are rare.

In Paris in 1901, following cadaveric experiments, Le Fort described a classification of patterns of mid-face fractures, as follows[32]: Le Fort I (horizontal maxillary fracture) involves only the maxilla, above the palate; Le Fort II (pyramidal fracture) is the most common mid-face fracture and involves the maxilla, nasal bones and medial aspect of the orbit; Le Fort III (craniofacial disjunction) separates the midfacial skeleton from the base of the cranium, with the fracture extending through the base of the nose and ethmoid region and across the orbits and zygomatic arches bilaterally.

Most mid-face fractures are combination injuries, with different Le Fort patterns on each side of the face. Le Fort II and III fractures may require urgent reduction in the ED to improve airway function and arrest ongoing haemorrhage. Patients with such injuries may demonstrate mid-face mobility, and these fractures are associated with skull-base fractures, leading to cerebrospinal fluid (CSF) rhinorrhoea. All of these patients require a complete eye examination, and these injuries necessitate referral.

Nasal fractures

These are common facial fractures. Diagnosis is largely clinical, as plain x-rays are unreliable and usually unnecessary. The major concerns for the emergency physician are control of epistaxis and exclusion of a septal haematoma. Displaced fractures should be reduced within 7 to 10 days, but early reduction in the ED may be necessary for gross anatomical deviation.

Nasoethmoidal fractures are more complicated and are caused by trauma to the bridge of the nose. Disruption of the medial canthal ligaments may produce rounding of the palpebral fissures or widening of the intercanthal distance (telecanthus).[33] Persistent epistaxis and CSF rhinorrhoea may also be evident. Referral for these patients is necessary.

Temporomandibular joint injury

Damage to the temporomandibular joint (TMJ) from trauma is associated with injury to the petrous temporal bone, putting at risk the middle and inner ear structures and the integrity of the base of the skull. Dislocation of the TMJ more commonly occurs simply from opening the mouth wide, especially in edentulous patients whose ligaments become slackened. Patients complain of inability to close the mouth and moderate discomfort. X-rays should be performed to confirm that no fracture is present, and dislocation will be evidenced by the appearance of the condyle anterior to the articular eminence of the fossa. A directed history will exclude extrapyramidal dystonia mimicking a dislocation. Reassurance, sedation and firm downward pressure of the physician's thumbs on the patient's posterior teeth, with upward tilting of the symphysis, is usually successful in relocating the mandibular condyles. Post-reduction x-rays are not always necessary. Analgesia and a soft diet should be prescribed and the patient warned to avoid wide opening of the mouth in the short term.[34]

Penetrating injuries to the face

Penetrating trauma to the face from gunshots, stab wounds and impaling foreign bodies is often dramatic at the time of presentation. Such isolated injury is rarely fatal but may result in significant morbidity due to the combination of soft tissue and bone defects. The wounding capability of penetrating projectiles (bullets and pellets) is proportional to the energy imparted to the tissue; therefore the mass of the slug, its velocity and design and the density of the body tissue penetrated determine the amount of tissue destruction.[35]

Early aggressive airway management is necessary in patients with gunshot wounds to the face, as respiratory decompensation may be rapid: approximately one-third of patients will require emergency airway intervention.[36] Shotgun and stab wounds are less likely to require an emergency airway, although the presence of a significant vascular injury or oedema remains a universal indication for airway intervention, and patients with mandibular entry sites are more likely to require an emergency airway than those with mid-facial entry sites. Orotracheal intubation can usually be achieved, with cricothyroidotomy the preferred alternative if necessary. Central nervous system injuries are common after gunshot injuries, and CT scans of the head and cervical spine will be required.[37]

Arterial injury is suggested by evidence of active bleeding and an expanding haematoma; angiography (carotid and vertebral arteries), which is required in approximately 35% to 40% of cases,[36,37] should be performed when the bullet trajectory suggests proximity to major vessels or the skull base or where the knife or foreign body is in close proximity to a major vascular structure.[37–39]

Peripheral nerve injuries, especially of the facial nerve and the mandibular branch of the trigeminal nerve, are also frequently present.[37] Careful eye examination is necessary, because ocular trauma is the most common overall complication of penetrating facial trauma.[40]

Antibiotics and tetanus prophylaxis are indicated and wounds are managed with conservative debridement, closed reduction of facial fractures and early repair of palatal injuries. Reduction of open facial fractures is usually delayed.[36]

Conclusion

Facial trauma is common in the ED; it encompasses many types of injury and, after rapid exclusion of life-threatening complications, requires thorough patient evaluation to exclude other more urgent injuries. The aim of management of isolated facial injuries is the maintenance of normal function and appearance.

CONTROVERSIES

- Placement of an immediate surgical airway versus attempted oral intubation in a patient with significant facial trauma and a compromised or deteriorating airway is a topic of debate.
- The role of angiography and selective embolization in the management of patients with significant haemorrhage from blunt and penetrating trauma is uncertain.
- There is disagreement on early intubation in the presence of midface fractures with ongoing haemorrhage in the supine patient with other system injuries.

3.5 Abdominal trauma

Garry Wilkes

ESSENTIALS

1 One in 10 deaths from trauma is due to abdominal injuries.

2 Abdominal injuries may be occult—overshadowed by more apparent external and orthopaedic injuries—and may be missed initially.

3 Detection of intra-abdominal injuries requires a high index of suspicion to avoid preventable morbidity and mortality.

4 Computed tomography scanning provides organ-specific diagnosis but requires sufficient stability for transfer from the resuscitation area.

5 Bedside investigations, such as focused assessment sonography in trauma (FAST), assist in the evaluation of suspected intra-abdominal trauma, but they have limitations.

6 Intra-abdominal trauma frequently coexists with other systemic trauma. Evaluation and disposition are greatly enhanced by early involvement of senior trauma surgeons.

Introduction

One in 10 deaths from trauma is due to abdominal injuries. These may be difficult to detect initially, as the abdominal cavity cannot be viewed with the naked eye; plain radiography is insensitive to intra-abdominal bleeding and solid organ injury. Moreover, signs and symptoms of blood loss may be attributed to more obvious injuries. It is therefore not surprising that missed abdominal injuries are a major cause of preventable death in trauma patients. A high index of suspicion should be maintained for this important cause of morbidity and mortality.

A stepwise approach to the management of the multiply injured patient will address the possibility of significant intra-abdominal injury. The principles of initial management are to identify the presence or otherwise of such injury, the need for surgery and the most appropriate timing of interventions. This process requires the presence of an experienced clinician at the earliest possible stage to direct and co-ordinate the trauma team. Ideally, the trauma surgeon should be present at the initial resuscitation.

The initial resuscitation, history, examination and specific investigations are reviewed in turn in the following text.

Primary and secondary surveys

Assessment of circulation during the primary survey may include evaluation for possible intra-abdominal haemorrhage, particularly in the unstable patient requiring continued fluid resuscitation without other identified sources of haemorrhage.

When the abdomen is being examined, expose the patient fully, including an examination of the back as well as the rectum and vagina.

History

The history and knowledge of the mechanism of injury will provide vital clues to the likelihood of significant intra-abdominal trauma (Box 3.5.1).

Box 3.5.1 Risk factors for intra-abdominal injury in trauma patients

- High-speed vehicular collisions
- Pedestrian struck by vehicle
- Fall from greater than standing height
- Hypotension or history of hypotension (systolic blood pressure <100 mmHg) at any time
- Presence of significant chest or pelvic injuries
- Significant injuries on physically opposing sides of the abdomen

Ambulance personnel will be able to provide valuable details of the incident. It is important to remember that trauma does not skip body regions and that significant intra-abdominal injuries frequently occur in the absence of external signs of abdominal trauma. Other important aspects of focused history are summarized by the acronym AMPLE: Allergies, Medications, Past medical history, Last ate and drank, Events associated with the trauma incident.

Abdominal examination

Penetrating injuries are overt and dramatic. Blunt trauma is more common and more difficult to assess on clinical grounds. Bruising and abrasions are associated with intra-abdominal pathology. The spleen and liver are the most commonly injured organs, with different patterns of injury seen in blunt and penetrating injuries (Table 3.5.1).[1] Marks from lap-type seatbelts carry a high association with Chance fractures (*most* common in T12, L1, and L2), small bowel injury and pancreatic injury. Palpation of the abdomen may reveal local/generalized tenderness and evidence of peritonism, but it is less reliable in detecting retroperitoneal injury and in the presence of an altered sensorium. Auscultation is rarely useful; however, the absence of bowel sounds should increase the suspicion of intra-abdominal injury.

Examination of the abdomen is not complete until the back, buttocks and perineum have been fully exposed. In obese patients, skin folds may obscure penetrating injuries. Rectal examination may demonstrate frank blood from injured bowel and may allow direct palpation of fractures or breaches of bowel wall integrity. Vaginal examination is similarly important and, in the unresponsive patient, may detect a tampon (essential to remove) or gravid uterus.

Table 3.5.1 Organ injuries associated with blunt and penetrating trauma

	Blunt trauma (%)	*Stabbing (%)*	*Gunshot (%)*
Spleen	40–55	–	–
Liver	35–45	40	30
Retroperitoneal haematoma	15	–	–
Small bowel	5–10	30	50
Diaphragm	–	20	–
Colon	–	15	40
Abdominal vascular structures	–	–	25

(Reproduced with permission from American College of Surgeons Committee on Trauma. *Advanced Trauma Life Support Student Course Manual.* 10th ed. Chicago: ACS; 2018.)

Although unexplained hypotension suggests intra-abdominal haemorrhage, not all patients with significant blood loss will display the typical pattern of hypotension and tachycardia, especially young patients and those on heart rate–limiting medications.[2,3] More important are trends over time in pulse, blood pressure and capillary refill time and in response to fluid resuscitation. Continuing falls in blood pressure and rises in pulse rate indicate ongoing haemorrhage, which, if no other source is identified, must be assumed to be intra-abdominal. Abdominal distension does not occur until several litres of blood have been sequestered and can initially be confused with obesity.

Once the patient has been examined, unless there is suspicion of a urethral injury, a urinary catheter should be inserted, Blood at the urethral meatus or a scrotal haematoma is suggestive of urethral injury, and a urological opinion should be sought before attempting to insert a catheter. In these circumstances, a suprapubic catheter may be preferable. Patients with a suspicion of abdominal injury also require a gastric catheter. Nasogastric catheterization is more comfortable for the patient than the oral route but is contraindicated by evidence of basilar skull fracture. Gastric decompression may be both diagnostic and therapeutic. Penetration of the stomach or proximal small bowel will produce a bloodied aspiration. Aspiration of air will relieve gastric tamponade, which is occasionally an unrecognized cause of hypotension from impaired venous return.

A penetrating object, such as a knife protruding from the abdomen, should be left in situ unless it is an immediate threat to life. It may be tempting to remove such an object from a stable patient, but this can lead to disastrous consequences if the object is adjacent to or penetrating vascular structures. The sudden release of a tamponade may be rapidly fatal. The only place to remove a penetrating object is in an operating theatre, with staff on hand capable of dealing with all possible complications.

Investigations

The initial resuscitation of all trauma patients includes blood drawn for full blood count, urea and electrolytes, blood sugar determination, cross-matching, blood gases (if available) and a trauma radiology series. There is little place for plain radiology of the abdomen.

Gunshot wounds are unpredictable in their path and they can produce secondary missiles and cavitation effects; all such wounds require laparotomy. Stab wounds that have penetrated the peritoneum may also require laparotomy and need immediate assessment by an experienced trauma surgeon. In cases where immediate laparotomy is indicated, the patient should be escorted to theatre with no further investigations (Box 3.5.2). However, if other urgent procedures are also required, further investigation such as trauma ultrasound may assist in determining the need for or timing of laparotomy. The final order is determined by the trauma team leader.

Unstable patients require surgical intervention as soon as possible. Stable patients can be investigated further, allowing better planning of further management. The difficulty arises in the common situation where there are multiple injuries and only a suspicion—not confirmation—of significant intra-abdominal pathology. Some patients are at risk of abdominal injury but cannot be assessed on clinical grounds. These include those with head, chest and spinal injuries; intoxicated or sedated patients; and those who will be inaccessible while undergoing lengthy operations on other body regions. For these patients, it is important to make a further assessment of the presence or otherwise of intra-abdominal injury. Additional investigations of benefit are ultrasound and computed tomography (CT). Each has advantages and disadvantages (Table 3.5.2). They may also be consecutive and complementary, thereby minimizing the disadvantages of each individually. Wounds poorly imaged by all modalities are hollow organ injuries, such as small bowel rupture and diaphragmatic injuries, and vascular compromise is another. Serial clinical examination is essential to detect these injuries, even if investigative results are normal, because signs and symptoms may be delayed for 24 hours or more.

Box 3.5.2 Indications for laparotomy

Immediate
Evisceration
Gunshot wound
Stab wound with peritoneum breached
Haemodynamic instability despite correction of estimated blood loss from extra-abdominal sites
Frank peritonism (initially or on repeat examination)
Free gas on imaging
Ruptured diaphragm

Emergent
Positive trauma ultrasound

Abdominal computed tomography

Abdominal CT is non-invasive and provides precise anatomic details of intra-abdominal pathology. The major disadvantages are radiation, reactions to intravenous contrast and the need for the patient to be transported from the resuscitation area to the CT scanner, where he or she is inaccessible during the procedure. Intravenous contrast may rarely produce allergic reactions and can precipitate or exacerbate renal impairment, particularly in higher doses and in the presence of renal hypoperfusion and hypofunction. Although modern machines complete scans in a single breath-hold, time is still required to load and unload the patient. Transport and transfer are events of maximum patient risk and minimum monitoring. Therefore only stable patients are suitable for transfer for CT scanning. Unstable patients require further or operative intervention if resuscitation is unsuccessful. The definition of *stable* is not agreed. The final decision can be made only by the most experienced physician available.

Table 3.5.2 Comparison of abdominal computed tomography and ultrasound for the investigation of abdominal trauma

Abdominal CT	*Ultrasound*
Advantages	
Anatomical information	Rapid, portable, repeatable
Non-invasive	Non-invasive
Visualizes retroperitoneum	Ideal in unstable patients
Also views chest, pelvis	Can be done in resuscitation room Also views chest, pelvis
Disadvantages	
Not suitable for unstable patients	Requires specific training
Requires transport from resuscitation. room	Operator-dependent
Patient safety—inaccessible while scanning	False positives from ascites
Time, cost, radiation	Retroperitoneal injuries not visualized
Can miss hollow viscus injuries	Can miss hollow viscus injury
Can miss diaphragm injury	Can miss diaphragm injury
Intravenous contrast reactions	Does not visualize free gas

CT, Computed tomography.

Interventional Radiology

Adding to the complexity of decision making is the increasing role of interventional radiology, where 'unstable' patients may be better managed by immediate embolisation; this is especially true with retroperitoneal and pelvic bleeds. Some centres are now moving towards 'hybrid' resuscitation suites, where CT, interventional radiology and full operating theatre equipment are located together.

Focused assessment sonography in trauma

Focused ultrasound is a skill practised by many clinicians involved in acute trauma management. Abdominal ultrasound is non-invasive, may be done at the bedside and can be repeated as needed. The technique can be easily learnt by clinicians and completed in less than 5 minutes without interfering with the function of a trauma resuscitation team.[4] Ultrasound combines the advantages of being rapid, accurate and non-invasive and can be performed at the bedside. It has similar results to CT in determining the presence of intraperitoneal injury. As a decision-making tool for identifying the need for laparotomy in hypotensive patients (systolic blood pressure [BP] <90), focused abdominal sonography for trauma (FAST) has a sensitivity of 100%, specificity of 96% and negative predictive value (NPV) of 100%.[5,6] Ultrasound may also detect blood in the pericardium, haemothorax and pneumothorax and in experienced hands can be used to assess cardiac function and volume status. If an experienced operator is available, it is the bedside investigation of choice.

Laparoscopy

Laparoscopy has been investigated in some centres, but the skills required and the time needed for a thorough examination limit the widespread usefulness of this modality in acute blunt trauma. However, it is helpful in excluding peritoneal penetration in abdominal stab wounds.

Resuscitative endovascular balloon occlusion of the aorta

Resuscitative endovascular balloon occlusion of the aorta (REBOA) is currently being promoted as a bridging resuscitation technique for patients with traumatic cardiac arrest or peri-arrest to allow definitive surgery to occur. There are a small number of patients with abdominal exsanguination who may benefit; however, the technique should not delay definitive surgery.

Penetrating injuries

Penetrating injuries produce a different pattern of injury (see Table 3.5.1) and are managed in a different manner from blunt injuries (Figs 3.5.1 and 3.5.2). Cavitation effects and the potential for secondary missiles causing widespread injury mandate formal laparotomy in all cases. Stab wounds with haemodynamic compromise or other indications should also proceed to laparotomy without delay for other investigations. Local exploration of stab wounds by experienced surgeons in patients without evidence of internal injury may be useful, as up to one-third of wounds do not breach the peritoneum. Selected patients may then be managed conservatively.

Disposition

Disposition decisions may be difficult in less seriously injured patients or those with suspected injury. Every patient suspected of or at significant risk for intra-abdominal injury should be admitted for observation and serial examinations, ideally by the same individual. Injuries to the bowel wall or intestinal blood supply may not be evident on initial clinical examination or investigation and may take 24 hours to declare themselves. A higher index of suspicion is required for patients who cannot be assessed clinically. Unconscious, intubated, head-injured and spinally injured patients are all at increased risk of abdominal injuries and less able to declare them. Serial investigations and clinical vigilance are vital.

Future directions

The difficulty in managing abdominal trauma is determining the presence, location and details of intra-abdominal injury. Current imaging techniques have their disadvantages and limitations. The refinement of modalities, such as ultrasound and portable CT, will rapidly provide more detailed information at the bedside in the resuscitation area without the need for invasive techniques. Non-operative management of injuries using radiological or minimally invasive surgical techniques continues to develop, thereby reducing the need for laparotomy.

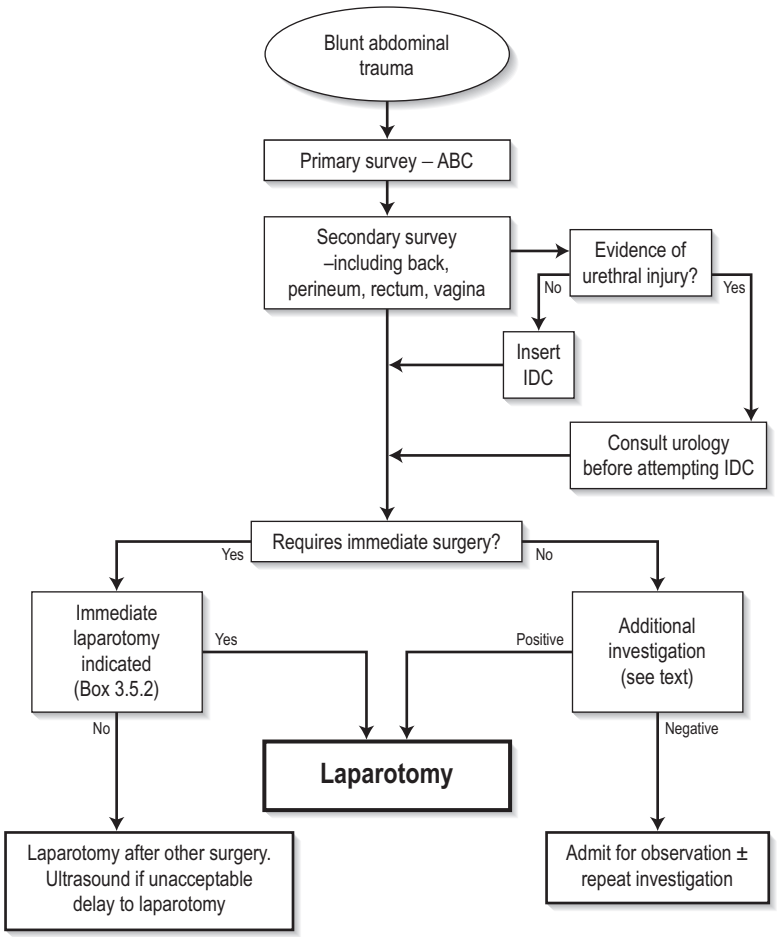

FIG. 3.5.1 Initial management of blunt abdominal trauma. *ABC*, Identify and treat immediate life threats in Airway, Breathing and Circulation; *IDC*, Indwelling urinary catheter.

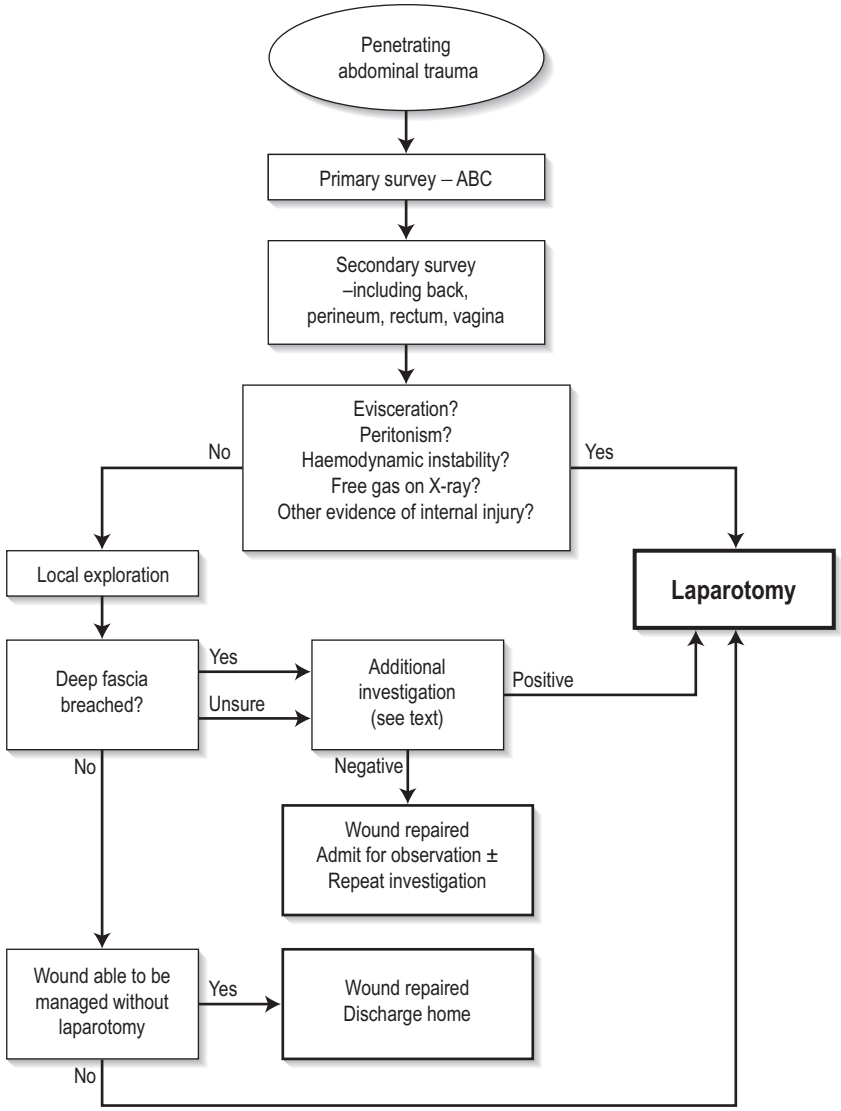

FIG. 3.5.2 Initial management of penetrating abdominal trauma. *ABC*, Identify and treat immediate life threats in Airway, Breathing and Circulation.

CONTROVERSIES

- Haemodynamic stability is not dictated by a single reading of pulse or blood pressure. The need for ongoing fluids in order to maintain adequate perfusion indicates instability even in the presence of normal vital signs.
- In the multiply injured patient, there is often difficulty in deciding whether to operate first on the head, chest, abdomen or limbs. All surgeons concerned must discuss the decision.
- Perhaps most difficult is deciding which is the most appropriate investigation in the otherwise stable patient. Both CT and FAST have inherent strengths and weaknesses. Repeated clinical examination, preferably by the same individual, is essential.
- Newer pharmacological treatment such as clotting factors, interventional radiology and REBOA are promising and require further evaluation. At present the most important therapy is early surgery for injury with ongoing bleeding.

3.6 Chest trauma

Mark Fitzgerald • Jeremy Stevens • Robert Gocentas

ESSENTIALS

1 **Initial management priorities are oxygenation, ventilatory support if required, pleural and pericardial decompression when indicated, circulatory support, adequate analgesia and early imaging to identify evolving and potentially life-threatening injuries.**

2 **Less than 10% of blunt chest trauma patients require thoracic surgery.**

3 **Supine chest radiographs do not reliably exclude haemothorax, pneumothorax, aortic transection, diaphragmatic disruption, cardiac tamponade or rib, sternal, thoracic spine and scapula fractures.**

4 **Multislice computed tomography with intravenous contrast is the 'gold standard' screening and diagnostic tool for thoracic injuries. Sonography may demonstrate haemothorax, pneumothorax, pulmonary contusion, cardiac tamponade and diaphragmatic injury.**

5 **Aseptic percutaneous digital identification of the pleural space is the essential first step for pleural decompression. Drainage and insertion of a chest tube is a secondary priority. Needle thoracocentesis is an unreliable means of decompressing the chest of an unstable patient.**

6 **Pleural decompression and chest tube insertion during resuscitation has a low complication rate.**

7 **There is a clear role for resuscitative thoracotomy in shocked patients with sonographic evidence of cardiac tamponade.**

8 **Non-invasive ventilation may avoid complications of mechanical ventilation in select patients with flail chest and pulmonary contusion.**

Introduction

Incidence

Thoracic trauma is responsible for 25% of all trauma deaths and contributes to a further 25%. In Australasia and the United Kingdom, 90% to 95% of chest trauma is secondary to blunt injury.

Principles of initial management

The initial management priorities are oxygenation, ventilatory support if required, pleural and pericardial decompression when indicated, circulatory support, adequate analgesia and early imaging to diagnose evolving and potentially life-threatening injuries. The majority of chest trauma patients may be managed non-operatively. Less than 10% of blunt thoracic trauma patients will require thoracotomy; the remainder require supportive care, including pleural decompression and drainage.

Supportive care—in particular resuscitation—is often suboptimal. Delayed or inadequate ventilatory resuscitation, inadequate shock management, insufficient monitoring of arterial blood gases, delay or failure to perform pleural decompression and drainage and delays in definitive diagnostic imaging remain identifiable problems that contribute to preventable morbidity and mortality.[1,2]

Thoracic injuries evolve. Life-threatening injuries—including flail chest, pulmonary contusion, thoracic aortic transection, pneumothorax, haemothorax, pericardial tamponade, respiratory insufficiency secondary to rib fractures and ruptured hemidiaphragm—may not be apparent on initial presentation. These diagnoses must be pursued and actively excluded. Supine chest radiographs do not reliably exclude these injuries. Multi-slice computed tomography (CT) with contrast is the 'gold standard' screening and diagnostic test for patients at high risk of potential life-threatening injuries.[3] However, life-saving procedures should be performed first (Table 3.6.1). Ultrasound screening provides early identification of cardiac tamponade and haemothorax.

Oxygen

Hypoxia may be absent at the initial reception and resuscitation of a patient with chest trauma yet may develop as injuries evolve. Supplemental oxygen may be required for mild desaturation, with the FiO_2 titrated to the clinical response. A higher FiO_2 may be achieved using positive airway pressure and invasive ventilation (continuous positive airway pressure [CPAP], expiratory positive airway pressure [EPAP]).

Increasing the normal inspiratory/expiratory (I/E) ratio may be beneficial in mechanically ventilated patients with severe hypoxia. The outcome benefits of independent lung ventilation, inhaled nitric oxide, prone position, partial liquid ventilation and extracorporeal membrane oxygenation in the initial resuscitation setting are unproven.

Support of pulmonary function

Pain, fatigue from increased work of breathing, disruption of lung mechanics and side effects of opiate analgesia may cause hypoventilation. The elderly as well as other patients with pre-existing poor chest wall compliance are particularly at

Table 3.6.1 Actions prior to computed tomography

Situation	*Response*
Pneumothorax or haemothorax on initial supine chest x-ray	Decompress pleural space and insert chest drain on affected side
Spontaneously breathing patient with unilateral decreased air entry and normal chest x-ray, oxygenation and haemodynamic status	Await computed tomography
Intubated and ventilated patient with unilateral decreased air entry and normal chest x-ray but with hypoxia or hypotension	Decompress pleural space and insert chest drain on affected side, then reassess
Intubated and ventilated patient with hypotension or hypoxia (no other apparent cause)	Decompress pleural spaces bilaterally and then insert chest drains

risk of hypoventilation in the setting of chest wall injury.

Non-invasive ventilation

Patients with pulmonary contusions and high oxygen requirements do not necessarily require intubation but may be safely managed with non-invasive ventilation (NIV).[4] By avoiding mechanical ventilation, mortality from nosocomial infection is significantly reduced.[5]

Mechanical ventilation

Contraindications to NIV in the trauma patient include the need for full spinal precautions, depressed conscious state and facial injury. Patients with pulmonary contusion and poor lung compliance require ventilation with low tidal volumes and low inspiratory pressures. This reduces barotrauma, secondary lung injury and mortality.[6]

Fluid resuscitation

There is evidence that 'permissive hypotension' prior to surgical control of blood loss may improve survival in hypotensive penetrating torso injury.[7] It may also reduce blood product requirements, coagulopathy and early postoperative mortality.[8] It is unclear whether these findings translate equally to hypotensive blunt trauma. Once haemorrhage has been controlled, fluid therapy to maximize cardiac output and oxygen delivery may reduce trauma mortality.[9]

Conservative fluid resuscitation has been recommended to minimize extravascular lung water in patients with pulmonary contusion.[10] However, under-resuscitation and tissue hypoperfusion may compound organ dysfunction and secondary lung injury. The early use of invasive monitoring to guide fluid replacement may be required.

Analgesia

Adequate analgesia reduces hypoventilation secondary to pain and facilitates coughing and chest physiotherapy. It reduces complications of atelectasis, consolidation and respiratory failure and improves pulmonary function.[11] Oral analgesia is often sufficient for single rib fractures. Parenteral narcotic analgesia, intercostal nerve block or thoracic epidural analgesia is usually required for multiple rib fractures. Intercostal nerve block involves a number of injections to treat multiple rib fractures, which limits its usefulness compared with other techniques. Advanced regional nerve blocks such as epidural, paravertebral or intercostal nerve blocks are technically challenging and carry a higher risk of complications. The serratus anterior plane block, a fascial plane block distant from neurovascular bundles and pleural space, is an alternative.[12]

Indications for emergency thoracotomy

Although more than 90% of chest trauma patients may be managed non-operatively, the following categories warrant surgical intervention[13]:

- Cardiac tamponade
- Acute deterioration—cardiac arrest in patients with penetrating truncal trauma
- Vascular injury at the thoracic outlet
- Traumatic loss of chest wall
- Massive air leak from chest tube
- Massive or continuing haemothorax
- Mediastinal traversing penetrating injury
- Endoscopic or radiographic demonstration of oesophageal injury
- Endoscopic or radiographic demonstration of tracheal or bronchial injury
- Radiographic evidence of great vessel injury
- Thoracic penetration with industrial liquids (especially coal tar products)

Resuscitative thoracotomy

The cruciform position with arms abducted at 90 degrees allows simultaneous bilateral procedural access to the chest, invasive monitoring and a sterile practical field for the resuscitation of patients with particularly demanding thoracic injuries.[14]

Left anterolateral thoracotomy as a resuscitative manoeuvre allows direct access to the heart and pericardial decompression for patients who have lost output following cardiac lacerations. Myocardial wounds can then be directly controlled. Right atrial catheterization facilitating fluid and blood administration, pulmonary hilar clamping, cross-clamping of the descending aorta and open cardiac massage are adjunctive procedures performed if indicated.

Left anterolateral thoracotomy allows pericardial decompression[15] in patients who have lost output following penetrating injury to the heart. Myocardial wounds can then be directly controlled. Survival rates of better than 40% have been reported in some subgroups of penetrating trauma arrest, specifically cardiac stab wounds. Survival was dependent on resuscitative thoracotomy performed within 10 minutes of arrest secondary to penetrating chest trauma and the presence of an organized cardiac electrical rhythm.[16-19] The role of resuscitative thoracotomy in blunt trauma arrest is more controversial, with a relatively low survival rate (<3%).[20]

Focused assessment with sonography in trauma (FAST) is an important triage tool in determining the presence of cardiac tamponade. Immediate use of ultrasonography can establish the diagnosis of haemopericardium, and prompt repair of the injury may improve overall survival. Unresponsive hypotension with a systolic blood pressure of less than 70 mmHg and a FAST positive for pericardial tamponade is a consensus-based indication for immediate resuscitative thoracotomy. For patients with severe hypotension or who are in extremis, the treatment of choice is resuscitative thoracotomy, decompression of the pericardium and control of the cardiac injury.[21] Given the widespread availability of ultrasound, arguments about resuscitative thoracotomy for blunt trauma should include the important decision support provided by sonography. Procedural training and credentialing is recommended.[21]

Thoracic injuries

Fractured ribs

Fractured ribs are a common sequela of focal trauma. They cause pain, which may then interfere with ventilation and coughing, leading to ventilatory impairment and atelectasis. Such impairment may not become manifest until hours and occasionally days after the injury.

Underlying structures—particularly the lungs, pleura and intercostal vessels—are often injured concomitantly. Fractures of the lower left ribs are associated with splenic injury, the lower right with hepatic injury and the lower posterior ribs with renal injury. The first and second ribs are stronger and less easily injured; fracture of these ribs is usually indicative of significant force to the upper mediastinum. Although first- and second-rib fractures have n traditionally been associated with thoracic aortic injury, the positive predictive value of this association has been questioned.[22]

Rib fracture is essentially a diagnosis based on the clinical findings of local tenderness with or without deformity and crepitus. Up to 50% of fractured ribs are not apparent on the initial chest x-ray.[23] Reliance on the x-ray to diagnose fractured ribs inevitably results in under-diagnosis, which may lead to delays in diagnosis and therapy and an adverse outcome, particularly with elderly patients and those with coexisting airway disease.

The management of rib fractures concentrates on actively excluding associated injury as well as adequate pain relief, including patient-controlled administration of narcotics and the use of local and regional anaesthetic blocks to allow breathing exercises, coughing and incentive spirometry. This, in turn, minimizes subsequent atelectasis and pulmonary sequelae.

Fractured sternum

This is a clinical diagnosis confirmed on CT scan, lateral chest x-ray or ultrasound. Associated intrathoracic injuries, specifically myocardial and other mediastinal injuries, must be identified.

The likelihood of associated underlying injury has been related to the mechanism of injury.

For example, in North America, it is reported that up to 66% of patients with sternal fractures have intrathoracic injuries. It is believed that low seatbelt usage results in sternal fractures secondary to impact against the steering wheel. In Australasia, where seatbelt usage is high, sternal fracture is more often caused by the restraining belt. Therefore comparatively lower deceleration forces are evident, resulting in a reduced association with underlying injury.[24,25]

For isolated sternal fractures, admission for analgesia is usually required, although this may be necessary for only 1 or 2 days. Monitoring is not required unless the mechanism or subsequent investigations suggest underlying cardiac injury.

Vertebral column and spinal cord injury

Spinal stability must be determined prior to sitting the patient upright to improve ventilation and reduce ventilation/perfusion (V/Q) mismatch. Exclusion of thoracic spine fractures and spinal cord injury forms part of the routine work-up of the chest trauma patient. Occult injuries are common and unstable injuries in ventilated patients require skilled nursing. Such injuries are easily overlooked.

Flail chest

Flail chest may occur where the continuity of the bony skeleton of the chest wall is disrupted in two places. It is characterized by paradoxical movement of the associated unanchored chest wall segment. Because of muscle spasm and splinting, this segment may not be apparent initially and may flail at some time after the accident. Clinical features of a flail segment may also be masked by positive-pressure ventilation, which splints the chest wall internally. Elderly patients have a less compliant chest wall and are at greater risk of developing a flail segment.

Flail chest is often associated with ventilatory insufficiency. Ventilatory disturbance is caused by hypoventilation of the affected hemithorax due to the mechanical disruption and associated pain, compounded by the underlying pulmonary contusion. Therapy concentrates on maintaining oxygenation, ventilation and euvolaemia. Adequate analgesia should be supplemented with intercostal nerve blocks or epidural analgesia. In general, patients with a significant flail, which impairs ventilation, will require respiratory support. Hypoxia may be managed with NIV. Mechanical ventilation is required if NIV is contraindicated or unsuccessful.

Some patients with severe wall instability may require operative fixation to facilitate the weaning of mechanical ventilation.[26] Operative reduction and internal fixation using malleable absorbable splints for the flail segment is associated with a reduction in ventilator days.[27]

Ruptured hemidiaphragm

Diaphragmatic tears may be difficult to diagnose. High-velocity lateral torso trauma or thoracoabdominal crush injury—as well as lateral rib fracture, penetrating truncal injury and fractured pelvis—are linked to an increased incidence of diaphragmatic disruption. Initial positive pressure ventilation may mask injury of the diaphragm. If herniation of abdominal contents into the thorax does occur, there may be respiratory compromise, with diminished air entry in the involved hemithorax. Placement of a radiopaque nasogastric tube will then facilitate the diagnosis of left hemidiaphragm disruption on chest x-ray. Although gross rupture may be apparent initially, the classic radiological findings of viscera in the thoracic cavity, the nasogastric tube coiled in the thoracic cavity or marked hemidiaphragm elevation are present only 50% of the time. No intrathoracic pathology is seen on at least 15% of occasions.[28]

CT scan will display major diaphragm injuries but may miss small defects. Diagnostic yield may be better with magnetic resonance imaging (MRI).[29] Smaller diaphragmatic injuries may evolve, with visceral herniation developing over time. Thus many diaphragmatic injuries present late. Occult diaphragmatic lacerations are associated with penetrating injuries of the thoracoabdominal region and should be actively excluded by laparoscopy, thoracoscopy or open surgery. The treatment of diaphragmatic disruption is surgical repair.

Open pneumothorax

Open pneumothorax presents an immediate threat to life. An open chest wall defect disrupts the generation of a negative inspiratory pressure. If the opening is approximately two-thirds the diameter of the trachea, air will pass preferentially through the defect (a 'sucking' chest wound) and respiratory failure will occur.[30]

Initial management includes covering the defect with a sterile dressing and taping it on three sides to achieve a flutter-valve effect prior to placement of an intercostal catheter and sealing of the defect. Definitive surgical closure is required.

Pneumothorax

Simple pneumothorax is characterized by a visceral or parietal pleural rent and pleural air preventing expansion of the associated lung. Although small (<20%) pneumothoraces may be managed expectantly, those that are larger mandate pleural decompression and drainage. There is no evidence that needle thoracotomy is a reliable means of pleural decompression (Fig. 3.6.1). The technique should be avoided during hospital trauma reception and resuscitation and used only as a measure of last resort.

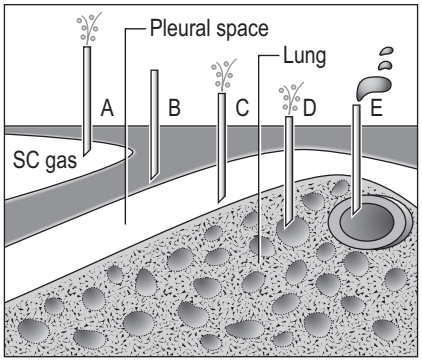

FIG. 3.6.1 Possible positions of needle thoracocentesis (NT). *(A)* False positive—as needle decompresses subcutaneous emphysema. *(B)* False negative—as needle does not reach the pleural space. *(C)* Correct position of NT with decompression of tension pneumothorax. *(D)* False positive—with needle intrapulmonary in bulla or bronchial tree. If the tension pneumothorax is loculated due to pulmonary adhesions and missed by NT, a false-negative result may occur with intra-pulmonary placement. *(E)* True negative—with needle in a major vessel or the heart. This may be misinterpreted as a false positive for haemothorax. Only *C* will decompress a tension pneumothorax. *A, B, D* and *E* have all been associated with failure to decompress the pleural space and fatal outcomes. (Reproduced with permission from Fitzgerald M, Mackenzie CF, Marasco S, et al. Pleural decompression and drainage during trauma reception and resuscitation. *Injury*. 2008;39:9–20.)

The mid-arm point reliably marks a safe site for decompression.[31] Blunt dissection, digital identification and decompression of the pleura using an aseptic technique should be the technique of first choice. Once pleural decompression has been successfully performed, the urgency of the situation is reduced, allowing time for the subsequent placement of a chest tube to facilitate ongoing pleural drainage.[32]

Intercostal catheters with underwater seal or flutter-valve drainage should also be inserted for pneumothoraces if positive-pressure ventilation is anticipated or has commenced. If small traumatic pneumothoraces are not drained, the patient should be followed closely with repeat chest x-rays or ultrasound. Intercostal catheters should be placed if the patient is to be transported to another facility by air. Clinicians should be aware of common problems with chest drain placement (Fig. 3.6.2).

Thoracic CT scanning will demonstrate pneumothoraces that may not be apparent on plain radiographs.[33] This should prompt consideration of intercostal catheter placement in ventilated patients. Small (occult) pneumothoraces in patients without major shunts may be managed expectantly.[34]

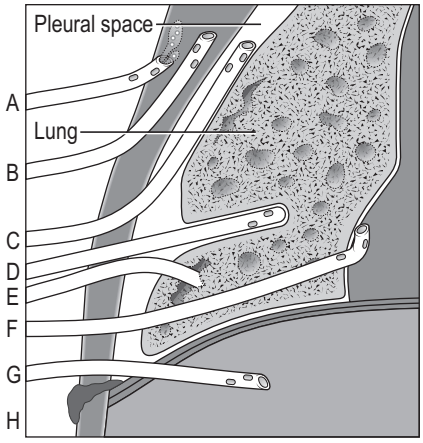

FIG. 3.6.2 Possible positions and complications of tube thoracostomy (TT). *(A)* Trauma to the intercostal neurovascular bundle. *(B)* Extrapleural placement. *(C)* Correct position in pleural space. *(D)* Intrafissural placement. *(E)* Intrapulmonary placement. *(F)* Mediastinal impingement or penetration. *(G)* Trans-diaphragmatic placement. *(H)* Infection. (Reproduced with permission from Fitzgerald M, Mackenzie CF, Marasco S, et al. Pleural decompression and drainage during trauma reception and resuscitation. *Injury.* 2008;39:9–20.)

Although extended FAST (eFAST) is superior to initial supine chest x-ray in the diagnosis of pneumothorax, it does not change the management of the patient, as the majority of small pneumothoraces are treated non-operatively. Conversely, a negative eFAST for pneumothorax may not sufficiently exclude the need for pleural decompression in the unstable patient.[35]

Tension pneumothorax

Tension pneumothorax occurs following the formation of a 'one-way valve' from the lung through disrupted visceral pleura. Pleural air collects under tension in the affected hemithorax, collapsing the lung and displacing the mediastinum, thus impairing ventilation and obstructing venous return. Tension pneumothorax is more commonly associated with positive-pressure ventilation. It is essentially a clinical diagnosis, characterized by tachypnoea, tachycardia, tracheal deviation away from the affected hemithorax, diminished ipsilateral breath sounds, diminished compliance, oxygen desaturation and hypotension.

If clinically suspected, the affected hemithorax should immediately be decompressed and an intercostal catheter inserted. There should be no attempt to delay chest decompression in an unstable patient while waiting for a chest x-ray.

Intubated and ventilated thoracic trauma patients may demonstrate subcutaneous emphysema on initial chest x-ray without a pneumothorax being visible. This should prompt pleural decompression and chest tube placement, as it may be a precursor of ipsilateral tension pneumothorax. The subcutaneous tissues in communication with the air leak offer less initial resistance and display air under pressure prior to tension developing within the pleural space.

Haemothorax

Blood may accumulate within the pleural space after lung laceration or laceration of a chest wall vessel and, less commonly, after mediastinal injury. It is indicated by fluid above the hemidiaphragm on eFAST, diffuse opacification of a hemithorax on supine chest x-ray or blunting of the costophrenic angle on an upright film. Haemothorax may be identified with high accuracy using eFAST.[36] Once digital pleural decompression has occurred, the haemothorax is best drained via placement of a 32-Fr or larger intercostal catheter positioned in the fifth or sixth intercostal space in the mid-axillary line on the affected side. The use of suction (20 cm H_2O) facilitates drainage.

Bleeding is usually self-limiting following drainage. Drainage of more than 1500 mL following initial intercostal catheter insertion (massive haemothorax) or a loss of more than 200 mL/h for more than 2 hours are indications for thoracotomy.[37] Large blood losses frequently come from intercostal arteries.

Clamping the intercostal catheter in an attempt to tamponade bleeding and 'buy time' for an intubated and ventilated, unstable patient with a massive and ongoing haemothorax may be considered if delays to thoracotomy arise. However, this technique is yet to be prospectively validated.

Pulmonary contusion

Pulmonary contusion is characterized by the leakage of blood into the alveoli and pulmonary interstitium, culminating in consolidation and atelectasis. Associated hypoxia may be profound. The initial chest x-ray may not demonstrate the severity of injury. Pulmonary contusion may take some time to become radiologically apparent, with 21% of experimentally incurred contusions still not visible on chest x-ray 6 hours after injury.[38]

CT provides the most sensitive test for gauging the extent of pulmonary contusion, although arterial blood gases offer the best measure of any physiological derangement requiring intervention. Therapy is based on ensuring adequate oxygenation, ventilatory support and fluid restriction. Ventilation should involve low-volume, low-pressure techniques to reduce barotrauma and secondary injury.

Tracheobronchial injury

Injuries to the trachea and bronchi are rare, accounting for less than 1% of injuries after blunt chest trauma. Eighty per cent of injuries occur near the carina, with resulting mediastinal and cervical emphysema. A persistent air leak post–intercostal drain insertion should alert the clinician to the possibility of a tracheobronchial injury. Fibreoptic bronchoscopy is the investigative modality of choice. Persistent air leaks often require operative repair.

Myocardial contusion

Although myocardial contusion is common, significant sequelae are rare. Cardiac failure and hypotension are uncommonly associated with myocardial contusion. Although the electrocardiogram (ECG) is used as a predictor of myocardial contusion, it is non-specific and portrays the right ventricle poorly—the area most commonly injured. Cardiac enzyme elevation does occur but is not predictive. Echocardiography may demonstrate dyskinesis of the ventricular wall. Diagnosis by MRI is sensitive and specific but requires resources and expertise.[39]

Patients with hyperacute ECG changes or conduction defects should be admitted and monitored for dysrhythmias.

Myocardial laceration and cardiac tamponade

Precordial penetrating injury is associated with underlying myocardial laceration. Bedside sonography is useful in demonstrating myocardial injury and pericardial collections. Patients presenting with signs of pericardial tamponade (hypotension, diminished heart sounds, jugular venous distension) require urgent surgical intervention.

Patients who acutely deteriorate into cardiac arrest yet had signs of life en route to hospital or on arrival are candidates for resuscitative thoracotomy in the emergency department.[40] Outcome for blunt trauma patients without initial signs is very poor (<2%), but penetrating injury has a higher survival rate. This procedure should be undertaken only when there is some chance of survival because of the infection risks to personnel. Prolonged (>9 minutes) external cardiac massage is futile for these patients.

Tension pneumopericardium

Tension pneumopericardium, albeit much less common than tension pneumothorax, is thought to arise via a similar 'one-way valve' mechanism, particularly after the institution of positive-pressure ventilation. It is characterized by raised jugular/central venous pressure and hypotension and responds to urgent pericardial decompression.[41]

Thoracic aortic transection

Eighty-five per cent of patients with transection of the thoracic aorta die before reaching hospital.

Lateral as well as frontal impact motor vehicle crashes are associated with aortic transection.[42] High deceleration forces cause the aorta to accelerate and twist against fixation points—usually the ligamentum arteriosum just distal to the left subclavian artery. The associated shearing forces transect and tear the artery. Tears of the aorta are commonly fatal at the time of injury or immediately after, as the aorta usually tears completely and the injured rapidly bleed to death. However, it has been estimated that up to 15% of patients with thoracic aortic injuries survive to reach hospital; this occurs when the outer concentric layers of the aorta remain intact. Without surgical intervention, 50% of these survivors die within the next 48 hours. Thus early diagnosis and treatment of incomplete transection of the thoracic aorta is important.

Initial vital signs are not indicative of aortic injury.[43] Mediastinal widening on chest x-ray is 85% sensitive and 10% specific for aortic transection.[44] Associated fractures of the thoracic spine also cause mediastinal widening and make interpretation difficult. No thoracic skeletal injury is a clinically useful predictor of acute thoracic aortic transection. Therefore patients involved in high-speed motor vehicle accidents require chest CT scans with contrast to exclude aortic injury.

Definitive treatment includes ensuring that the blood pressure is not elevated to reduce shearing and the radiologically guided placement of a stent across the injured aorta.[45–49]

Open surgical repair of the injured thoracic aorta is now uncommon and has a high mortality and morbidity. Published mortality rates of patients with thoracic aortic injury are as follows: endovascular stent 9%, open surgical repair 19% and non-operative management without a stent 46%.[50]

Transoesophageal echocardiography has been used as a screening tool for aortic tears and is useful for patients in theatre or those unable to be moved to angiography.[51,52]

Oesophageal perforation

Oesophageal rupture after blunt chest trauma is rare. The lower third of the oesophagus is the commonest site of rupture, presumably secondary to a forced Valsalva manoeuvre. Mediastinitis is a subsequent development. Retrosternal pain is common and mediastinal air may be seen on chest x-ray. CT scanning with a Gastrografin swallow is the study of choice. Mortality is directly related to time to operative repair.[53]

Gunshot injuries across the truncal midline more commonly involve mediastinal and spinal structures and therefore have a much greater mortality than unilateral injuries.[54] With penetrating and transmediastinal wounds, it is important to exclude oesophageal injury early, as there is significant morbidity and mortality in those patients who survive to arrival at hospital.[55]

Likely developments

Better systems of care, improved imaging and newer technologies will result in earlier diagnosis and treatment of injuries, thus preventing subsequent evolution and deterioration.

There is a trend towards the increased use of NIV and operative rib fixation for flail chest. The role of ultrasound is evolving and there is increasing use of ultrasound in the assessment of chest trauma. Conservative management of occult pneumothoraces is likely to increase; more prospective studies are required to prove the safety of conservative management.

Conclusion

The significance and severity of chest trauma may not be obvious on initial examination, as injuries evolve. Most seriously injured patients with blunt thoracic trauma require supportive care, including chest decompression and drainage. The indication for immediate chest decompression is ventilatory or respiratory compromise (Fig. 3.6.3). Patients with underlying airway disease and elderly patients with diminished compliance are at particular risk. Delayed or inadequate ventilatory resuscitation, inadequate shock management, insufficient monitoring of arterial blood gases, delay or failure to perform pleural decompression and drainage and inadequate diagnostic imaging remain identifiable problems in emergency departments.

3.7 Limb trauma

Amit Maini • Christopher Groombridge

ESSENTIALS

1 **Optimal trauma resuscitation and fracture management will reduce limb and life-threatening complications.**

2 **Skin under pressure over a fracture is an orthopaedic emergency.**

3 **Fracture management consists of reduction, immobilization and rehabilitation.**

4 **Specific limb trauma assessment is part of the secondary survey.**

5 **Early renal replacement therapy is potentially life saving in crush syndromes.**

Introduction

Injuries to the limbs account for most of the trauma-related presentations to emergency departments (EDs) and are a common source of disability in this patient group. These injuries span a spectrum, from seemingly trivial and benign to limb and life threatening. Injuries may involve the soft tissues and, bones as well as the neurovascular structures and can occur as discrete injuries in isolation or in combination, as is the case with more severe trauma.

The major consideration in managing injuries of the extremities in patients with major trauma is treatment of the individual as a whole rather than being distracted by any particular injury or fracture. A full primary survey should be performed on all patients, with simultaneous assessment and management of life-threatening injuries as the priority. Orthopaedic injuries should be picked up as part of the secondary survey, although bleeding from long bone fractures (especially open femoral fractures) may be categorized under the circulation component of the primary survey.

Specific complications of open fractures and crush injuries include bleeding, crush syndrome and hyperkalaemia as well as sepsis. Early consideration should be given to these with respect to early haemorrhage control and early administration of appropriate antibiotics. Other complications include compartment syndrome and fat embolus syndrome, which is considered later.

The only immediate threat to life from fractures is haemorrhagic shock. Limb trauma may pose a therapeutic challenge in trauma resuscitation by limiting available vascular access. Deformed or injured limbs should, as a rule, be avoided when placing intravenous cannulae, and patients with multiple injured limbs may require early central venous access. Estimates of blood loss, in addition to external scene and ED blood loss, include the following:

- 1200 to 1500 mL for femoral fracture
- 500 to 1000 mL for tibial fracture
- 500 mL for humeral fracture

The immediate goal of management in the multi-trauma patient is control of haemorrhage, followed by limb salvage. The overall aim of limb trauma care is a return to full pain-free function and good cosmesis. The function of the upper limb is to communicate a person's will to the external world and manipulate his or her surroundings. The function of the lower limbs is independent ambulation. Rehabilitation plays an essential part in recovery and must be considered, with early involvement of physio- and occupational therapists.

Fractures

A fracture is a soft tissue injury with loss of bone continuity. The soft tissue component is often underestimated. Tense or white skin over a closed fracture is an orthopaedic emergency requiring urgent reduction, even before imaging. Ischaemic skin over bone, as in the area of the anterior tibia, has a high rate of necrosis and a poor response to skin grafting, which may ultimately result in the disastrous complication of limb amputation.

All transferred patients should have splints removed and the underlying tissues carefully assessed. No splint should remain over skin for more than 8 hours without removal and reassessment. Discharged patients should have clear instructions for returning should there be an increase in pain, tightness under a plaster or splint or numbness and pain in the limb distal to the fracture. Planned early follow-up is essential.

Fractures where the overlying skin is intact are closed. Open or compound fractures are defined by their being exposed to the environment. Compound fractures may be classified as follows[1]:

- Grade I: an open fracture with a wound less than 1 cm long and clean
- Grade II: an open fracture with a laceration greater than 1 cm long without extensive soft tissue damage, flaps, or avulsions

- Grade III: either an open segmental fracture, an open fracture with extensive soft tissue damage, or a traumatic amputation
- Grade IIIA: an open fracture with adequate soft tissue coverage of a fractured bone despite extensive soft tissue laceration or flaps or high-energy trauma regardless of the size of the wound
- Grade IIIB: an open fracture with extensive soft tissue injury/loss with periosteal stripping and bone exposure, usually associated with massive contamination
- Grade IIIC: an open fracture associated with arterial injury requiring repair

Patients at high risk of fracture complications from single-limb trauma include the elderly, the immunocompromised, alcoholics (from repeated falls and poor follow-up) and patients with peripheral vascular disease. High-risk mechanisms include falls from over 3 m; also, pedestrians, motorcyclists and high-speed motorists face higher risks. Haemodynamically unstable patients, those with open fractures, with delayed (>6 hours) presentation times, and the severely head-injured also form a group with injuries at high risk of complications. Severely head-injured patients are prone to coagulopathy, further increasing fracture bleeding. Clinical assessment of limb trauma may also be difficult in patients with an altered conscious state due to head injury or sedation.[2–6]

Associated injuries

Vascular injury

Arterial injury is a limb- and (potentially) life-threatening emergency. Ischaemia times of 4 to 6 hours may result in permanent damage to tissues. Peripheral circulation and distal pulses must always be assessed and sides compared. All splints in transferred patients should be removed and underlying tissues and distal circulation assessed. High-risk patients include unconscious and shocked patients, as these states may mask local limb ischaemia.

In patients with active haemorrhage from an injured limb, focal pressure and haemostatic dressings should be applied and may be sufficient to control bleeding. Ongoing bleeding warrants the application of a tourniquet proximal to the injury, which should temporize the situation until definitive management can occur.

The presence of a distal pulse does not exclude arterial injury, which may be incomplete. Other signs to consider include the presence of a dislocation, limb deformity or open fracture in that limb, brisk bleeding from an open wound, reduced pulses compared with the other side (either clinically or on Doppler) and an expanding wound haematoma. Delayed signs include a false aneurysm or the presence of a bruit on examination.

Sites at specific risk of arterial injury include the following:

- Brachial artery in the upper limb
- Popliteal artery around the knee and adductor canal of the medial distal femur
- Deep femoral artery at the trochanter level of the femur
- The anterior tibial artery in the tibia

Computed tomography (CT) angiography (CTA) has largely replaced formal angiography as the investigation of choice; if a vascular injury is suspected, early discussion with a vascular surgeon is recommended.

Nerve injury

Nerve injury in limb trauma may be a direct result of laceration by foreign bodies or fracture fragments. Nerves may be crushed, bruised or stretched. Ischaemia must be excluded as a cause of neurological deficits. Nerve injury due to penetrating trauma should ideally be explored in the operating theatre.

Nerve injuries may be classified into three major groups:

- Neuropraxia. This is a transient change in conduction. It usually follows crush or contusion or stretching of a nerve. There is usually some return of function within days and complete return of function within 8 weeks.
- Axonotmesis. Complete denervation with an intact nerve sheath, usually as a result of blunt trauma causing severe bruising and stretching. Regeneration along the intact nerve sheath takes place over months.
- Neurotmesis. Complete division of a nerve and its sheath. Spontaneous regeneration is not expected and surgical repair is required. This represents the most severe end of the spectrum and full recovery cannot be guaranteed.

The neurovascular status of the injured limb should be assessed and documented before and after any manipulation and relocation. Specific nerve injury presentations include the following:

- Wrist drop from radial nerve injury of the middle or distal third of the humerus
- Foot drop from peroneal nerve injury to the proximal fibula
- Shoulder skin numbness and deltoid muscle weakness from axillary nerve injury in shoulder dislocation
- Lower limb numbness and weakness from sciatic nerve injury due to posterior dislocations of the hip
- Hand numbness and weakness from median nerve injury in distal fractures of the wrist and dislocations of the carpal bones
- Hand numbness and weakness from ulnar nerve injury in injuries to the medial forearm or humerus

Presentation

History and examination

Injury history and pre-hospital care should be presented in the MIST format on arrival at hospital:

- Mechanism
- Injuries identified or suspected; specifically, estimates of external blood loss, limb deformity (and correction) or amputation
- Symptoms and signs: in particular vital signs, whether the patient mobilized at the scene, areas of limb weakness or numbness and pale or pulseless limbs
- Treatments commenced and the responses to them with a note made of all splints placed and their type (hard, soft or anatomic)

The general history should also include the patient's normal state of health, medications and allergies, hand dominance, tetanus prophylaxis and fasting state. The history should be presented when the primary survey commences. Only when this is completed should a meticulous secondary survey start. All splints should be removed for limb trauma assessment, especially in patients transferred between hospitals, given the often long intervals before definitive assessment and treatment.

The assessment of limbs for trauma includes the following:

- Looking for deformity, bruising, open fractures, bleeding, skin blistering (which denotes soft tissues under pressure) and white or pressured skin. Comparison should always be made with the other limb.
- Feeling for local pain, crepitus or deformity.
- Active (patient-controlled) and passive (examiner-controlled) movement. Joints with a full active range of movement are almost never dislocated. Full active movement of the elbow may exclude an elbow fracture and straight leg raising a major pelvic fracture. Passive movement should include an assessment of ligament stability, although this can be difficult to assess in the acutely injured knee.
- Peripheral vascular assessment includes pulses and capillary refill.
- Peripheral neurological assessment includes motor power and sensation. The most accurate indicator of sensory function is two-point discrimination.
- Vascular injury should be suspected in elbow and knee dislocations regardless of whether the peripheral vascular examination is normal after reduction. Abnormal peripheral vascular signs include absent or decreased distal pulses, prolonged capillary refill, pale peripheries unilaterally, ongoing wound bleeding or an expanding haematoma.

Investigations

Plain radiography

Plain x-rays constitute the investigation of choice in the diagnosis of limb fracture. They may be performed in the trauma bay where available or in the radiology area once the patient is stable for transfer.

Two views in two planes are required for accurate diagnosis and planning of reduction. The joints above and below the injury site should also be imaged.

Other indicators of injury that may alter management include the presence of air or foreign bodies around injury sites and joints and soft tissue swelling, such as the sail sign in distal humerus fractures. Joint injury may be indicated by soft tissue swelling and lipohaemarthroses, which may indicate an underlying fracture.

Joints and fractures should be x-rayed again after reduction. Timed repeated x-rays may be used in injuries where there is doubt about the presence of a fracture (e.g. the scaphoid in peripheral wrist injuries).

Ultrasound

Ultrasound is now commonplace in trauma centres and many EDs and is increasingly being used in the pre-hospital setting. Also, many emergency physicians and registrars are becoming proficient in its use. Bedside ultrasonography is cheap, reliable, safe, non-invasive and easily repeatable. Its role in major trauma is to exclude traumatic cardiac tamponade and haemoperitoneum. Doppler scanning may be used to identify peripheral pulses.

The role of ultrasound in limb trauma is less well defined but includes the diagnosis of muscle or tendon ruptures (the rotator cuff and the Achilles tendon, respectively) and soft tissue foreign bodies or free fluid. Therapeutically, ultrasound may aid in peripheral and central line placement as well as the accurate placement of peripheral nerve blocks in the patient with limb trauma.

Computed tomography

CT scans are playing an increasing role in the acute management of fractures, particularly in operative planning. Indications may include further imaging and quantification of tibial plateau fractures, particularly the posterior component of the tibial plateau, and carpal and tarsal injuries that may be difficult to assess on plain x-ray. CT has been used in the diagnosis of suspected femoral neck fractures in the elderly.

Computed tomography angiography

Although historically digital subtraction angiography (DSA) was the preferred method for assessing vascular integrity, it has now (for the most part) been superseded by CTA owing to the latter's widespread availability and the fact that it is relatively non-invasive; also the imaging acquisition times are shorter, all the while maintaining diagnostic accuracy.[7]

CT angiography is indicated in

- all dislocations or disruptions of the knee joint, as tears of the media of the popliteal artery may not otherwise be safely excluded.
- all limb injuries with vascular compromise distally, in particular high-velocity injuries such as firearm wounds.

Angiography

In cases where CT angiography is diagnostically inconclusive, traditional angiography may be employed to delineate further vascular integrity in those patients where arterial injury is suspected. It would also be the primary choice in patients with penetrating trauma, where shrapnel might cause considerable image artefact—for instance, in blast or gunshot injuries.[7]

Angiograms may be performed in the angiography suite or in theatre and specialist staff, such as interventional radiologists, must be alerted early, as angiography suites may require some time to staff and prepare. In major trauma centres, this may take up to an hour in out-of-hours scenarios.

Magnetic resonance imaging

The indications for emergency magnetic resonance imaging (MRI) do not include limb trauma. Compartment syndromes may be identified using MRI, but this is of limited value in the acute setting. The role of MRI is usually limited to acute spinal injury with neurological deficits.

Bone scan

There is no place for bone scans in the early management of limb trauma. Bone scans are most reliable 3 days after injury in the diagnosis of occult fractures. They may also be used in the diagnosis and assessment of osteomyelitis as a complication of fracture.

Manometry

Pressure manometry is used specifically in the measurement of compartment pressures. Tools such as the Stryker manometer or a peripheral cannula connected to an arterial line manometer may be used repeatedly in the ED.

Management

Resuscitation and the primary survey take precedence in limb trauma. Splints and limb injuries may distract the team or clinician from this process. Limb trauma may impede or limit the placement of peripheral cannulae. In the primary survey, limb trauma assessment is limited to the control of visible haemorrhage by external pressure. Open wounds should be covered with sterile dressings and fractures splinted in the initial phase of care.

All rings, bracelets and other constricting foreign bodies, such as clothing, should be removed from the affected limbs.

Tetanus prophylaxis should be provided. Severely contaminated wounds should receive tetanus immunoglobulin and urgent debridement in theatre.

There is good evidence that early systemic antibiotics reduce infection rates in open fractures.[8] Antibiotics are not a substitute for good wound care, which includes decontamination, irrigation and early surgical debridement. Crushed, penetrating and macerated injuries should receive antibiotic prophylaxis against *Staphylococcus aureus*, *Streptococcus pyogenes*, *Clostridium perfringens*, and aerobic gram-negative bacteria. Recommended antibiotics include cephazolin and metronidazole. Piperacillin plus tazobactam or ticarcillin plus clavulanate are indicated in the case of severely soiled wounds, severe tissue damage or devitalized tissue to cover against gram-negative organisms and *Clostridium perfringens*, respectively. If there has been significant fresh or saltwater exposure, ciprofloxacin and clindamycin should be used.[9]

Compound fractures should be protected from secondary injury and decontaminated by gentle washing with normal saline and a sterile moist dressing placed over the wound. A digital photograph should be taken of the wound to avoid repeated wound exposure during subsequent clinical assessment.

Pain should be managed promptly; analgesia options include pharmacological and non-pharmacological interventions. Non-pharmacological measures include splinting and fracture reduction.

Pharmacological analgesia may be general or local. General agents include opioids, which should be titrated to comfort and physiological response. The use of ketamine is increasingly widespread in the pre-hospital transport of injured patients and in reduction of fractures and dislocation in the ED. It should be used by experienced clinicians in monitored, selected patients. Some procedures—such as the reduction of disrupted joints or those in patients who are uncooperative, intoxicated or have multiple traumas—may require general intravenous anaesthesia and intubation.

Local anaesthesia nerve blocks may prove useful. Specifically, in splinted fractures of the femoral shaft, the femoral nerve block is very useful in reducing quadriceps muscle spasm.

The role of splints

Splinting is important at every stage of limb trauma care, from scene to long-term rehabilitation.

The role of splints includes communication, analgesia, haemorrhage control, tissue protection, immobilization, facilitating transport and, perhaps, reduction of fat embolism. All splinted areas should be treated as fractured until proved otherwise. All splints should be noted and removed when possible and a full inspection made of the whole limb. Pain relief is assisted by less movement of injured tissue. Splinted reduced injuries have less local bleeding and oedema, and definitive bone apposition will reduce fracture bleeding. Injured tissues may be protected during transport until definitive assessment and care can occur. Patient immobilization may facilitate safe and efficient transfer to definitive care. Fat embolism may be reduced, although the role of early splinting is controversial and based on poor historical evidence.

Splints may be classified by area (general splints, such as spine boards, or local, such as cervical spine collars) or type (anatomic, such as the unaffected leg, soft, rigid, air or slings).

All splints are foreign bodies, with consequent complications: they may cause local skin pressure and necrosis, compartment syndromes, loss of limb function and distal hypoperfusion. A limb cannot be adequately assessed while a splint is in place.

The definitive management of fractures and dislocations is reduction, immobilization and rehabilitation. Ideally, all deformed injured limbs should be splinted to an anatomically neutral position. Early reduction may provide pain relief by distracting fracture edges and pressure on local innervated tissue. Pressure on the overlying skin and nearby neurovascular structures is also reduced. Limb deformities with overlying skin under pressure are true orthopaedic emergencies that should be reduced before imaging. Any suspected penetrating joint injury should be definitively explored under general anaesthesia.

Injured limbs should be immobilized in the pre-hospital setting in the anatomic or neutral position where possible. The joints above and below an injured area should also be immobilized. Some specific injuries, such as femoral shaft fractures, will require traction immobilization to overcome local muscle spasm. Examples of commercial femoral traction devices include the CT-6 or Kendrick traction device. The distal neuromuscular status of limbs should be reassessed after splint application.

Rehabilitation of limb trauma commences in the ED. Early movement of uninjured limbs should be encouraged. Supervised practice with crutches and the removal and care of slings will improve outpatient independence and reduce complications from these devices. Timed follow-up of all fractures, complicated wounds and patient groups otherwise at risk of complications is essential. Patients should be discharged home from the ED when limb- and life-threatening injuries have been excluded, when patients are safely ambulant, are tolerating food and drink, have adequate oral analgesia and have planned follow-up arranged.

Although open fractures should still be considered surgical emergencies, definite time thresholds for proceeding to surgical debridement and subsequent risk of associated complications have yet to be established. The timing of debridement should be guided by the nature of injuries and resource availability, with patient safety prioritized.[10]

Wound management

The role of wound irrigation agents in the acute setting is controversial. There is no evidence to support the use of full-strength povidone-iodine; if used, it should be diluted to less than 1%. Povidone-iodine has been shown to delay wound healing and increase infection rates in chronic wounds. Shaving of wounds should be avoided as it promotes local inflammation.

Gross contaminants should be removed and the wound irrigated using normal saline. The efficacy of normal saline is related to the irrigation pressure. Pulsatile pressure at 7 to 10 psi (48 to 69 kPa) removes debris and bacteria without further dissemination of microorganisms into the tissue. This pressure may be produced with a 20-mL syringe and a 19-gauge needle with a splash guard. There is no evidence that high-pressure irrigation offers any benefit. Reviews of the techniques and materials used in wound irrigation recommend normal saline.[11–13]

Management of the mangled extremity

The mangled extremity, though often graphic in appearance, should not distract the trauma team from initiating rapid simultaneous assessment and management of life-threatening injuries in the multitrauma patient. A systematic approach in the ED will comprise restoration of anatomic alignment of the extremity as well as evaluation for vascular and nerve injury.

The goals of management of the mangled extremity are as follows:

- Control of ongoing haemorrhage using direct pressure. If this fails, application of a tourniquet may be life saving as a temporizing measure to prevent further major bleeding until definitive haemostasis is achieved in the operating theatre.[14,15]
- Timely reperfusion of ischaemic tissues.
- Early reduction of long bone fractures using traction or splints. This may also improve perfusion by relieving potential impingement of vasculature.[16]
- Provision of adequate analgesia. Repeated titrated doses of fentanyl may facilitate the humane manipulation of fractures. Ketamine is also a safe, useful adjunct to analgesia for experienced providers in the setting of extremity trauma.
- Early communication with surgical specialists to expedite necessary early operative intervention.
- Assessment and careful documentation of extremity neurological status.

Hyperbaric oxygen therapy

The role of hyperbaric oxygen therapy (HBOT) in acute limb injuries is controversial and remains unresolved. Theoretically it enhances oxygen delivery to areas affected acutely by hypoxia and at risk of such by cellular and tissue oedema. This may reduce the number of cells at risk from delayed ischaemia and necrosis from local oedema. Animal and human case studies have demonstrated benefit in crush injury, compartment syndrome and mal-united or non-united fractures.[17,18] The US Hyperbaric Society lists crush injury and compartment syndrome as indications for hyperbaric therapy. A systematic review has demonstrated a possible benefit of HBOT in the management of acute, difficult-to-heal wounds.[19] Clinicians should be aware of the recommendations and practice in their region.

Disposition

The ED is a critical care area, not a final disposition. Patients will be discharged home, admitted to a general or trauma ward, taken to theatre or admitted to the intensive care unit (ICU). In the interim, some patients may require transfer for angiography, CT scanning or MRI. Patients who have been completely managed in the ED may be discharged home with a written care plan and timed follow-up with their general practitioner, an injury or fracture clinic, or the ED. Elderly patients with splints should be assessed for mobilization safety and appropriate aids provided by the allied health team. Adequate oral analgesia should be prescribed for at least a week, with specific care taken to cover weekend and holiday periods. Non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided, particularly in the elderly, as they offer no benefit and may cause harm. Sleep with injured limbs may be interrupted and difficult. Slings should be removed during rest periods and adequate replacements, such as cushions, planned for. Minor sedatives may be prescribed in some cases.

Patients with a plaster should have documented evaluation of the plaster, the affected limb or limbs and use of any splints or walking aids, such as crutches. Upper limb slings should have cushioned supports where they come in contact with the neck, especially at the site of any securing knot. All injured limbs should be elevated for the first 48 hours, preferably in a splint such as a sling or with specific instructions, such as elevation of the leg above the height of the hip when sitting or lying. Patients should be instructed to return if their injury becomes too painful to cope with or if the distal area becomes numb, painful to move or pale or blue in colour. Initial plasters should be reviewed at 24 hours and changed at 1 week or earlier should they become tight, wet or damaged, at which point the injury and the patient should be reassessed.

Operating theatre

Urgent transfer to the operating theatre specifically for limb injury is indicated in

- uncontrollable haemorrhage.
- severely contaminated wounds or open fractures.
- limbs ischaemic for over 6 to 8 hours.
- crushed limbs requiring amputation as a life-saving procedure.
- infected limbs requiring amputation as a life-saving procedure.

In patients with complex polytrauma, patients in extremis with an otherwise high intra-operative mortality risk or in departments where the surgical workload will overload theatre resources, damage-control surgery may be indicated. In the 1970s, early fixation of fractures resulted in a dramatic fall in fat embolism syndrome (FES) and so became standard practice. Damage control orthopaedic surgery is the initial temporary fixation of fractures in patients in whom the overall burden of definitive surgery may be too great, with a definitive secondary procedure planned for a later date. The aims of damage-control surgery are to control haemorrhage, contamination and wound swelling and to reduce the potential risk of skin necrosis and FES. The patient is then usually transferred to an ICU for haemodynamic stabilization and correction of gross physiological derangements.[20–22]

General or trauma ward

Patients transferred to a general or trauma unit ward should have the same documented attention as discharged patients. Specific issues include fasting status, fluid requirements, mobilization restrictions and analgesia with a particular emphasis on systemic analgesia for breakthrough pain or pain after wound care on the ward. Considerable care should be given to adequate siting, labelling and communication of any procedures planned. Other general care issues include bladder and bowel care, pressure care and elevation of injured limbs in splints or on pillows.

Complications

Compartment syndrome

Acute limb compartment syndrome (ALCS) is a limb- and (occasionally) life-threatening complication of limb trauma. It is caused by bleeding or oedema in a closed muscle compartment surrounded by fascia, interosseous membrane and bone. The syndrome leads to muscle and nerve ischaemia and the release of potassium, hydrogen ions and myoglobin. Untreated compartment syndrome leads to muscle necrosis, limb amputation and, if severe, can lead to acute renal failure and death.

Clinical suspicion, elevation with local ice packs, occasional measurement of compartment pressure and surgical decompression with fasciotomy are the mainstays of treatment.

Clinically, the outstanding sign is ischaemic muscle pain. That is, pain that is difficult to control and out of proportion to the injury seen. This may be brought on by passive flexion or extension of the distal digits. Peripheral pulses are usually present and their loss is a very late sign. Affected muscle compartments are firm, tense and tender on palpation.

Causes of compartment syndrome include crush injuries, closed fractures, injections or infusions into compartments, reperfusion following arterial ischaemia, snakebite, electric shock, burns, exercise and hyperthermia. Splinting of suspected limbs and removal of any circumferential casts, splints or dressings is essential so as not to increase compartment pressure further.

Areas in which ALCS occurs most commonly are the leg (anterior, lateral, superficial and deep posterior compartments), thigh (quadriceps) and forearm (volar and dorsal compartments). Less commonly it may also occur in the buttocks (gluteals), the hand (interosseous muscles) and the arm (biceps and triceps).

The investigation of choice is compartment pressure monitoring. Normal compartment pressure is 4 to 8 mmHg. The pressure mandating fasciotomy remains controversial, but most departments would agree on an orthopaedic review with a view to fasciotomy for any pressure above 40 mmHg. Compartment pressure may be monitored with commercial devices such as the Stryker pressure monitor or by insertion of a cannula connected to an arterial pressure monitoring transducer.

Patients who should have compartment pressure measured include all those with tense compartments whose contralateral limbs cannot be clinically compared, patients with distracting injuries, such as compound fractures, and intoxicated or intubated patients.

The definitive management of compartment syndrome is surgical decompression with fasciotomy.[23–25]

Fat embolism syndrome

Fat embolism, the passage of fat from one area of the body to another via the vascular system, is a normal consequence of long bone fractures and was first described in 1862. FES—the self-limiting, life-threatening multi-organ syndrome affecting the lungs, brain cardiovascular system and skin—is very rare, occurring in perhaps less than 1% of all long bone fractures. The exact incidence is difficult to measure, given that FES may be subclinical or masked by other syndromes, such as acute respiratory distress syndrome (ARDS). It usually occurs 6 to 48 hours after long bone fracture. Other causes include closed cardiac massage, severe burns, liver injury, bone marrow transplantation and liposuction.

Clinically, patients deteriorate with hypoxaemia, chest x-ray changes, skin petechiae and an altered conscious state. The respiratory syndrome is similar to that seen in ARDS.

Investigations are useful only in the exclusion of other causes, such as ARDS, pulmonary contusion or pulmonary embolism. Some tomographic changes may be more specific for FES; these are thought to represent the fat emboli themselves and the systemic inflammatory response to them. Treatment is both prophylactic and supportive. The aims of general ICU management include the maintenance of adequate oxygenation/ventilation and haemodynamic stability as well as prophylaxis for deep vein thrombosis (DVT) and stress-related upper gastrointestinal bleeding.

Studies support early fixation of fractures to prevent recurrent FES. There is controversy regarding the role of reaming with intramedullary nails for fractures of the long bones, such as the femur and tibia, as by this technique relatively large amounts of fat are released into the systemic circulation.[26–33]

Crush syndrome

Crush syndrome is a life-threatening systemic manifestation of muscle damage resulting from pressure or crushing. Crush syndrome was first described in the early 20th century following the Messina earthquake of 1906 and work in Germany in World War I and by Beals and Bywater in London in 1941. Following the Armenian earthquake of 1988, the International Society of Nephrology established the Renal Disaster Relief Task Force in direct response to the overwhelming demand for dialysis of crush injury survivors in these earthquakes. Specific protocols for the prevention and management of renal failure due to crush syndrome have been established.

Crush syndrome is a result of both external pressure on muscles and time. Crushed or compressed muscle cells may immediately burst due to overwhelming external compressive force, releasing potassium, hydrogen ions (causing hyperkalaemia and acidosis, respectively) and myoglobin, oxygen free radicals and phosphate ions (causing acute renal injury and death from renal failure). The release of these may occur in cells not initially crushed but at risk of cell wall breakdown from local ischaemia, as in compartment syndrome, or cell membrane damage without disruption from external compressive force. The toxic metabolites listed earlier are initially usually restricted to the local tissue environment, as venous return is impeded by the crush injury itself. Creatinine kinase (CK) is also released and may be a measure of myoglobin load, predicting renal injury and dialysis. The release of crushed tissue from a compressive environment and the re-establishment of local blood flow may release all of the above systemically. Therefore pre-hospital fluids and administration of sodium bicarbonate may be able to pre-empt renal injury and death before a limb is released from compression.

Diagnosis is from the history of a crush injury. Apart from earthquake survivors, other groups at risk include trapped victims of motor vehicle accidents, users of intravenous drugs who collapse unconscious on a limb and elderly collapsed patients who remain unattended for some time (e.g. after a hip fracture). Other causes of rhabdomyolysis are the destruction of skeletal muscle, heat stroke, severe exertion, cocaine and amphetamine use, serotoninergic syndrome and snakebites.

Clinically, as with compartment syndrome, patients may exhibit tense, hard, tender muscles with overlying skin that may be bruised or blistered due to high interstitial pressure. They may be hypothermic and shocked due to prolonged exposure and inadequate fluid intake. The urine is dark (like machinery oil or black tea) and reflects the presence of myoglobin and other toxic haem proteins. The bedside investigation of choice is an ECG to assess for the consequences of life-threatening hyperkalaemia. Blood tests may initially demonstrate only hyperkalaemia but, in time, will reflect metabolic acidosis and worsening acute renal failure. The CK is often raised above 5000 in significant crush injury. A CK over 75,000 is predictive of acute renal failure and death.

Early deaths from crush syndrome are due to arrhythmias from hyperkalaemia and hypovolaemic shock. At 3 to 5 days after injury, death is from renal failure, coagulopathy and haemorrhage (disseminated intravascular coagulopathy [DIC]) and sepsis. Treatment is aimed at stabilizing the cardiac milieu against hyperkalaemia, aggressive volume therapy to prevent shock and renal failure, enhancing haem protein elimination and limiting haem protein cytotoxicity.

Trapped patients should have aggressive fluid loading with normal saline before extraction. They may also receive calcium gluconate or bicarbonate intravenously to counter ensuing hyperkalaemia. In severe crush injury, fluid requirements in addition to baseline needs average 12 L in the first 48 hours to prevent renal failure.

Once in the ED, patients should be monitored with an arterial line, with consideration for an indwelling urinary catheter and a central venous line.

Once urine flow has been established, an alkaline-mannitol diuresis is recommended, aiming at an output of 2 mL/kg per hour. Mannitol increases renal tubular blood flow; it is a renal vasodilator and free-radical scavenger. It is also an osmotic diuretic. It may have an effect on compartment pressures, although compartment syndrome should be treated by fasciotomy, as mentioned. Urine pH should be maintained at over 5, at which level myoglobin is over 50% soluble and thus prevented from precipitating into the renal tubules. Bicarbonate at 50 mmol/h after the first 3 L of normal saline will help to achieve this.

Acute renal failure is common following crush syndrome and, ideally, renal replacement therapy should be utilized in the early stages of management where possible, especially in the anuric patient with refractory hyperkalaemia and fluid overload. This is logistically challenging in the disaster/earthquake scenario, as was found in the January 2010 earthquake in Haiti.[34]

Local assessment and management of affected limbs, as outlined earlier, is mandatory.[34–45]

Immobilization

Some patients may require prolonged periods of immobilization, usually in hospital, but also in rehabilitation facilities or at home. The consequences of prolonged immobilization include pressure sores and skin breakdown, muscle atrophy and weakness (with an increased risk of falls subsequently), postural hypotension, lung atelectasis and secondary pneumonia, constipation, insomnia, social isolation and depression. Management plans that are well communicated and documented should prevent and manage many of these complications.

CONTROVERSIES

- The role of limb compartment pressure monitoring, in particular continuous pressure monitoring, remains a subject of debate.
- There is no consensus on optimal timing of surgical debridement of open fractures.
- Clinicians disagree on the optimal timing of early fracture fixation and reduction to prevent fat embolism syndrome and skin necrosis.
- The role of hyperbaric therapy in the management of acute limb trauma is controversial.

3.8 Radiology in major trauma

Anthony P. Joseph • Brett Lurie

ESSENTIALS

1 The initial trauma series x-rays should include a chest x-ray (CXR) and pelvic x-ray (PXR). Computed tomography (CT) of the cervical spine is essential to rule out a major fracture/dislocation.

2 CT of the brain will rule out most types of intracranial haemorrhage but not diffuse axonal injury (DAI), which is best diagnosed by magnetic resonance imaging (MRI).

3 CT of the cervical spine will rule out any bony injury but not ligamentous, disc or spinal cord injury.

4 MRI of the spine is required if there is suspicion of ligamentous, disc or spinal cord injury.

5 CT of the facial bones is essential to rule out bony facial injury.

6 Unconscious victims of major trauma will often require a CT panscan (whole-body CT scan) to rule out injury where an adequate physical examination cannot be made. However, clinical judgement should always be used before ordering a CT scan.

7 Conscious victims of major trauma should have CT scan evaluation of areas of clinical suspicion only.

8 Most injuries to the chest/abdomen/pelvis can be ruled out by CT scan of those areas before and after intravenous contrast.

9 Injuries to the thoracolumbar (TL) spine are best evaluated by sagittal and coronal reconstruction of axial CT scans of the chest/abdomen/pelvis.

10 If blunt cerebrovascular injury (BCVI) is suspected by the presence of relevant signs, symptoms or risk factors, a CT angiogram is the investigation of choice.

11 The clinical team should be mindful of the risks of radiation for both the patient and the team members. In particular, clinicians should carefully weigh the pros and cons of performing CT scans in paediatric patients.

Hazards of radiation

The trauma team should take precautions to avoid being exposed unnecessarily to ionizing radiation. The clinical team should also ensure that patients are exposed to 'As Low As Reasonably Achievable (ALARA)' ionizing radiation.[1]

The number of x-rays taken in the resuscitation area should be kept to a minimum. As radiation exposure decreases inversely with the square of the distance from the source, staff should position themselves at a maximal possible distance from the x-ray equipment whenever it is being used. The use of permanent lead barriers should be considered.

Ionizing radiation in x-ray and computed tomography (CT) examinations may directly or indirectly damage DNA, which may not be corrected by cellular repair mechanisms. Such damage has been associated with an increased risk of developing cancer. A large Australian study conducted over 20 years (1985 to 2005) found that overall cancer incidence was 24% greater for patients exposed to ionizing radiation from CT scans than those not exposed, and the incidence rate ratio was greater after exposure at younger ages. The cancer risk was increased for many types of solid organ cancers and haematologic malignancies. The authors suggested that future scans should be limited to situations where there is a definite clinical indication, with every scan optimized to provide a diagnostic CT image at the lowest possible radiation dose.[2]

The radiation dose from various diagnostic imaging examinations may be calculated as an 'effective dose' for the purpose of comparison and quantification of risk. Effective dose, evaluated in millisieverts (mSv), refers to the radiation dose from an examination averaged over the entire body and accounts for the relative sensitivities of the different tissues exposed.[3–4]

A single CT scan gives tissue doses in the range of 10 to 30 mSv. The US Food and Drug Administration estimates that CT examination with an effective dose of 10 mSv may carry a 1:2000 lifetime risk of inducing fatal cancer.[5]

Table 3.8.1 gives typical whole-body effective doses for selected radiological examinations.

The trauma series

The initial trauma x-rays usually consist of a supine chest and PXR. A lateral x-ray of the cervical spine may provide limited information, and an axial CT scan of the cervical spine from occiput to T4–T5 with sagittal and coronal reconstruction will accurately rule in or out bony injury to the cervical spine (Fig. 3.8.1).

A CT scan of the cervical spine should include the occipital condyles and atlanto-axial junction and extend to the T4–T5 level (Fig. 3.8.2).

The CXR performed is usually a supine (antero-posterior [AP]) rather than an erect (postero-anterior [PA]) film owing to the inability to sit the patient up until the spine has been cleared. The CXR should include both clavicles as well as the ribs, lungs, mediastinum and diaphragm. If there is adequate penetration, the thoracic spine may be seen. The CXR will exclude significant injuries such as massive haemothorax, pneumothorax, multiple rib fractures or a widened mediastinum (Fig. 3.8.3)

Table 3.8.1 Whole-body effective doses

Examination	*Radiation dose (mSv)*
Annual background radiation	2.4
Chest x-ray[1]	0.02
Pelvic x-ray[1]	0.44
Skull x-ray[1]	0.07
Cervical spine x-ray	0.2
CT head[4]	1–2
CT chest[4]	5–7
CT abdomen/pelvis[4]	8

CT, Computed tomography

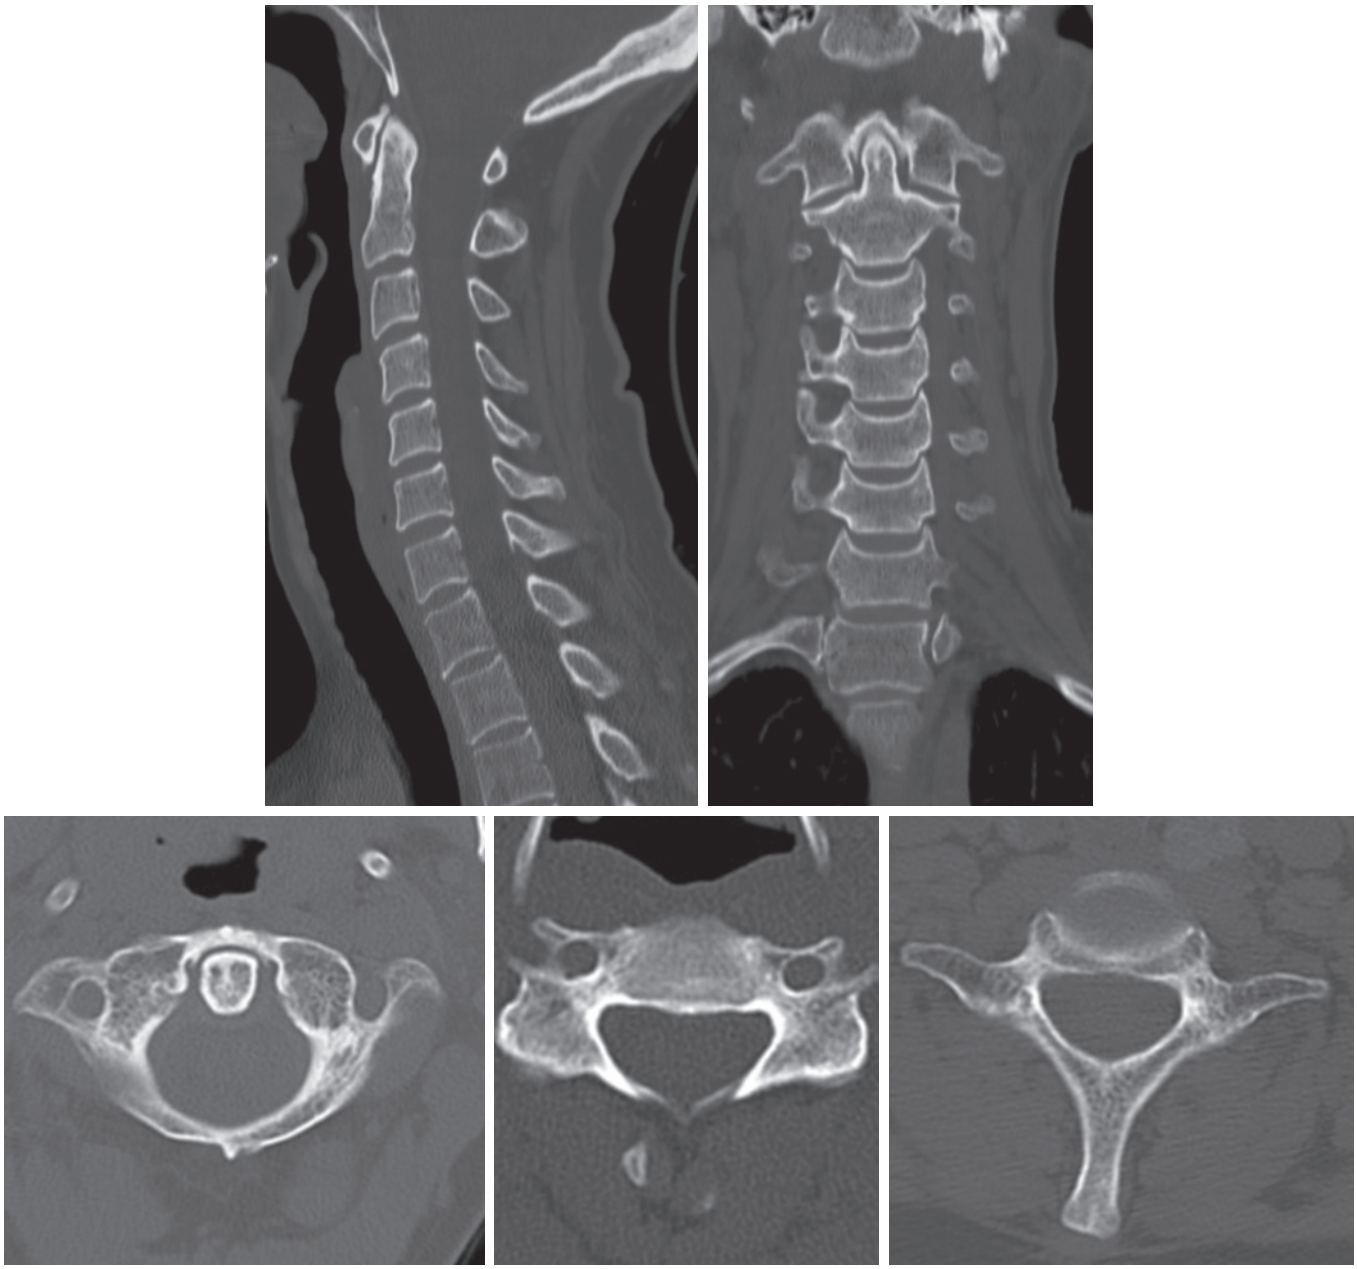

FIG. 3.8.2 Normal Computed Tomography of the Cervical Spine. Sagittal and coronal reconstructions *(top).* Axial *(bottom row)* images at C1, C4 and C7 demonstrating normal vertebral anatomy.

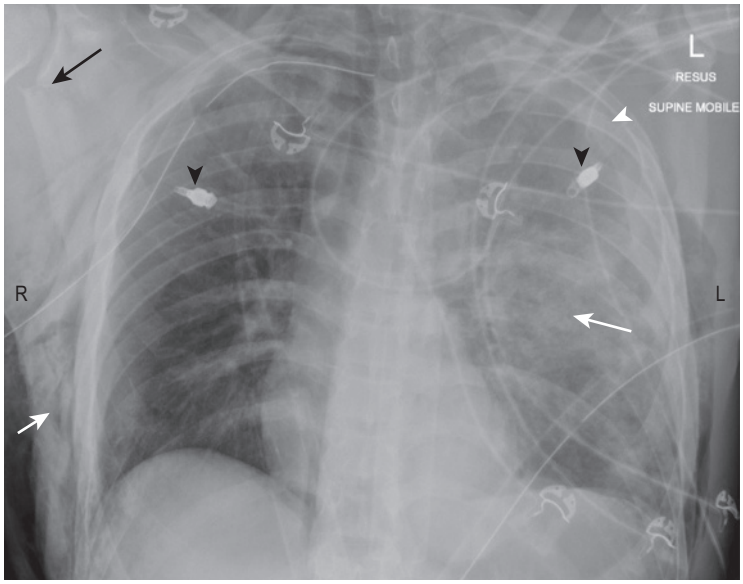

FIG. 3.8.3 Supine antero-posterior chest radiograph post-trauma showing multiple injuries: left-sided pulmonary contusion *(long white arrow)* and haemothorax *(white arrowhead)*; right-sided pneumothorax treated with an intercostal catheter with surgical emphysema over the right lateral chest wall *(short white arrow)*; right scapular fracture *(black arrow)*. Note bilateral catheters inserted by paramedics prior to arrival at the emergency department *(black arrowheads)*.

Table 3.8.2 Indications for a computed tomography brain scan in significant head injury

Glasgow Coma Scale (GCS) score <9 after resuscitation
Neurological deterioration of 2 or more GCS points
Drowsiness or confusion (GCS 9–13) that persists for longer than 2 h
Persistent headache or vomiting
Focal neurological signs (e.g. pupillary abnormalities or focal neurological signs)
Skull fracture known or suspected
Penetrating injury known or suspected
Age over 50 years with a suspicious mechanism of injury
Any head injury in a patient on anticoagulation therapy

Specific regional radiology

Head

Head trauma is responsible for up to 90% of pre-hospital trauma deaths. Some 75% of brain injuries can be classified as mild, 15% as moderate and 10% as severe.[6] The spectrum of head injury ranges from mild concussion to diffuse axonal injury (DAI) incompatible with life; it includes all causes of intracranial haemorrhage.

A CT brain scan is the investigation of choice for all but minor head injuries (see Table 3.8.2 for CT indications in serious head injury). A non-contrast CT brain scan with bone windows is adequate for the detection of intra-cranial haematoma, cerebral oedema with or without midline shift and skull vault fractures (Figs 3.8.4–3.8.6).

The Canadian CT Head Rule[7] for patients with minor head injury also provides guidance for CT brain scanning in patients with minor head injury (Glasgow Coma Scale [GCS] score 13 to 15). This rule found that the presence of any of the high-risk factors (Table 3.8.3) was 100% sensitive for predicting the need for neurological intervention and the presence of medium-risk factors was 97.2% sensitive for detecting clinically important brain injury.

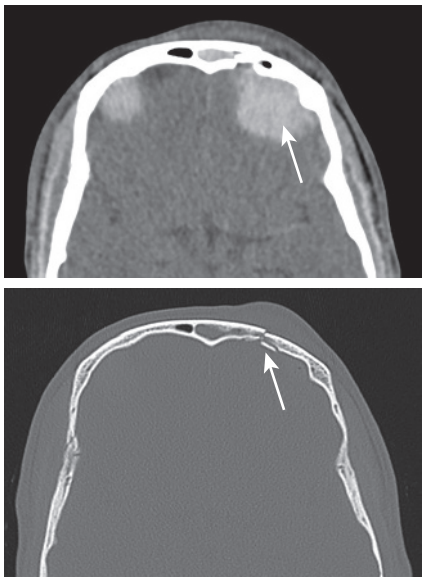

FIG. 3.8.4 Axial reconstructions of a computed tomography scan of the brain demonstrating a left frontal extradural haematoma *(long white arrows)*. Note the overlying comminuted and mildly depressed fracture of the left frontal bone *(short white arrow)*.

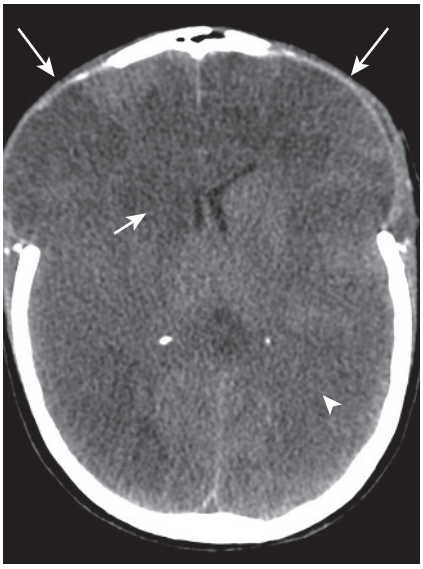

FIG. 3.8.5 Axial non-contrast computed tomography scan of the brain in a trauma patient after bi-frontal craniectomy *(long arrows)* to manage widespread cerebral oedema *(arrowhead)*. Multiple areas of infarction are present in the frontal lobes bilaterally and in the right basal ganglia *(short arrow)*. A catheter angiogram subsequently demonstrated multiple traumatic intracranial arterial dissections as causative.

FIG. 3.8.6 Base-of-Skull Fracture in a Trauma Patient. The *long white arrows* indicate a transverse fracture of the left temporal bone. Fluid/haemorrhage is noted in the middle ear cavity *(arrowhead)* and mastoid air cells *(short arrow)*.

Table 3.8.3 The Canadian computed tomography head rule (required only for patients with minor head injuries with any one of the following)

High risk (for neurological intervention)
• GCS score <15 at 2 h after injury • Suspected open or depressed skull fracture • Any sign of basal skull fracture (haemotympanum, 'racoon' eyes, cerebrospinal fluid otorrhoea/rhinorrhoea, Battle sign) • Vomiting ≥2 episodes • Age ≥65 years
Medium risk (for brain injury on computed tomography)
• Amnesia before impact >30 min • Dangerous mechanism (pedestrian struck by motor vehicle, occupant ejected from motor vehicle, fall from height >3 feet or five stairs)
Minor head injury is defined as witnessed loss of consciousness, definite amnesia or witnessed disorientation in a patient with a GCS score of 13–15.

GCS, Glasgow Coma Scale.

If a compound or depressed fracture of the skull is suspected clinically, a CT brain scan should be performed. A compound depressed skull fracture is considered a neurosurgical emergency because of the increased risk of infection, such as meningitis or brain abscess.

Magnetic resonance imaging (MRI) scan of the brain is the investigation of choice for the diagnosis of DAI. MRI sensitivity for the detection of contusions, shear injury, and extra-axial hematomas is higher than that of CT scan, although it is lower for fractures. It may detect white matter lesions consistent with shear injury in patients presenting with normal CT scan findings (Fig. 3.8.7).

Classification of intracranial haemorrhage

Intracranial bleeding may be classified according to location. This includes: subdural, subarachnoid, extradural, intraventricular or parenchymal bleeding. These commonly coexist in the setting of trauma.

Extradural haematomas are commonly secondary to arterial bleeding due to a skull fracture with subsequent disruption of the middle meningeal artery. The haematoma is ovoid or lentiform and does not cross cranial sutures, but it may cross the midline (see Fig. 3.8.4).

Subdural haematomas usually occur as a result of venous bleeding. These haematomas are crescentic in shape, may involve a larger area when compared with an epidural haematoma and may cross cranial sutures, but they do not cross the midline (Fig. 3.8.8).

Subarachnoid haemorrhage may be due to disruption of small subarachnoid vessels or occur by direct extension from a parenchymal contusion/haematoma. Subarachnoid haemorrhage may be visualized in the sulci of the cerebral convexities or within the subarachnoid cisterns at the base of the skull (Fig. 3.8.9).

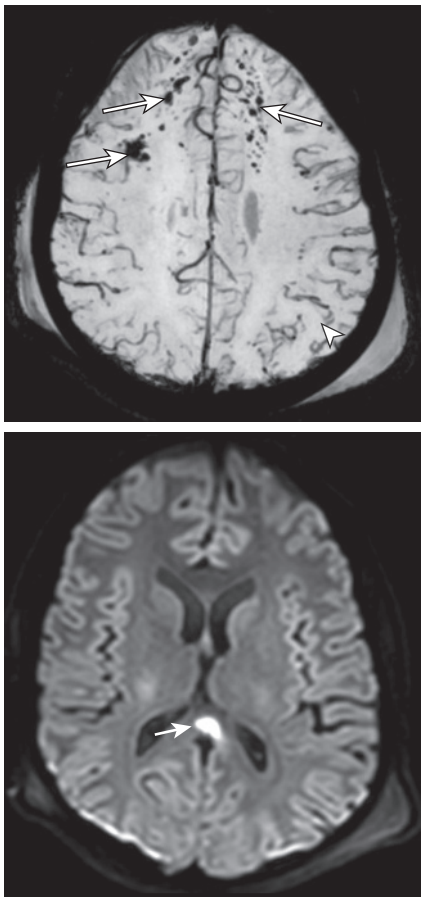

FIG. 3.8.7 Magnetic Resonance Imaging. (A) Axial gradient-echo sequence showing multiple areas of low signal intensity *(long white arrows)* (B) Axial diffusion-weighted image demonstrates restricted diffusion in the corpus callosum due to DAI *(short white arrow)*. White arrow head demonstrates normal vessels.

Intraventricular haemorrhage (see Fig. 3.8.9) may be caused by tearing of subependymal veins on the surface of the ventricles or by direct extension from a parenchymal contusion/haematoma. These blood products tend to layer dependently on a CT scan with the patient imaged in a supine position, particularly within the occipital horns of the lateral ventricles.

Cerebral contusions represent foci of bleeding within the parenchyma of the brain. These may occur within superficial grey matter/subcortical white matter due to direct contact from bony protuberances of the calvarium or base of skull. Deeper parenchymal contusions are caused by disruption of intraparenchymal blood vessels. Cerebral contusions commonly increase in size and number within the first 24 hours post-trauma due to continued bleeding (see Fig. 3.8.9). These haematomas also develop adjacent oedema, which may increase the associated mass effect on the remainder of the intracranial structures.

Also noteworthy is the increased presentation of patients taking anticoagulation or antiplatelet therapy who fall and suffer head injuries. The bleeding as a result of the injury may progress over 24 hours and may occur in all of the previously noted locations despite both pharmacological and neurosurgical attempts at reversal.

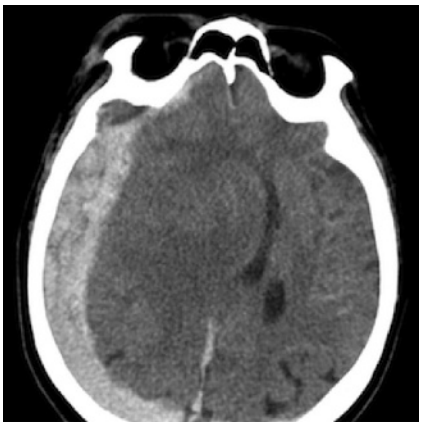

FIG. 3.8.8 Right Cerebral Convexity Subdural Haematoma.

FIG. 3.8.9 Axial non-contrast computed tomography image of the brain demonstrating acute subarachnoid haemorrhage *(short arrow)*, parenchymal haemorrhage *(long arrow)* and intraventricular haemorrhage *(arrowhead)* in a trauma patient.

DAI occurs due to acceleration/deceleration forces and is a shearing-type injury to the brain. It may be initially difficult to visualize on a non-contrast CT but can be identified as tiny foci of petechial haemorrhage at the grey/white matter interface, within the corpus callosum or within the brain stem. MRI is the investigation of choice for DAI (see Fig. 3.8.7)

Non-contrast CT is also capable of identifying areas of acute established infarction. In the setting of trauma, this may be secondary to acute vascular injury or mass effect due to cerebral oedema (see Fig. 3.8.5).

Blunt cerebrovascular injury

Blunt injury to the carotid or vertebral vessels (BCVI) occurs in about 0.1% of all trauma patients in the United States. Many of these injuries are diagnosed after the development of symptoms and signs due to central nervous system ischaemia, with neurological morbidity of up to 80% and mortality approaching 40%. However, when asymptomatic patients are screened for BCVI, the incidence rises to 1% for all admitted blunt trauma patients and up to 2.7% for those with an injury severity score (ISS) greater than 15.[8]

The Denver Modification of Screening criteria (Table 3.8.4) provide both risk factors as well as symptoms and signs for BCVI. CT angiography (CTA) is now the investigation of choice for the diagnosis of BCVI.[8] Table 3.8.5 shows a grading scale for BCVI as proposed by Biffi et al.[9]

A dissection of the right vertebral artery due to blunt trauma in a patient with bilateral facet dislocation is shown in E-Fig. 3.8.1; E-Fig. 3.8.2 demonstrates dissection of the right internal carotid artery with a large associated pseudoaneurysm; and E-Fig. 3.8.3 shows a posterior inferior cerebellar artery infarct in a patient with a vertebral artery dissection.

Facial injury

Facial trauma may range from relatively minor undisplaced nasal bone fractures to the life-threatening problems of airway protection and haemorrhage associated with mid-facial (Le Fort) fractures. Underlying cerebral injury may also be associated with frontal bone fractures.

Table 3.8.4 Denver modification of screening criteria for blunt cerebrovascular injury

Symptoms/signs of BCVI
Arterial haemorrhage
Cervical bruit
Expanding cervical haematoma
Focal neurological deficit
Neurological findings incongruous with CT scan findings
Ischaemic stroke on secondary CT scan
Risk factors for BCVI
High-energy transfer mechanism with:
Le Fort 2 or 3 fractures
Cervical spine fracture patterns: subluxation, fractures extending into the foramen transversarium, fractures of C1–C3
Basilar skull fractures with carotid canal involvement
Diffuse axonal injury with GCS score <7
Near hanging with anoxic brain injury

BCVI, Blunt cerebrovascular injury; *CT*, computed tomography.

The commonest injury to the mid-face is the blowout fracture caused by a direct blow to the orbit, which results in a fracture of the orbital floor or the medial wall of the orbit in the region of the paper-thin lamina papyracea (E-Fig. 3.8.4). There may be tenderness over the fractured bone associated with diplopia due to entrapment of orbital contents or (less commonly) visual disturbance due to globe or optic nerve injury. These fractures are best seen on CT scans with multi-planar reconstructions. Blowout fractures with entrapment of orbital contents require surgical elevation.

Mandibular fractures are usually obvious clinically because of pain, malocclusion and drooling. Mandibular fractures may be difficult to demonstrate on standard PA and oblique x-ray views. A panoramic view or orthopantomogram (OPG) is more useful, but CT of the mandible provides optimal demonstration of mandibular fractures, including those involving the mandibular neck, condyle and temporomandibular joint (TMJ) (E-Fig. 3.8.5). Dislocation of the TMJ is also optimally diagnosed on CT (E-Fig. 3.8.6).

Fractures of the zygoma are classified as (1) tripod fractures and (2) isolated fractures of the zygomatic arch. The tripod fracture or zygomatico-maxillary fracture separates the malar eminence of the zygoma from its frontal, temporal and maxillary attachments. Tripod fractures are usually caused by a significant force to the body of the zygoma or malar eminence. The three fractures that constitute the tripod fracture are located in the inferior orbital margin, the lateral orbital margin or the zygomaticofrontal suture and the zygomatic arch. These fractures are best viewed on CT scans (Fig. 3.8.10).

The Le Fort fractures are caused by direct trauma to the mid-face. The Le Fort 1 fracture involves the maxilla at the level of the nasal floor and will allow mobility of the palate ('floating palate') (Fig. 3.8.11). The Le Fort 2 fracture passes through the nasal bones as well as the medial, inferior and lateral walls of the maxillary antrum. The Le Fort 3 or 'craniofacial dysjunction/floating face' fracture involves the nasal bones, the medial and lateral orbital walls and the zygomatic arch.

Frontal sinus fractures commonly occur as a result of direct force and are often compound, with the risk of associated intracranial infection. There may be an associated intracranial haematoma or cerebral contusion. A CT scan will best evaluate these fractures and determine the involvement of the posterior sinus wall. These fractures often require surgical exploration for debridement and repair.

Table 3.8.5 Grading scale for blunt cerebrovascular injury

Grade 1: intimal irregularity with <25% narrowing
Grade 2: dissection or intramural haematoma with >25% narrowing
Grade 3: pseudoaneurysm
Grade 4: occlusion of lumen
Grade 5: transection with extravasation

Spinal injury

Cervical spine

Injuries of the cervical spine can be classified into those with

- fractures: stable or unstable.
- fractures and no neurological deficit.
- fractures associated with neurological deficit.
- cord injuries associated with contusion, haemorrhage or oedema without bony injury, which are seen in a small group of patients.

The bony cervical spine is best evaluated for fracture by axial CT scan with coronal and sagittal reconstruction. The cervical cord, discs and ligamentous stability are best imaged by MRI.

The incidence of adult cervical spine injury after blunt trauma is 2% to 6%, and any blunt trauma patient with physical findings of posterior midline neck tenderness, altered mental status or neurological deficit is considered at high risk for cervical spine injury. Cervical spine injury occurs in 5% to 10% of patients with traumatic brain injury, with potentially devastating consequences when such an injury is missed in these patients. Some 55% of spinal injuries occur in the cervical region, 15% in thoracic spine, 15% at the thoracolumbar (TL) junction and 15% in the lumbosacral area. CT scan of the cervical spine is the investigation of choice for the detection of bony fractures/dislocations with 3-mm axial cuts from occiput to C3 and 5-mm cuts from C4 to T4–T5 and sagittal/coronal reconstruction (see Fig. 3.8.2).

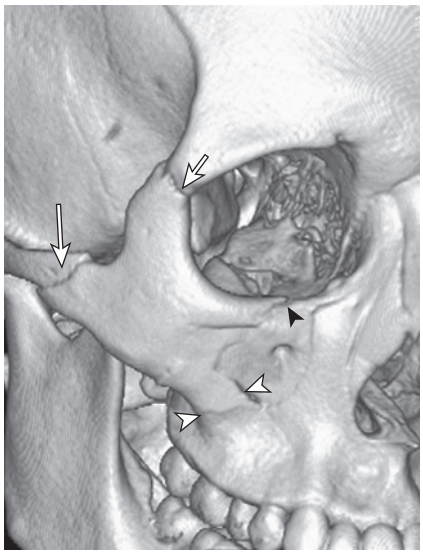

FIG. 3.8.10 Three-Dimensional Reconstruction of a Tripod Fracture. Fracture of the zygomatic arch *(long white arrow)*, zygomatico-frontal suture *(short white arrow)*, maxillary sinus walls *(white arrowheads)* and inferior orbital rim *(black arrowhead)*.

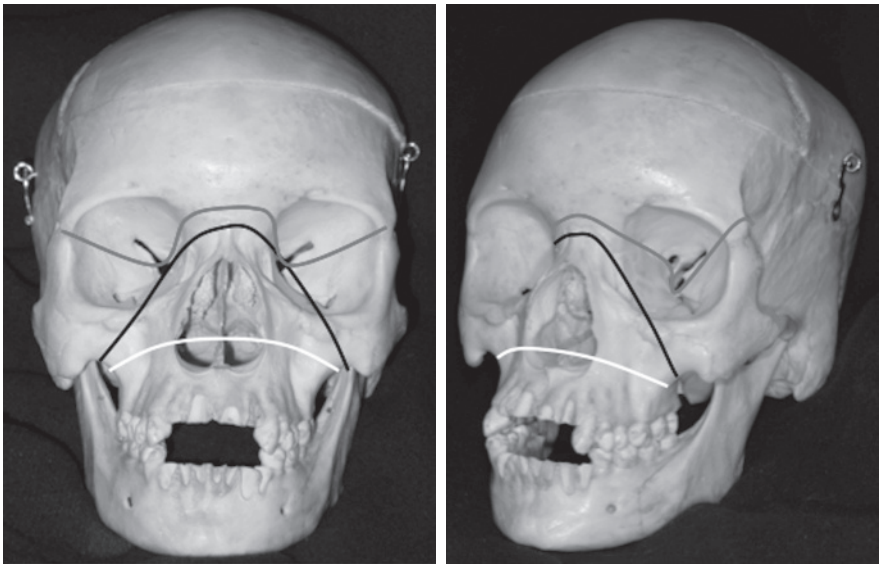

FIG. 3.8.11 Classification of Le Fort Fractures. Le Fort 1 *(white line)*, Le Fort 2 *(black line)* and Le Fort 3 (*red line).* (Courtesy of Associate Professor Alf Nastri, Department of Maxillofacial Surgery, Royal Melbourne Hospital.)

There are also established criteria for identifying patients with a low risk for cervical spine injury who do not require imaging, as derived from the NEXUS Study (National Emergency X-Radiography Utilization Study) (Table 3.8.6).[10] The NEXUS study found 818 spinal injuries out of 34,000 patients and identified patients as at low risk for cervical spine injury if all four high-risk clinical findings were absent. Study results were 99.6% sensitive for clinically important cervical spine injuries with a low specificity of only 12.9%.

The Canadian C-Spine Rule for radiography in alert and stable trauma patients[11] may be more valuable clinically and is well validated in a prospective cohort study (Table 3.8.7). This rule demonstrated 100% sensitivity and 42.5% specificity for clinically important cervical spine injuries, and there was good inter-observer agreement for each variable, with a κ value greater than 0.6 and a strong association with outcome (spinal injury $P < .05$).

These clinical decision rules should be applied with caution in the elderly, those with pre-existing spinal disease or the very young (<2 years). Owing to the relative immobility of the cervical spine or pre-existing spinal disease, such as ankylosing spondylitis, these patients may sustain cervical spine fractures even in the presence of a seemingly trivial injury.

If the cervical spine cannot be cleared clinically, then a radiological examination must be performed.

A CT scan of the cervical spine is the investigation of choice to exclude any bony injury to the cervical spine. MRI scan of the cervical spine will exclude any ligamentous, disc or cord injury.

Table 3.8.6 High-risk criteria for radiological clearance of the cervical spine in a multi-trauma patient (National Emergency X-radiography Utilization Study criteria)

Disturbed conscious state, e.g. head injury, intoxication for any reason
Any neurological motor or sensory signs
Midline cervical tenderness
Other major distracting injuries in a multi-trauma patient

There are some normal variants in children, which should be familiar to clinicians treating these patients. Any imaging of the cervical spine should include the cervico-thoracic junction, and most trauma radiologists will now image to the level of T3–T4 when performing a CT scan of the cervical spine.

Indications for MRI of the cervical spine include the following:

- Patients with complete or incomplete neurological deficit
- Deteriorating neurological status
- Suspected ligamentous or intervertebral disc injury

MRI will provide clear and concise images of all structures, particularly the spinal cord, intervertebral discs and soft tissues. Bone structures and bone oedema are also demonstrated, but fine bony detail is best seen on a CT scan. A range of different MRI sequences may be utilized in trauma patients to identify a number of spinal pathologies (Table 3.8.8). A MRI scan also provides information regarding spinal cord injury patterns, such as central cord syndrome, which have been previously unavailable with other imaging modalities (Fig. 3.8.12).

In the unconscious patient there is no role for dynamic flexion/extension films of the cervical spine when looking for evidence of ligamentous instability.

There remains some controversy regarding whether CT or MRI of the cervical spine is the investigation of choice to exclude ligamentous instability in the obtunded trauma patient. Some trauma surgeons[12] propose the use of a high-quality CT scan of the cervical spine to exclude a critically important unstable injury of the cervical spine in unconscious patients. However, they concede that the use of this approach may result in a non-zero rate of neurological deterioration. Limited MRI of the cervical spine is highly sensitive for the detection of ligamentous injury, disc and spinal cord oedema or haemorrhage, which is often not apparent on CT of the cervical spine. The use of MRI to clear the cervical spine in obtunded patients is now a standard of care in many trauma centres despite the lack of high-quality studies validating this approach (Fig. 3.8.13).

Thoraco-lumbar spine

The second most frequently injured area of the spinal column after the cervical spine is the TL junction (T11–L2). Cord injuries in this region comprise about 15% of all spinal cord injuries. The main reasons for the susceptibility of this vertebral region are the abrupt transition from the rigidly fixed thoracic spine to the more mobile lumbar spine and the fact that the spinal canal in the thoracic region is smaller in diameter than the cervical or lumbar spinal canals, resulting in increased risk to the spinal cord.

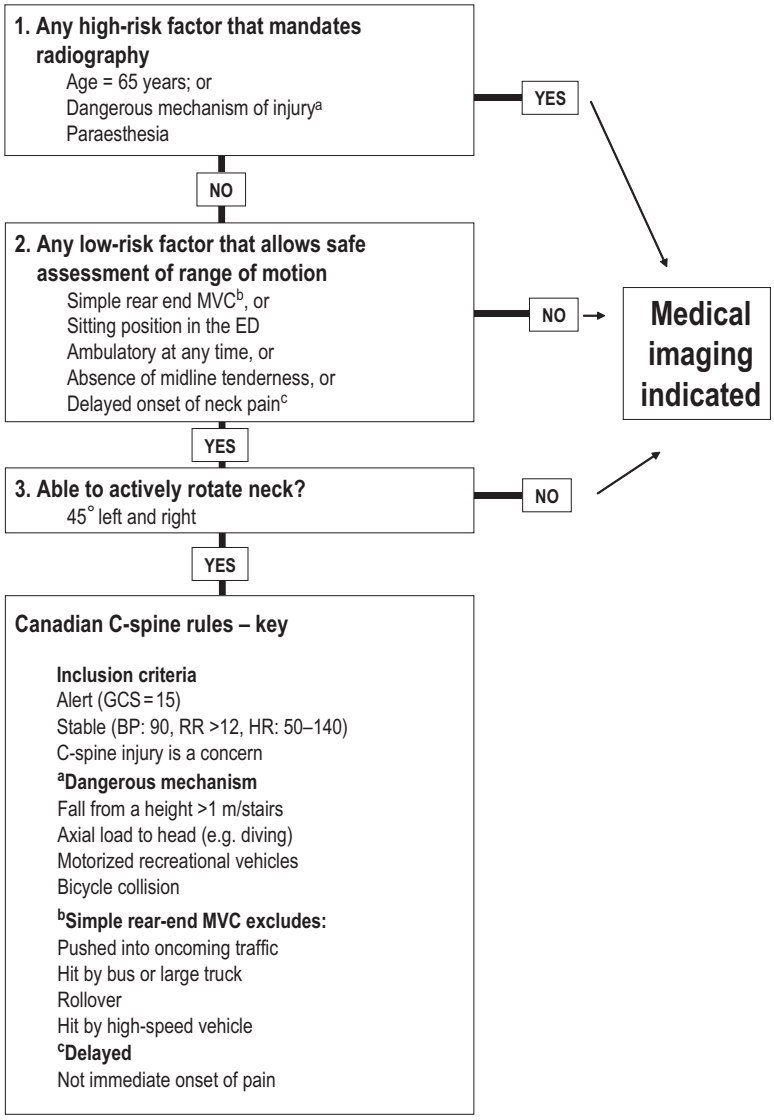
An important concept for interpreting TL injuries is the 'three-column' theory.[13] This widely accepted concept divides a vertebra into three columns:

- The anterior column, which consists of the anterior longitudinal ligament and the anterior half of the vertebral body
- The middle column, which includes the posterior half of the vertebral body and the posterior longitudinal ligament
- The posterior column, which includes all the bony and ligamentous structures posterior to the posterior longitudinal ligament

Fractures involving the anterior column are considered stable, whereas fractures involving the anterior and middle columns or all three columns are considered unstable.

It is also of note that injuries in the region from T1 to T10 comprise 16% of cord injuries and lumbosacral injuries, such as cauda equina lesions, and represent approximately 4% of spinal neurological injuries.

Table 3.8.7 The Canadian C-spine rule for alert (Glasgow Coma Scale score = 15) and stable trauma patients where cervical spine injury is a concern



GCS, Glasgow Coma Scale; *MVC*, Motor Vehicle Crash.
(Reproduced with permission from the Canadian CT Head and C-Spine (CCC) Study Group. Canadian C-spine rule study for alert and stable trauma patients: I. Background and rationale. *CJEM*. 2002;4(2):84–90.)

Table 3.8.8 Spinal abnormalities seen on magnetic resonance imaging

Spinal cord injury (haemorrhage or oedema)
Disc herniation
Epidural haematoma
Epidural abscess
Occult bone fracture/dislocation
Ligamentous rupture
Facet joint—disruption or capsular injury
Nerve root avulsion and plexus injury (brachial or lumbosacral)

Classification of thoraco-lumbar spine injuries

- Stable fractures, which include transverse process fractures, spinous process fractures, pars interarticularis fractures and wedge compression fractures involving the anterior two-thirds only of the vertebral body.
- Unstable fractures/dislocations, which include compression fractures with middle and/or posterior column disruption, the Chance or horizontal fracture (E-Fig. 3.8.7), the burst fracture (Fig. 3.8.14) (E-Fig. 3.8.8) and flexion/distraction injuries.

Fractures in a fused thoracic spine (ankylosing spondylitis, diffuse idiopathic skeletal hyperostosis [DISH] and advanced degenerative disc disease with bridging osteophytes) constitute a unique subset. Due to the rigidity of the spine, they are likened to a long bone fracture and may be called 'carrot stick' fractures (Fig. 3.8.15). These injuries are typically a result of hyperextension; they usually involve all three columns and are therefore unstable. Cord damage is common in this type of fracture.

If a patient is unable to be examined clinically because of pain or tenderness of the TL spine or is unconscious, this area must be imaged. If a CT scan of the chest and abdomen/pelvis is performed, then sagittal and coronal reconstructions of the TL spine can be done.

X-rays of the TL spine can be used in an attempt to identify bony injury in this area, but CT scan is the investigation of choice if there is clinical suspicion of bony injury.

The Chance fracture is an example of a distraction or seatbelt injury. This fracture is directed in a horizontal plane through the entire bony column—including vertebral body, pedicles, laminae and spinous processes—and is by definition unstable (Fig. 3.8.16). This fracture may also be associated with injuries to the abdominal contents (e.g. pancreas or duodenum).

Fractures of the lower lumbar spine and sacrum may involve the cauda equina and associated sacral nerve roots. There may be bladder, bowel and sexual dysfunction as well as variable motor and sensory deficits in the lower limbs. There is often significant neuralgia that is disabling and may be difficult to treat. CT and MRI scans are required for definitive information if surgical fixation is required.

Coccygeal fractures are due to direct blows and are both treated and diagnosed clinically (Fig. 3.8.17).

Chest trauma

The CXR still has a key role in the investigation of multiple trauma involving the thorax. The CT chest and CTA with intravenous contrast are the investigations of choice to rule out most chest injuries associated with major trauma. A CXR will provide rapid information about the presence pneumothorax, haemothorax, mediastinal widening and fractures of the sternum and/or ribs. An extended focused assessment with sonography in trauma (eFAST) examination will also provide information about pneumothorax (absence of lung sliding), haemothorax (hypoechoic fluid) and pericardial blood or effusion.

Small pneumothoraces and haemothoraces are also difficult to detect on the supine CXR because the air distributes as a thin film anteriorly and blood as a thin homogeneous layer posteriorly. A haemothorax of 200 to 300 mL will normally be visible on a good-quality erect CXR, whereas it will usually require 800 to 1000 mL to produce the 'fuzzy' appearance of a haemothorax seen on the supine CXR.[14]

Examination of the CXR will often begin with a review of the bones and soft tissues. The CXR

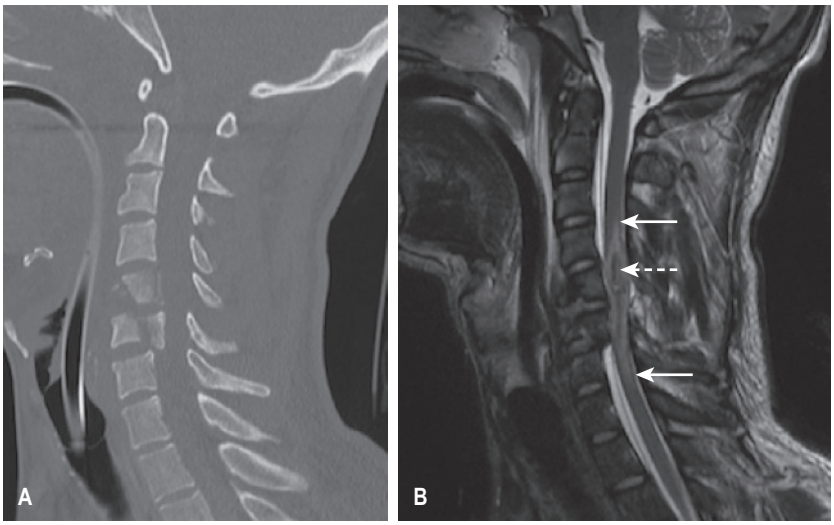


FIG. 3.8.12 Cord Contusion. (A) Sagittal computed tomography of the cervical spine shows fractures of the C5 and C6 vertebral bodies, with associated retropulsion. (B) Sagittal T2-weighted magnetic resonance imaging demonstrates a cord contusion extending from C4 to C7 *(solid arrows)* and a focus of haemorrhage within the cord at C5 *(dashed arrow)*.

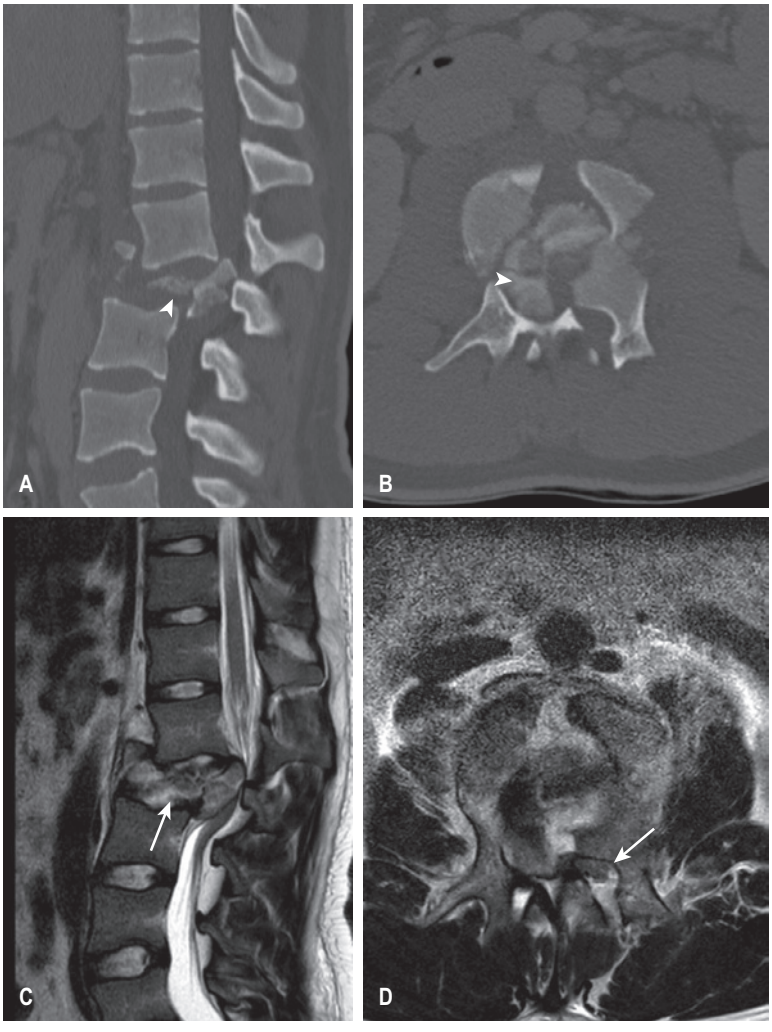

FIG. 3.8.13 Sagittal and axial Computed Tomography (A, B) and T2-weighted Magnetic Resonance Imaging (C,D) sequences of the thoracolumbar spine demonstrating a burst fracture *(white arrow heads)* with retropulsed fragments completely effacing the spinal canal. The cauda equina is compressed and displaced towards the left *(long white arrow)*.

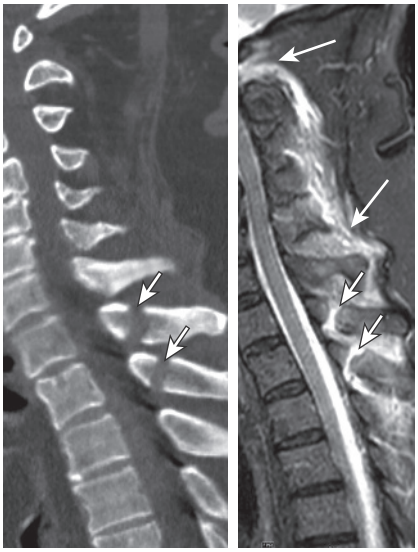

FIG. 3.8.14 Sagittal computed tomography and sagittal fluid-sensitive magnetic resonance imaging (MRI) of the cervical spine demonstrating multiple spinous process fractures *(short arrows)*. MRI better demonstrates extensive ligamentous injury involving the atlanto-occipital membrane, interspinous ligaments, supraspinous ligaments and ligamentum nuchae *(long arrows)*.

is a poor diagnostic aid for rib fractures, as it will miss up to 50% of anterior and lateral fractures; instead, the assessment should be directed more towards the complications of rib fractures, such as pneumothorax, haemothorax and lung contusion. It is also important to remember that the clavicles, glenohumeral joints and scapulae are visible on the CXR (E-Fig. 3.8.9). Fractures of these bones, along with fractures of the first and second ribs, are indicators of significant blunt thoracic trauma and should prompt a careful examination for underlying visceral and vascular injuries.

Sternal fractures are best seen on CT. The significance of sternal fractures will largely direct the examination towards underlying mediastinal injuries.

Subcutaneous emphysema may be seen on the CXR and may result from injury to the lung, the tracheobronchial tree, the larynx, pharynx and oesophagus (see Fig. 3.8.3). Subcutaneous emphysema should prompt a careful examination for evidence of a pneumothorax and pneumomediastinum. Subcutaneous emphysema and pneumothorax are common findings in traumatic injury to the lung and also occur in tracheobronchial injury.

The lung parenchyma may become opacified by contusion, aspiration, pulmonary fat embolism and either cardiogenic or non-cardiogenic pulmonary oedema. Rib fractures are frequently associated with pulmonary contusions, although the ribs are more compliant in paediatric patients and young adults, resulting in lung contusion without fracture.

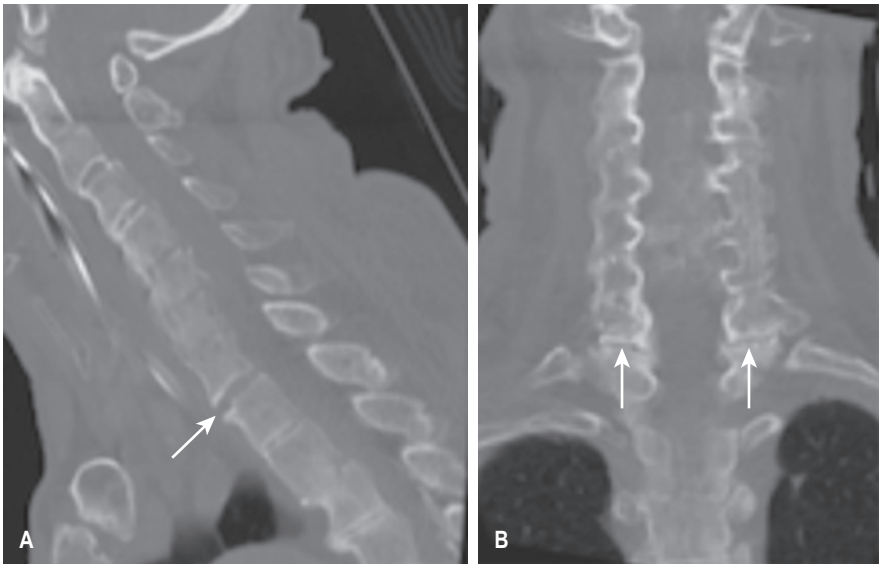

FIG. 3.8.15 Fractures through a fused spine (long white arrows) in A (sagittal) and B (coronal) Computed Tomography views of the cervical spine are called 'carrot stick' fractures because they traverse the entire width of the vertebral column (like breaking a carrot). Note that 'DISH' refers to 'diffuse idiopathic skeletal hyperostosis'.

FIG. 3.8.16 Sagittal computed tomography of the thoracolumbar spine demonstrating a flexion-distraction injury extending horizontally through the superior aspect of T12 with widening of the intervertebral disc space and increased distance between the spinous processes due to disco-ligamentous disruption.

Diaphragmatic injuries are more frequent in penetrating than in blunt trauma. In blunt trauma, however, 80% of diaphragmatic injuries occur on the left side because the liver and its ligamentous attachments protect the right side (Table 3.8.9).

If a nasogastric tube is in situ, it may be seen to pass down into the abdomen and back up into the chest contained within the herniated stomach. Lower rib fractures are often seen in association with injuries to the diaphragm.

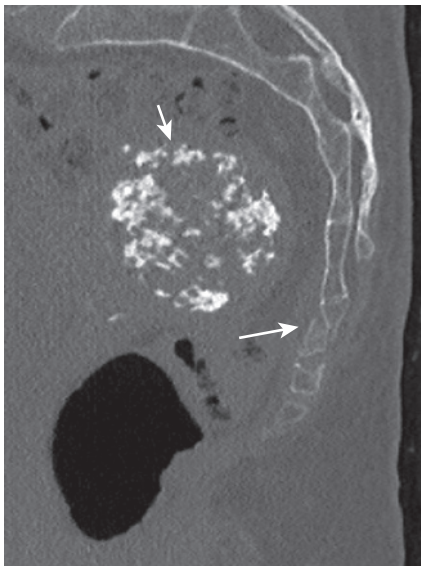

FIG. 3.8.17 Sagittal computed tomography of the sacrum and coccyx shows a minimally displaced fracture of the coccyx *(long arrow)*. A calcified uterine fibroid is incidentally noted *(short arrow)*.

Thoracic aortic injury

Ninety per cent of traumatic aortic injuries (TAIs) occur in the region of the aortic isthmus (i.e. that part of the proximal descending aorta between the origin of the left subclavian artery and the site of attachment of the ligamentum arteriosum [1.5 cm in length]). The ascending aorta is involved in only 5% of cases.

The mediastinal width is measured at the top of the aortic knob. A width greater than 8.0 to 8.5 cm in a supine film or 6 cm in an erect film is suggestive of a mediastinal haematoma (Fig. 3.8.18).

Table 3.8.9 Signs of diaphragmatic injury on chest x-ray

Elevated hemidiaphragm
Abnormal or indistinct contour of the diaphragm
Collapse of the lower lung fields
Inhomogeneous mass in the relevant hemithorax
Displacement of the mediastinum away from the injury

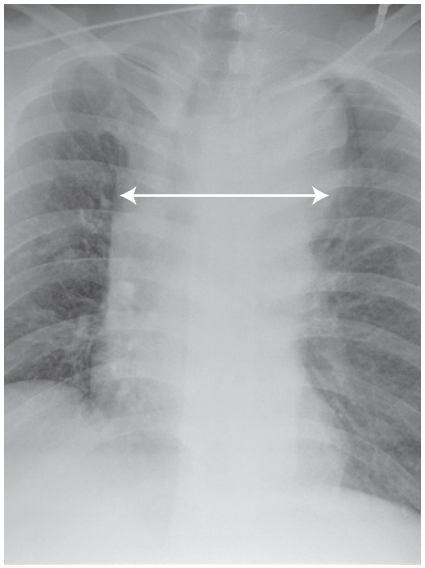

FIG. 3.8.18 Plain radiograph of the chest following an aortic transection. Note the marked widening of the superior mediastinum *(long white arrow)* and loss of the normal contours of the aorta.

The sensitivity of a widened mediastinum on CXR for the detection of thoracic aortic injuries has been estimated at 90% and the specificity at 10%, but approximately 7% of patients with aortic rupture have normal chest radiographs (Table 3.8.10).[15]

Injuries to the oesophagus are uncommon; they may occur in association with both blunt and penetrating chest trauma. The predominant x-ray finding in oesophageal injury is pneumomediastinum, which may be associated with subcutaneous emphysema, pneumothorax, a left pleural effusion or a widened mediastinum.

Thoracic computed tomography scan

Thoracic CT has become a common diagnostic aid in investigating the multitrauma patient with chest injuries.

Chest CT is also a sensitive test for detecting rib fractures, pneumothorax, pneumomediastinum, mediastinal haematoma, pulmonary contusion, haemothorax. With intravenous contrast, it may demonstrate an intimal tear or pseudoaneurysm of the traumatized aorta (Fig. 3.8.19).

Table 3.8.10 Splenic injury scale

Grade	*Type of injury*	*Description of injury*
I	Haematoma	Subcapsular: <10% surface area
	Laceration	Capsular tear: <1 cm parenchymal depth
II	Haematoma Laceration	Subcapsular: 10%–50% surface area; intraparenchymal, <5 cm in diameter Capsular tear: 1–3 cm parenchymal depth that does not involve a trabecular vessel
III	Haematoma Laceration	Subcapsular: >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma ≥5 cm or expanding >3 cm parenchymal depth or involving trabecular vessels
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)
V	Laceration Vascular	Completely shattered spleen Hilar vascular injury devascularizing the spleen

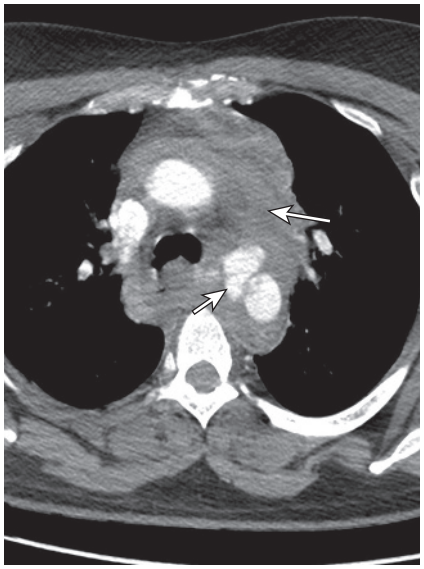

FIG. 3.8.19 Axial post-contrast computed tomography following aortic transection with a mediastinal haematoma *(long white arrow)* and active contrast extravasation from the thoracic aorta *(short white arrow)*.

If mediastinal major vascular injury is initially suspected, CTA is the investigation of choice, and most of these images are managed with an endovascular stent.

Oral contrast studies

Oral contrast provides useful information in the investigation and diagnosis of oesophageal and diaphragmatic injuries. In cases of oesophageal perforation, diatrizoate (Gastrografin) is the preferred contrast medium as it is less irritating than barium should there be a leak into the surrounding mediastinal tissues.

A CT swallow study can also be performed. This would involve a non-contrast (control) study of the chest and upper abdomen, followed by a second study after the ingestion of oral contrast. In unconscious patients, a nasogastric tube is placed with its tip in the upper oesophagus, and oral contrast is administered via this tube.

Flexible or rigid oesophagoscopy may also be used to exclude oesophageal perforation.

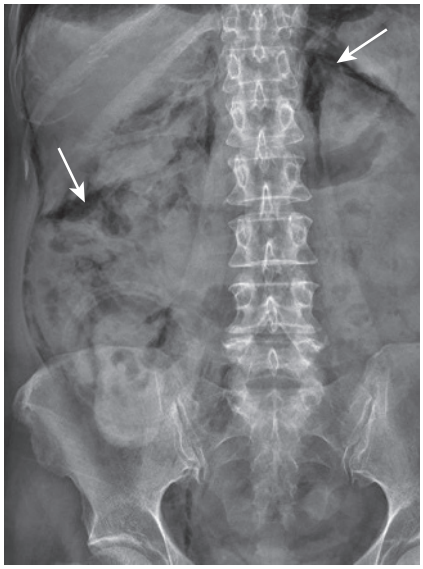

FIG. 3.8.20 Plain radiograph of the abdomen demonstrating retroperitoneal gas following injury to the duodenum *(long arrows)*.

Abdomen/pelvis

The role of the plain abdominal x-ray (AXR) in the investigation of abdominal trauma is extremely limited (Fig. 3.8.20). A CXR may be more useful for the detection of free air under the diaphragm in the rupture of a hollow viscus or pneumoperitoneum (Fig. 3.8.21).

Abdominal computed tomography scan

Abdominal CT is usually performed with both oral and intravenous contrast. However, as most multitrauma patients have delayed gastric emptying, the bulk of the oral contrast tends to remain in the stomach and upper gastrointestinal tract. This phenomenon has led some authors to suggest that oral contrast is of little use in this setting.[16] The increased speed of the helical CT scanner has resulted in excellent resolution for the detection of vascular injuries involving the liver, spleen and kidneys after intravenous contrast. The American Association for the Surgery of Trauma (AAST) has developed a scoring system that grades the severity of injury to the solid intra-abdominal viscera, including the spleen, liver, kidney, adrenal gland and pancreas (Tables 3.8.10–3.8.14).[17]

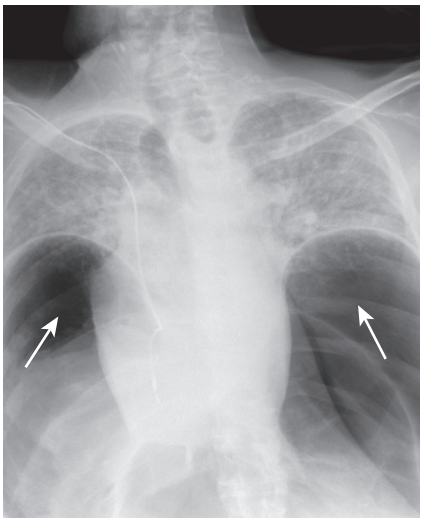

FIG. 3.8.21 Chest radiograph demonstrating a large volume of free intraperitoneal gas *(arrows)*, with marked diaphragmatic elevation indicating a rare tension pneumoperitoneum.

In stable patients with possible intra-abdominal injuries, the abdominal CT has become the investigation of choice because, as well as being non-invasive, it reliably identifies intraperitoneal fluid, solid organ and hollow visceral injury, retroperitoneal injuries and spinal and pelvic fractures (Figs 3.8.22–3.8.24). The use of intravenous contrast will also give some indication of both renal perfusion and function as contrast is excreted into the ureters and bladder. One of the main limitations of abdominal CT is that the investigation must be carried out in the radiology department and so is inappropriate for any unstable patient. Injuries that may be identified on abdominal CT include upper intestinal perforation as well as injury to the diaphragm, pancreas and bladder (Figs 3.8.25 and 3.8.26).

Visceral angiography and embolization

In haemodynamically stable patients, solid visceral injuries may be treated conservatively. In haemodynamically unstable patients with solid intra-abdominal visceral injuries and active bleeding, either surgical or endovascular management could be considered in centres where both interventions are available. Embolization agents may be classified as temporary or permanent. Permanent agents include metallic coils, glue and

embolization particles, whereas gelatin sponge (Gelfoam) is a temporary agent. Gelatin sponges can stop active bleeding long enough to enable recanalization of the embolized vessel. The spleen and kidneys are the most commonly embolized viscera after trauma (E-Figs 3.8.10 and 3.8.11).

Pelvic trauma

In addition to plain radiology, pelvic CT scanning and CTA are becoming increasingly important in the diagnostic and therapeutic workup of pelvic trauma. The trauma room AP x-ray of the pelvis should include all the bony pelvic components as well as both hip joints and the proximal femora, including the greater and lesser trochanters.

Most anterior pelvic fractures are seen on the AP film, but up to 30% of posterior fractures involving the sacrum and sacroiliac joints will not be seen on plain radiology. These fractures will be best seen on a two-dimensional or reformatted three-dimensional CT of the pelvis.

Acetabular fractures are often difficult to visualize on AP views and a CT of the pelvis may be required (Fig. 3.8.27).

There are a number of radiological classifications of pelvic fractures that must be interpreted in association with the clinical impression of the fracture and the associated complications. The greater the AP disruption of the pelvic ring and the larger the volume of the pelvic cavity, the greater the potential for severe haemorrhagic shock and visceral damage.

A useful classification is that of Young and Resnik (Table 3.8.15), which is a modification of the Pennel and Tile classification of pelvic fractures.[18]

This classifies fractures by mechanism of injury into AP compression, lateral compression, vertical shear and a combination and takes into consideration rotational and/or vertical instability of the pelvic ring [E-Figs 3.8.12 and 3.8.13]. If the pelvic ring is fractured anteriorly and posteriorly, stability is usually lost, with disruption of the posterior ligaments (sacroiliac, sacrotuberous and sacrospinous), and there will be widening of the sacroiliac joint or joints on the AP view. This classification provides a graded probability of bleeding related to the fracture, the development of haemorrhagic shock and associated organ damage.

Table 3.8.11 Liver injury scale

Grade	*Type of injury*	*Description of injury*
I	Haematoma	Subcapsular: <10% surface area
	Laceration	Capsular tear: <1 cm parenchymal depth
II	Haematoma	Subcapsular: 10%–50% surface area; intraparenchymal <10 cm in diameter
	Laceration	Capsular tear 1–3 cm parenchymal depth, <10 cm in length
III	Haematoma	Subcapsular: >50% surface area of ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma >10 cm or expanding
	Laceration	>3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25%–75% hepatic lobe or 1–3 Couinaud segments
V	Laceration	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe
	Vascular	Juxtahepatic venous injuries; i.e. retrohepatic vena cava/central major hepatic veins
VI	Vascular	Hepatic avulsion

Table 3.8.12 Kidney injury scale

Grade	*Type of injury*	*Description of injury*
I	Contusion	Microscopic or gross haematuria, urological studies normal
	Haematoma	Subcapsular: non-expanding without parenchymal laceration
II	Haematoma	Non-expanding perirenal haematoma confined to renal retroperitoneum
	Laceration	<1.0 cm parenchymal depth of renal cortex without urinary extravasation
III	Laceration	<1.0 cm parenchymal depth of renal cortex without collecting system rupture or urinary extravasation
	Laceration	Parenchymal laceration extending through renal cortex, medulla and collecting system
IV	Vascular	Main renal artery or vein injury with contained haemorrhage
V	Laceration	Completely shattered kidney
	Vascular	Avulsion of renal hilum devascularizing the kidney

Computed tomography scan of the pelvis

Computed Tomography (CT) and plain radiography are complementary modalities in the evaluation of pelvic fractures. Patients with pelvic fractures associated with haemodynamic instability are usually not safe to place in the CT Scanner.

In stable patients, CT is useful for demonstrating posterior fractures involving the sacrum and sacroiliac joints as well as sacroiliac joint diastasis. Reformatted three-dimensional images

Table 3.8.13 Adrenal injury scale

Grade	*Description of injury*
I	Contusion
II	Laceration involving only cortex (<2 cm)
III	Laceration extending into medulla (≥2 cm)
IV	>50% parenchymal destruction
V	Total parenchymal destruction (including massive intraparenchymal haemorrhage) Avulsion from blood supply

Table 3.8.14 Pancreas injury scale

Grade	*Type of injury*	*Description of Injury*
I	Haematoma	Minor contusion without duct injury
	Laceration	Superficial laceration without duct injury
II	Haematoma	Major contusion without duct injury or tissue loss
	Laceration	Major laceration without duct injury or tissue loss
III	Laceration	Distal transection or parenchymal injury with duct injury
IV	Laceration	Proximal transection or parenchymal injury involving ampulla
V	Laceration	Massive disruption of pancreatic head

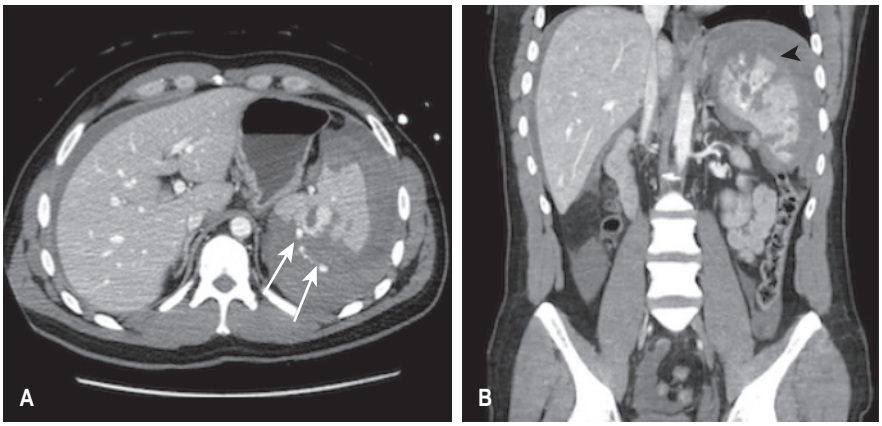

FIG. 3.8.22 Axial (A) and Coronal (B) Computed Tomography images of the abdomen demonstrating a shattered spleen with active bleeding (white arrows) and a large Grade 5 splenic haematoma (black arrow head)".

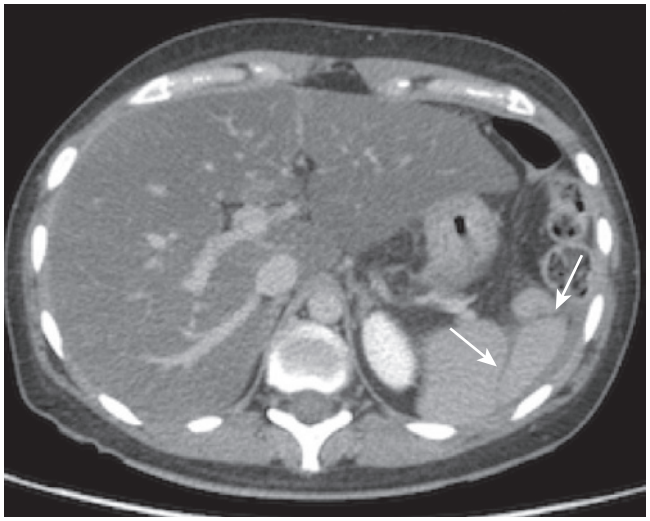

FIG. 3.8.23 Grade III splenic lacerations *(arrows).*

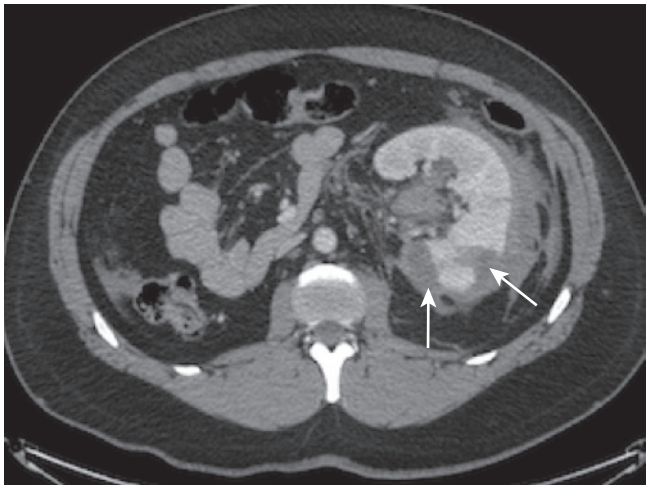

FIG. 3.8.24 Grade IV renal laceration *(arrows)* with surrounding perinephric haematoma.

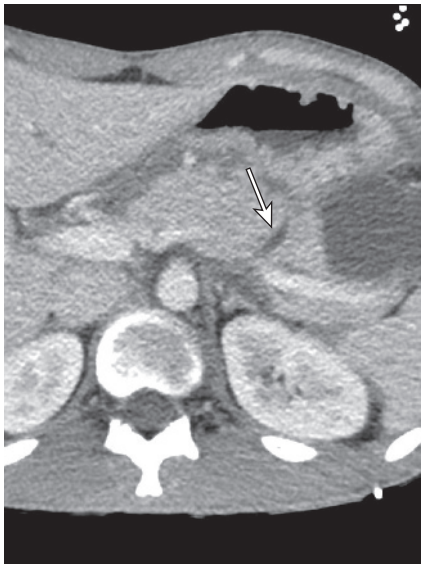

FIG. 3.8.25 Axial post-contrast computed tomography of the abdomen demonstrating a laceration of the pancreas *(arrow).*

FIG. 3.8.26 Following blunt abdominal trauma, axial computed tomography of the abdomen demonstrates contusion and laceration of the duodeno-jejunal flexure *(long white arrow).* Note the subtle alteration of density in the bowel wall at the site of injury. Also note the associated fluid in the retroperitoneum *(short white arrow)*

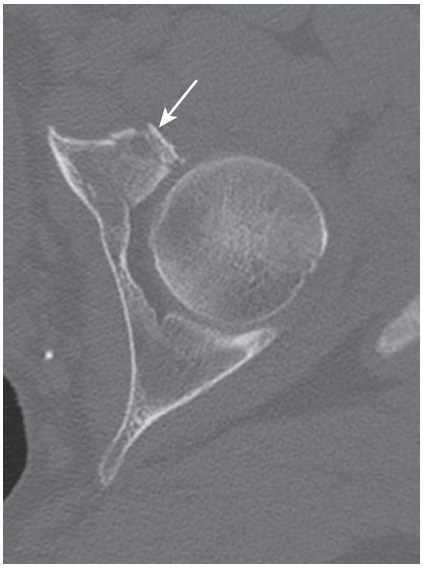

FIG. 3.8.27 Axial computed tomography of the left hip demonstrating a comminuted minimally displaced fracture of the anterior aspect of the acetabulum *(arrow)*, which was not appreciable on plain radiographs.

Table 3.8.15 Young and Resnick classification of pelvic fractures

Antero-posterior compression
Type 1: Disruption of the symphysis pubis with less than 2.5 cm diastasis; no significant posterior pelvic injury
Type 2: Disruption of the symphysis pubis of more than 2.5 cm with tearing of the anterior sacroiliac, sacrospinous and sacrotuberous ligaments
Type 3: Complete disruption of the pubic symphysis and posterior ligament complexes with hemipelvic displacement
Lateral compression
Type 1: Posterior compression of the sacroiliac joint without ligament disruption; fracture of the oblique pubic ramus
Type 2: Rupture of the posterior sacroiliac ligament; pivotal internal rotation of the hemipelvis on the anterior sacroiliac joint with a crush injury of the sacrum and an oblique pubic ramus fracture
Type 3: Findings as in type 2 injury with evidence of an antero-posterior compression injury to the contralateral hemipelvis
Vertical shear
Complete ligament or bony disruption of a hemipelvis associated with hemipelvis displacement

This classification does not take into consideration isolated fractures outside the bony pelvic ring or acetabular fractures

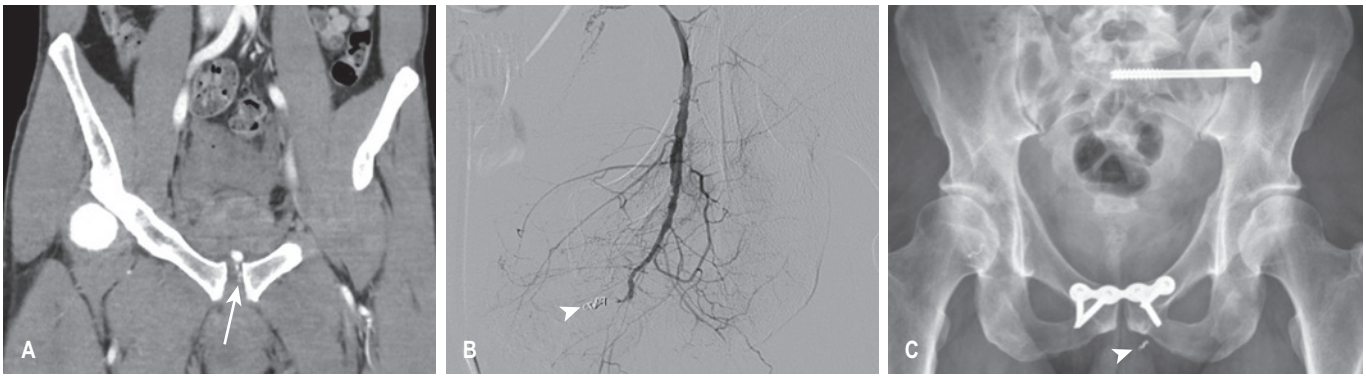

FIG. 3.8.28 (A) Coronal computed tomography demonstrating contrast extravasation, indicative of active bleeding adjacent to the pubic symphysis and complicating pubic symphysis diastasis *(long arrow)*. (B) Invasive angiogram with catheterization of the left internal iliac artery and deployed micro-coils in a pelvic branch *(arrowhead)*. (C) Radiograph following internal fixation of the pubic symphysis and left sacroiliac joint, showing embolic coil material *(arrowhead)*.

are particularly useful for the assessment of acetabular and pubic bone fractures.

The speed and definition of Multi-detector Computed Tomography MDCT scanners have meant that contrast-enhanced MDCT is a highly accurate, non-invasive way of identifying ongoing arterial bleeding; improved localization of the bleeding point can then direct the interventional radiologist for embolization or coil placement (Fig. 3.8.28).

Urological injuries

The main contrast studies used in pelvic fractures are the urethrogram and the cystogram. Rupture of the membranous urethra may occur in association with pelvic fractures, particularly those involving distraction of the pubic symphysis or fractures of both the superior and inferior pubic rami. If there is clinical and radiological suspicion of potential urethral damage, a urethrogram should be performed (Fig. 3.8.29). If there is obstruction to the passage of dye or a false track is identified, a suprapubic catheter will be required. After further contrast is injected into the bladder, PA and oblique x-rays or CT scans can be performed to assess for extravasation of contrast suggesting bladder rupture. A grade 4 renal injury with contrast extravasation is demonstrated in Fig. 3.8.30.

Extremity injury

Missed injuries occur in about 2% to 6% of patients with blunt trauma. One retrospective study[19] found that musculoskeletal injuries and spinal fractures featured highly (6%) among the injuries not found after the initial primary and secondary surveys. The musculoskeletal injuries comprised mainly fractures and a small number of soft tissue injuries.

A careful clinical examination of all joints and limbs looking for swelling, deformity and crepitus must be made in order to direct radiological investigation. Fractures, dislocations and ligamentous instability are more likely to be missed in the smaller, peripheral bones. It is important that these injuries be diagnosed, as they may lead to ongoing disability due to late diagnosis and then constitute a potential source of litigation. Dislocations of joints, such as those of the anterior shoulder and elbow, should be readily obvious, but less so are posterior shoulder (Fig. 3.8.31) and lunate/perilunate dislocation in the wrist (Fig. 3.8.32).

FIG. 3.8.29 Coronal computed tomography of the pelvis with contrast injected via an in-dwelling catheter demonstrates extravasation *(long arrow)* from the bladder into the extra-peritoneal space, complicating multiple pelvic fractures *(short arrows)*.

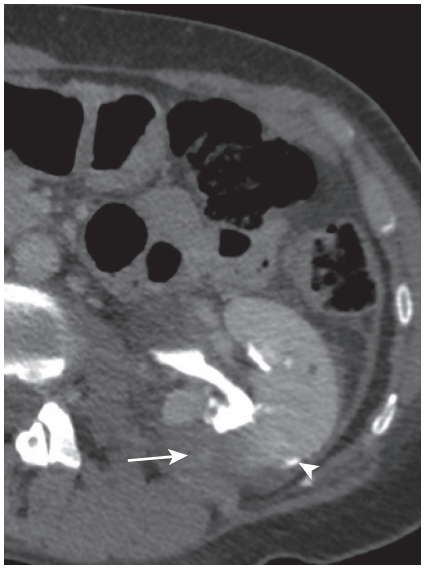

FIG. 3.8.30 Axial delayed-phase post-contrast computed tomography demonstrating a left renal laceration *(arrow)* with extension to the collecting system. Note the extravasated contrast from the collecting system pooling in the peri-renal space posteriorly *(arrowhead)*, indicating grade IV injury.

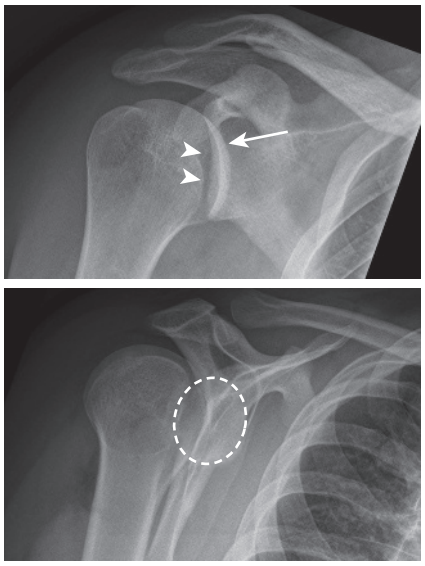

FIG. 3.8.31 Post Dislocation of the Right Shoulder. Antero-posterior (AP) and lateral radiographs demonstrating a posterior dislocation of the right shoulder. Note that the humeral head overlaps abnormally with the glenoid on the AP projection *(long arrow)*. A trough sign is noted, indicating a reverse Hill-Sachs impaction fracture *(arrowheads)*. The humeral head is posterior to the glenoid *(dotted circle)* on the lateral projection.

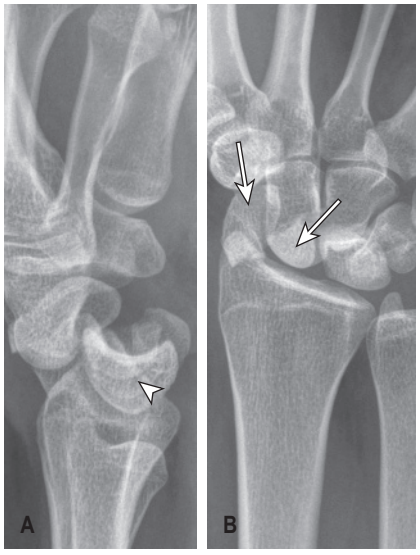

FIG. 3.8.32 Lateral (A) and frontal (B) radiographs of the wrist demonstrate a fracture of the scaphoid *(arrows on fragments)* and transcaphoid perilunate dislocation. Note that the lunate remains congruent with the radius and ulna *(arrowhead)*, differentiating this injury from a lunate dislocation.

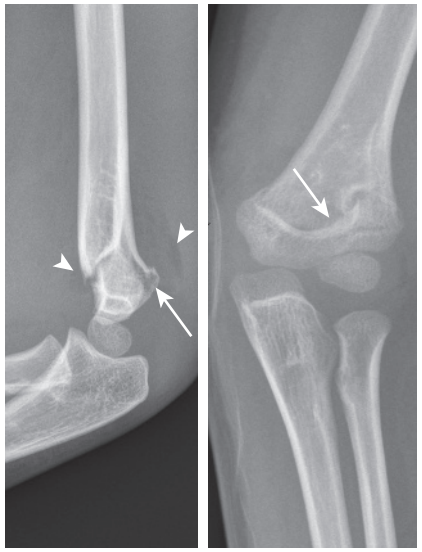

FIG. 3.8.33 Lateral and antero-posterior radiographs of the elbow in a child demonstrating a posteriorly angulated supracondylar fracture *(long arrows)* with a large elbow joint effusion resulting in fat pad displacement *(arrowheads)*.

FIG. 3.8.34 Coronal reconstruction from a computed tomogram of the wrist demonstrating a minimally displaced fracture of the triquetrum *(long white arrow)*.

Bony fractures in the upper limb that are commonly missed include medial or lateral epicondylar fractures and supracondylar fractures of the elbow in children (Fig. 3.8.33). In the adult, fractures of the carpal bones, in particular the scaphoid and triquetrum (Fig. 3.8.34), may be missed unless carefully looked for, and these injuries may result in significant disability.

In the lower limb, posterior dislocation of the hip and knee joints may cause serious sciatic nerve and popliteal artery damage, respectively; such injuries require urgent reduction. In the lower limb, fractures of the tibial plateau (Fig. 3.8.35), talus (Fig. 3.8.36) and calcaneus, which may occur as a result of a fall, may be missed unless sought both clinically and radiologically.

Appropriate AP and lateral x-rays should be taken of these areas. In the foot, loss of the Boehler angle (normal 25 to 40 degrees) may indicate a depressed fracture of the subtalar part of the calcaneus (Fig. 3.8.37). Falls and calcaneal

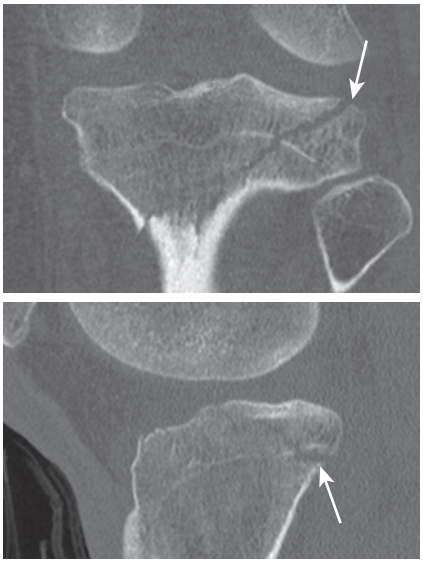

FIG. 3.8.35 Coronal and sagittal reconstruction from a computed tomogram of the knee demonstrating a non-displaced fracture of the lateral tibial plateau *(long arrows)*.

FIG. 3.8.36 Sagittal computed tomography of the ankle demonstrating a non-displaced fracture of the talus *(white arrow)*, which was poorly delineated on plain radiography.

FIG. 3.8.37 Calcaneal fracture with loss of Bohler angle (posterior angle of crossed white lines).

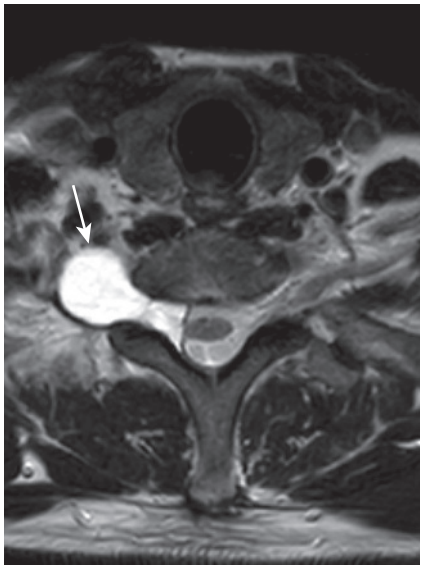

FIG. 3.8.38 Brachial Plexus Injury. Axial T2-weighted magnetic resonance imaging of the cervical spine shows a pseudomeningocoele *(arrow)* resulting from nerve root avulsion.

fractures may be associated with fractures of the upper lumbar spine.

Angiography is required when there is suspected or clinically obvious vascular compromise to an upper or lower limb. The brachial plexus (Fig. 3.8.38) can also be damaged in trauma around the shoulder joint, and MRI is the investigation of choice in order to confirm the diagnosis. The commonest serious vascular injury to the lower limb may be associated with posterior dislocation of the knee and intimal disruption of the popliteal artery. Angiography will give accurate information regarding the degree of arterial damage and the state of the collateral flow.

Conclusion

Radiology in the multi-trauma patient requires judicious decision making and interpretation of x-rays and other specialized modalities, such as CT and MRI. Currently there is less reliance on plain x-rays and more emphasis on CT or MRI scans to rule in or out serious injury in the head, spine, chest, abdomen and pelvis. Radiation exposure should be considered and limited as much as possible for all imaging involving ionizing radiation, especially with regard to CT scans in younger trauma patients.

CONTROVERSIES

- A trauma pan scan involving head, cervical spine and then chest/abdomen/pelvis pre- and post-intravenous contrast with thoraco-lumbar reconstruction is the investigation of choice in the undifferentiated multi-trauma patient.
- Clearance of the cervical spine in obtunded trauma patients is controversial. Some centres clear on the basis of a normal CT of the cervical spine, whereas most others will continue spinal precautions until MRI of the spine can rule out ligamentous disruption, an acute disc prolapse, bony oedema associated with occult fractures and spinal cord injury, which can be transection, haemorrhage or oedema.
- CTA is the investigation of choice in the investigation of BCVI to the neck.
- Chest CT with CT angiography is the investigation of choice to exclude significant intrathoracic injury including traumatic aortic injury.
- Pelvic angiography and embolization should be part of the resuscitation protocol in haemodynamically unstable patients with major pelvic fractures.

3.9 Trauma in pregnancy

Steven Troupakis

ESSENTIALS

1 **Trauma in pregnancy is the most common cause of non-obstetric maternal death, with most deaths due to head injury and haemorrhagic shock.**

2 **Fetal death occurs more often than maternal death and is dependent on the severity of the maternal injuries. Placental abruption and direct fetal trauma cause most fetal deaths.**

3 **Common causes of trauma are motor vehicle collisions, falls and assaults.**

4 **Important sequelae are bruising, fractures, premature labour, placental abruption, disseminated intravascular coagulopathy, feto-maternal haemorrhage, intra-abdominal injuries, uterine rupture and haemorrhagic shock.**

5 **The physiological changes that occur with pregnancy, such as the relative hypervolaemia and the gravid uterus, can make clinical assessment of the patient difficult.**

6 **Continuous cardio-tocographic monitoring for at least 4 hours is the best predictor of placental abruption and fetal distress.**

7 **Bedside ultrasound allows the early detection of intraperitoneal fluid and evaluation of the fetal heart.**

8 **Maternal resuscitation remains the best method of fetal resuscitation.**

Introduction

Trauma during pregnancy presents a unique set of challenges for the emergency department (ED), as the anatomical and physiological changes that occur during pregnancy will influence the evaluation and management of the patient. An appreciation of these changes is important. Aggressive resuscitation of the mother remains the best treatment for the fetus. A multidisciplinary approach with early obstetric consultation will help to improve the outcomes of these patients.

Anatomical and physiological changes in pregnancy

Cardiovascular

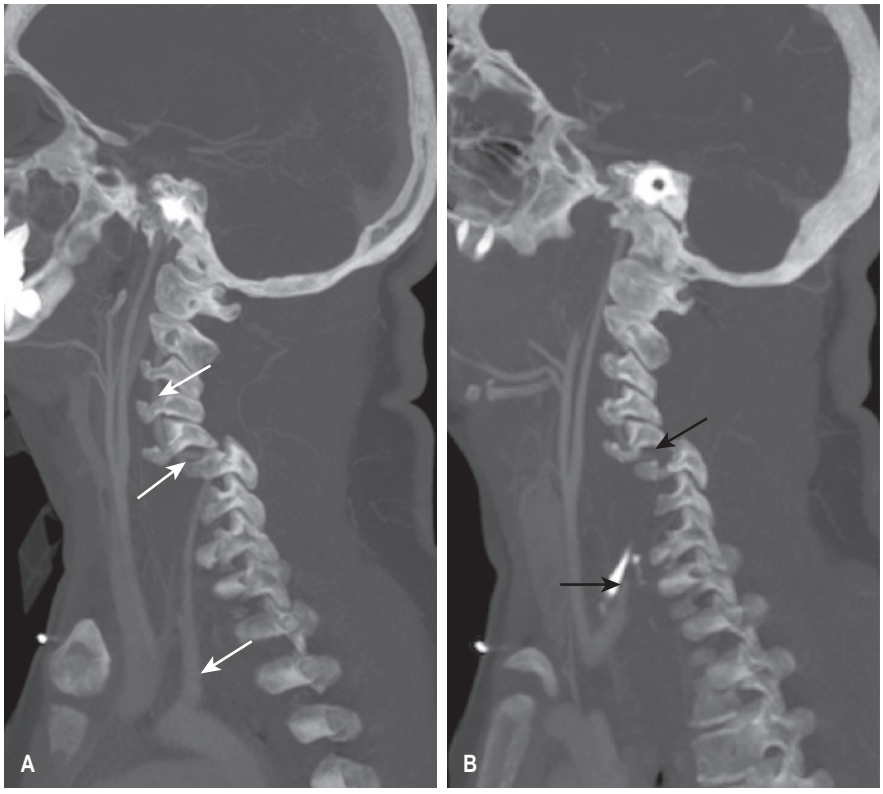
Blood volume increases by about 50% by the end of the third trimester.[1] With relative hypervolaemia, the patient may lose up to 35% of her blood volume before signs of haemorrhagic shock appear. Maternal cardiac output increases by 30% to 50% by the end of the second trimester. The resting heart rate increases by 15 to 20 beats/min by the end of the third trimester. Systolic and diastolic blood pressures fall by 10 to 15 mmHg during the second trimester but rise again towards the end of the pregnancy. Electrocardiographic (ECG) changes may occur with cephalic displacement of the heart, such as left axis deviation by 15 degrees, T-wave inversion or flattening in leads III, V1 and V2 and Q waves in III and AVF.[1] After 20 weeks' gestation, supine positioning may cause inferior vena cava (IVC) obstruction by the gravid uterus, leading to a fall in cardiac output.

Haematological

Blood volume expands by about 1500 mL during pregnancy, of which 1000 mL is plasma volume and 500 mL is erythrocytes.[2] This results in a dilutional anaemia with a fall in haematocrit (31% to 35% by the end of pregnancy). Pregnancy induces a leucocytosis, with levels up to 18,000/mm^3 in the third trimester. Coagulation factors increase (fibrinogen, factors VII, VIII, IX, X), increasing the risk of venous thrombosis. The buffering capacity of the blood is reduced.[3]

Respiratory

There is increased airway oedema.[2] The diaphragm is elevated by about 4 cm. Increased levels of progesterone stimulate the medullary respiratory centre.[4] Tidal volume and minute volume increase by 40%. A respiratory alkalosis results, with a fall in PCO_2 to 30 mmHg. The anteroposterior diameter of the chest is increased and the mediastinum is widened on chest x-ray.



E-FIG. 3.8.1 Vertebral Artery Dissection. Maximal intensity projection images of a computed tomography angiogram in a patient with bilateral C5–C6 facet dislocation. (A) Image demonstrating the abnormal course of the left vertebral artery due to the dislocation *(white arrows)*. E-FIG. 3.8.11 Right renal angiogram demonstrating active bleeding from the inferior pole (*arrows* in A and B). (C and D) Image showing successful embolization using particles.

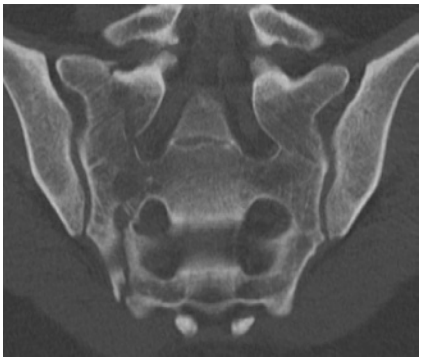
E-FIG. 3.8.12 Vertical Shear Injury. There is asymmetry of the heights of the iliac crest due to a vertical shear fracture of the right side of the sacrum. There are also bilateral fractures of the superior and inferior pubic rami.



E-FIG. 3.8.13 Vertical shear sacral fracture corresponding to the same patient as Fig. 3.8.24. The computed tomography scan better delineates the sacral fracture, which can be difficult to visualize on plain film.

Gastrointestinal

Cephalic displacement of intra-abdominal structures reduces gastro-oesophageal sphincter tone; combined with delayed gastric motility, there is an increased the risk of aspiration. The intestines are displaced to the upper part of the abdomen and may be shielded by the uterus. The spleen becomes engorged and is more susceptible to injury.[4] The peritoneum is stretched by the gravid uterus, which may make signs of peritonism less reliable.[3] Alkaline phosphatase levels may triple because of placental production.

Urinary

Dilatation of the renal pelvis and ureters occurs from the 10th week of gestation. The bladder becomes hyperaemic and is displaced into the abdomen from the 12th week, making it more susceptible to trauma.

Uterine

There is a massive increase in uterine size. Blood flow to the uterus increases from 60 to 600 mL/min by the end of the pregnancy.

Epidemiology

The incidence of trauma during pregnancy is approximately 6% to 7%, the causes being similar to those in the general population.[1,5] Blunt trauma is the commonest injury, with motor vehicle accidents, falls and assaults being the other common causes and in that order. Penetrating injuries are less common and usually the result of domestic violence. Stab wounds have a better prognosis for the fetus than do projectile wounds. Most trauma is of a minor nature, resulting in bruising, minor fractures and threatened labour. Maternal death from trauma is rare but is the leading non-obstetric cause of death, with most fatalities due to head injuries and internal haemorrhage. Younger (age <20) and older (age >35) multiparous women at gestational ages of less than 28 weeks have a higher risk of adverse outcomes.[6] Women who are discharged undelivered continue to have delayed morbidity, with increased rates of placental abruption and low-birth-weight infants. Fetal death occurs in about 1% to 2% of cases and is dependent on the gestational age and the pattern and severity of maternal injury. Most fetal deaths are due to placental abruption or direct trauma. High-speed (>80 km/h) and broadside motor vehicle accidents have a higher incidence of placental abruption as well as fetal and maternal death than do frontal collisions.[7] Similarly, ejection from a vehicle and motorcycle and pedestrian collisions are associated with poor fetal outcome.[8]

Specific injuries

Pelvic fracture

Pelvic fracture is often the result of a high-speed motor vehicle accident. Massive haemorrhage can occur from the uterus as well as bladder, urethral and ureteric lacerations. Retroperitoneal haemorrhage occurs and may be difficult to diagnose. Direct fetal skull fractures can lead to fetal death. The majority of patients with a pelvic fracture can be delivered vaginally.

Placental abruption

Placental abruption complicates 1% to 5% of patients with minor trauma and between 20% and 50% of cases with major trauma.[5,9] The placenta separates from the underlying decidua because of shearing forces between the relatively inelastic placenta and the more elastic uterus. This leads to fetal hypoxia and death. Thromboplastin release may lead to the development of disseminated intravascular coagulopathy (DIC).

Uterine rupture

Uterine rupture is rare but leads to considerable haemorrhage, with 10% maternal mortality and almost 100% fetal mortality.[5] It usually occurs as a result of direct trauma to women with a uterine scar. It should be suspected when there is maternal shock, fetal death, difficulty defining a uterus, easily palpable fetal parts and intraperitoneal fluid on ultrasound.

Feto-maternal haemorrhage

Feto-maternal haemorrhage is the transplacental spread of fetal blood into the maternal circulation. It occurs in approximately 8% to 30% of trauma cases and may lead to rhesus (Rh) sensitization of the mother, neonatal anaemia, fetal cardiac arrhythmias and fetal death.[3] The Kleihauer-Betke test is used to identify and quantify feto-maternal haemorrhage. All Rh-negative pregnant trauma victims should receive Rh immunoglobulin with additional Rh immunoglobulin if the Kleihauer-Betke test indicates a transplacental haemorrhage of greater than 30 mL.[10]

Presentation

History

Questions should be directed to determining the severity and type of trauma as well as an obstetric history. In a motor vehicle accident and in high-speed or side collisions, ejection from the vehicle and improper use of seat belts and lap belts alone are associated with a greater likelihood of serious injuries.[5] Direct trauma to the abdomen is more likely to cause fractures/splenic and hepatic injuries, whereas indirect trauma via shearing forces is more likely to cause placental abruption. Pelvic pain, uterine contractions and vaginal bleeding may indicate placental abruption. The gestational age (>22 weeks) is the main determinant of fetal viability. Lack of fetal movements may indicate fetal death.

Primary survey

The patient's airway should be assessed and cleared. Intubation may be difficult because of aspiration risk, laryngeal oedema, breast enlargement and cervical trauma. Breathing should be assessed and the patient given supplemental oxygen. If the patient is more than 20 weeks pregnant, she should be placed on her side (preferably the left) to relieve caval compression. If spinal immobilization is necessary, wedges can be placed underneath a spinal board or, alternatively, the uterus can be displaced to the left manually. The blood pressure and circulation can then be assessed, remembering that signs of shock may present late because of relative hypervolaemia.

An assessment of conscious level and any major neurological deficits should be made. The patient should be adequately exposed for a thorough examination but protected from hypothermia.

Secondary survey

The sequence of the secondary survey is the same as in the non-pregnant patient but with an obstetric examination included in the abdominal examination. The uterus should be assessed for fundal height, tenderness, contractions, fetal heart tone, fetal movements and position. Focused abdominal sonography for trauma (FAST) should be performed to assess for intraperitoneal haemorrhage. Bedside ultrasound can also be used to assess the fetal heart rate. The availability of FAST scans and computed tomography (CT) have caused diagnostic peritoneal lavage to fall out of routine use.[11] An obstetrician should perform the pelvic examination, looking for trauma to the genital tract, cervical dilation, fetal presentation and station relative to the ischial spines. Nitrazine paper can be used to test for the presence of amniotic fluid: it turns blue in the presence of the alkaline fluid. Rectal examination and urinalysis are essential.

Investigations

Blood tests

Routine blood tests – such as full blood count, electrolytes, coagulation studies, group and hold – should be performed looking for evidence of anaemia and DIC. A Kleihauer-Betke test will indicate the necessary dose of Rh immunoglobulin in Rh-negative patients.

X-rays

In severe trauma, it is necessary to take cervical spine, chest and pelvic films. The abdomen should be shielded and repetition of films avoided. There is negligible risk to the fetus when radiation exposure has been limited to less

than 0.1 Gy; after 20 weeks' gestation, radiation is unlikely to cause abnormalities.[12] A standard pelvic film delivers less than 0.01 Gy.

Ultrasonography

Ultrasonography is useful in determining gestational age, placental position and fetal well-being and estimating amniotic fluid volume.[13] Bedside FAST can be used to assess for free fluid in the peritoneal, pericardial and pleural cavities and has high sensitivity (83%) for detecting intraperitoneal fluid in pregnant patients.[10] Ultrasonography will detect only 40% to 50% of placental abruptions.[5]

Cardio-tocography

Cardio-tocography (CTG) monitoring beyond the 20th week of pregnancy has proved to be a sensitive way of diagnosing placental abruption early. It should be instituted early and continuously for at least 4 hours.[3] Fetal distress on CTG may be the earliest indicator of impending shock. Frequent uterine contractions and fetal distress are suggestive of placental abruption. In one study, no placental abruptions were missed if CTG monitoring remained normal for the first 4 hours.[9]

Computed tomography

CT is an accurate and non-invasive way of assessing uterine and retroperitoneal structures, but it is time-consuming and involves a higher radiation dose than normal x-rays, with exposure for abdominal CT being between 0.05 and 0.1 Gy. Chest and head CT expose the fetus to far less radiation, especially if uterine shielding is used with radiation exposure of about 0.001 Gy.[5]

Management

Maternal resuscitation is the best method of fetal resuscitation. If the injuries are severe, the patient should be managed in a resuscitation area with a multidisciplinary team approach and early surgical, anaesthetic and obstetrical consultation. Attention to adequate oxygenation, proper positioning and aggressive fluid replacement is important. Oximetry, ECG, blood pressure monitoring and CTG should be started early. If intubation is needed, a smaller endotracheal tube than usual may be required for successful intubation because of laryngeal oedema. Paralytic agents may affect the delivered infant.[4] A nasogastric tube should be inserted to reduce the risk of aspiration, as should an indwelling catheter for urinalysis and to allow better assessment of the uterus. X-rays as indicated should be performed as well as a FAST scan and CT as necessary to evaluate abdominal injuries. If the patient remains unstable with hypotension or continued bleeding, laparotomy is indicated. Ultrasound is particularly useful in the resuscitation phase to assess fetal heart rate and uterine bleeding.

If a thoracostomy is required, the entry point should be one or two intercostal spaces higher than normal to avoid the diaphragm and abdominal structures.

The presence of vaginal bleeding, abdominal tenderness or pain, hypotension, absent fetal heart sounds, fetal distress on CTG and amniotic fluid leakage requires an urgent obstetric opinion and possibly a caesarean section.

The use of leg veins for intravenous access should be avoided, as the gravid uterus may affect venous return and compromise drug delivery. The uterine vasculature is very sensitive to catecholamines. If ionotropes are required, adrenaline and noradrenaline should be avoided. Ephedrine and dopamine at doses less than 5 µg/kg can be used to improve maternal blood pressure (BP) without compromising uterine blood flow.[1,5]

Premature labour can be treated with tocolytic agents, such as intravenous salbutamol. However, salbutamol causes maternal and fetal tachycardia, which may mask symptoms of hypovolaemia. Magnesium sulphate is recommended as an alternative tocolytic in abdominal trauma.[5]

DIC may develop as a result of placental abruption, amniotic fluid embolism and fetal death. Clotting factors may need to be replaced.

In general, penetrating injuries should be explored by laparotomy, especially if they involve the upper abdomen, where there is a high possibility of bowel perforation. Some authors argue that stab wounds over the uterus can be treated conservatively if there is no evidence of visceral injury, the entrance wound is below the fundus and the patient is stable.[1]

Peri-mortem caesarean section should be considered within the first 4 minutes of a maternal cardiac arrest. There have been many cases of fetal survival up to 20 minutes after maternal death. Maternal cardiopulmonary resuscitation (CPR) should be continued during the delivery of the fetus. Fetal delivery may improve venous return and increase the chance of maternal survival.[10]

Disposition

Patients who are haemodynamically unstable and who have extensive head or chest injuries will require surgical intervention and intensive care support. Patients who are stable but show signs of fetal distress should undergo caesarean section. All patients with minor injuries who are more than 20 weeks pregnant should have CTG monitoring for at least 4 hours, preferably in a labour ward.

Prognosis

Most women who sustain trauma during pregnancy suffer few complications. There is greater maternal and fetal mortality in pregnant women with higher injury severity scores. Placental abruption can still occur as a result of minor trauma 24 to 48 hours after an accident, but 4 hours of CTG monitoring should detect this group of patients.[3]

Prevention

Properly worn seatbelts reduce both maternal and fetal mortality. A three-point seat bar system should be used, with the lap portion as low as possible, preferably over the thighs and with the shoulder portion passing between the breasts and above the gravid uterus.

CONTROVERSIES

- The duration of cardio-tocography monitoring: most authors agree that 4 hours should be enough to predict placental abruption, although some argue that 24 to 48 hours may be needed.
- Exploration of penetrating wounds to the abdomen: some authors argue for a conservative approach to a wound below the uterine fundus, whereas others argue that all such wounds should be explored.

3.10 Wound care and repair

Gim Tan

ESSENTIALS

1 Good cosmesis can be achieved in the emergency department with conservative treatment, thorough debridement and accurate apposition of everted skin edges.

2 Choose a suture that is monofilament, causes little tissue reactivity and retains tensile strength until the strength of the healing wound is equal to that of the suture.

3 Dirty, contaminated, open wounds should generally be cleansed, debrided and closed within 6 hours to minimize the chance of infection.

4 Suspected tendon injuries require examination of the full range of motion of joints distal to the wound while observing the tendon in the base of the wound for breaches. This is often done under anaesthesia.

5 The success of a tendon repair (as measured by function) relates in large part to the postoperative care and therapy, not simply to the suture and wound closure.

6 Appropriate splinting and elevation of limb wounds at risk of infection takes precedence over antibiotics in the postoperative prevention of infection.

7 If prophylactic antibiotics are used, they should be given intravenously prior to wound closure to achieve adequate concentrations in the tissues and haematomas that may collect. There is no need for antibiotics with simple lacerations not involving tendon, joint or nerves.

8 Wounds that breach body cavities, such as the peritoneum and joints, or involving flexor tendons, nerves and named arteries, should be referred to a specialist for consideration of repair and inpatient care.

9 Foreign bodies, such as clay, chemically impair wound healing.

10 Puncture wounds such as bites may be managed by either second-intention healing after thorough lavage or, better still, by excisional debridement, lavage, antibiotics and atraumatic closure, if less than 24 hours old (preferably less than 6 hours).

Introduction

Open-wound injury comprises a significant component of the emergency department (ED) workload. Data from the Victorian Injury Surveillance System[1] showed that 72% of all ED presentations for unintentional cutting and/or piercing injury that did not require admission were open wounds. In addition, open wounds may accompany other injuries, such as fractures. Of open wounds that occur in the home, 19% are in the paediatric age group (0 to 14 years), 62% occur in people under 35 years of age, and less than 10% are seen in the group above age 65. Overall, 65% of patients are male.

Location data show that more than 53% of these wounds occur in the home,[1] mostly during activity described as leisure. The three major causes are falls up to 1 m, contact with cutting or piercing objects, or having been struck or collided with. Most are unintentional and only 3% are due to an assault. Injuries to the face, head and neck comprise

12% and the upper extremity is involved in 62%. Eighty-eight per cent of all presentations are repaired in the ED and the patient is discharged home. Almost half are referred to general practitioners (GPs) and specialists for review. Wounds suitable for ED repair are discussed further.

Clinical presentation

An initial general assessment of the patient is important, as it defines the likely mode of repair as well as the injured structures and identifies factors for complications. The assessment includes the traditional history, examination and investigation of the patient.

It is important in the history to identify the time and mechanism of injury, the likely presence of foreign bodies and the patient's tetanus immunization status. Past medical history, allergies to agents—such as local anaesthetics, antibiotics, preparation solutions and tapes, and current medications such as warfarin or cytotoxics—all have a bearing on management. For example, there is a greater risk of infection and poor wound healing in diabetic patients with extremity wounds of the lower limbs sustained in a crush injury. Other relevant general conditions, particularly in the setting of dirty wounds such as bites, include prior mastectomy and other causes of chronic oedema of the affected region, prior splenectomy, liver dysfunction, immunosuppression or autoimmune disease, such as systemic lupus erythematosus (SLE). Smokers have impaired collagen production in healing wounds.[2]

The general examination comprises a search for all injuries sustained and concurrent medical illness that may have a bearing on the results of repair, such as poor circulation in patients with peripheral vascular disease. The patient must be recumbent (beware of syncope) and any clothing that may obstruct a thorough examination must be removed. Constricting rings or other jewellery that encircle the injured body part should also be removed. A general examination is performed, followed by a local examination of the wound coupled with initial cleansing. Function and nerve or vessel injury are then looked for. A detailed examination of the depth of the wound, which usually requires good anaesthesia, is then performed. A surface wound caused by the entrance of a foreign body does not necessarily mean that the foreign body has remained in the vicinity. A decision is made regarding the requirement for further investigations, which include radiographs for fractures and some foreign bodies or ultrasound for radiolucent foreign bodies.

An injury to a tendon in the base of the wound may become apparent only when the joints over which it acts are in a particular position, reflecting the position of the limb at the time of injury. At other positions, the tendon injury may slide out of view. Marked pain with use may be a clue to a partial tendon injury.

Any tendon injury or other factors, such as nerve damage, indicate the need for referral to a plastic surgeon.

Wound cleansing

To provide optimum conditions for healing without infection, it is essential to remove all contaminants, foreign bodies and devitalized tissue prior to wound closure.

Table 3.10.1 Preparation solutions and their properties

Solution	*Properties*	*Mechanism of action*	*Uses*	*Disadvantages*
Normal saline	Isotonic, non-toxic	Simple washing action	In wound for irrigation	No antiseptic action
Chlorhexidine 0.1% w/v—aqueous	Bacteriostatic	Antibacterial and washing action	Cleanse skin surrounding wound	Not near eyes (causes keratitis), perforation of ear drum or meninges
Chlorhexidine 0.1% w/v + cetrimide 1% w/v	Bacteriostatic	Antibacterial and soap action, removes sebum, 'wetting' the skin	Cleanse skin surrounding wound	Not near mucous membranes, eyes (causes keratitis), perforation of ear drum or meninges
H_2O_2 3%	Bactericidal to anaerobes	Forms superoxide radicals	Severely contaminated wounds with anaerobic-type pathogens	Obstruction of wound surface capillaries and subsequent necrosis
Povidone–iodine 10% w/v	Bactericidal, fungicidal, viricidal, sporicidal	Releases free iodine	On surrounding skin, or in severely contaminated wounds (dilute 1% w/v)	Use on/in large wounds may cause acidosis due to iodine absorption

Universal precautions, including eye protection (goggles or similar), clothing protection (gown) and gloves, must be used for all wound care and repair. Gloves should be powder free to avoid adding starch as a foreign body to the wound, which will delay healing and produce granulomas.[3] One must be aware of the risk of latex allergy to both the glove wearer and the patient.[3]

If necessary, hair can be removed by clipping 1 to 2 cm above the skin with scissors. Shaving the area with a razor damages the hair follicle and is associated with an increased infection rate. Scalp wounds closed without prior hair removal heal with no increase in infection.[4]

The skin surface should be cleansed using sterile normal saline. This has the lowest toxicity and there is no benefit in using antiseptic.[5]

Recent studies have shown that the use of tap water in the cleansing of simple lacerations is as effective as normal saline.[6]

A wide variety of cleansing solutions is available (Table 3.10.1), with differing attributes.

Anaesthesia is necessary for wounds to be cleansed adequately. Extensive wounds, or particularly heavily contaminated wounds that need vigorous scrubbing, such as road debris tattooing, may require general anaesthesia. Local anaesthetic may be given by local infiltration or as a regional nerve block. Needles introduced through the wound cause less pain but may theoretically track bacteria into the tissues, although this has not been demonstrated to be a problem clinically. After anaesthesia, irrigation with a pressure of at least 8 psi (55 kPa)[7,8] is required to dislodge bacteria and reduce the incidence of infection. This can be achieved with a 19-gauge needle, a 25- to 50-mL syringe, a three-way tap and a flask of fluid, such as sterile saline (Fig. 3.10.1).[9] High-pressure irrigation (>20 psi, 138 kPa) may cause tissue damage.[10]

Radiopaque foreign bodies—such as gravel, metal, pencil lead and glass greater than 2 mm in size[11]—may be identified using x-rays. A radiopaque marker, such as a paper clip, can be placed at the wound to help identify the position of the foreign body.[12] This is not sensitive for plastic or wood, however,[13] which may be detectable with ultrasound if larger than 2.5 mm. However, if there is gas due to an open wound, this will make ultrasound less sensitive.

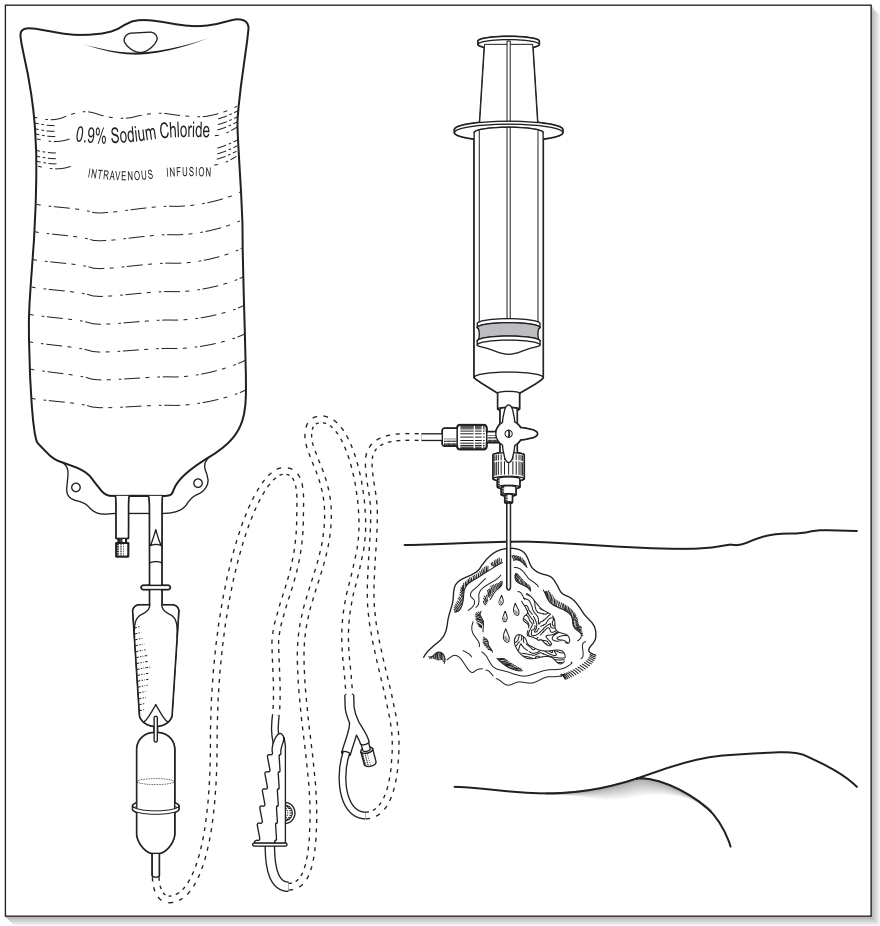

FIG. 3.10.1 Wound irrigation set-up comprising flask of fluid, intravenous tubing, three-way tap, syringe and 19-gauge needle designed to deliver fluid at a pressure of at least 8 psi (55 kPa). (From an original drawing by Elaine Wheildon.)

Adequate debridement of devitalized tissue has always been a tenet of surgical practice. More recently, there has been a change in emphasis from radical to meticulous debridement. If the skin is devitalized, it should be removed using a scalpel blade. Viable tissue will bleed when cut and viable muscle will contract when stimulated. If viability is in doubt, it may be better to wait for demarcation over the following days with regular close observation. Fat and fascia are relatively avascular; if they are semi-viable in contaminated wounds, they should be removed.

Semi-viable muscle can usually be preserved when it is well drained.[13] Nerves, major vessels and tendons should not be debrided in the ED. Lavage and debridement should be continued until the wound is clean. Organic material and anionic soils, such as clay, pose the greatest risk of infection if not removed. The highly charged clay particles directly affect leucocytes, preventing phagocytosis of bacteria. They also react chemically with antibiotics, limiting their action.

Once the wound is clean, the decision to close immediately or later is made.

Guidelines for delayed closure may include the following:

- Puncture wounds, such as made with a tooth or a knife
- Wounds that cannot be adequately debrided
- Contaminated wounds more than 6 hours old
- Too much tension in the wound, particularly with crush injury

In some cases, such as thoroughly lavaged puncture wounds, it may be prudent to allow healing by secondary intention. If in doubt, consult with a plastic surgeon. When repair in the ED may be delayed, it is prudent to have nursing staff perform a preliminary preparation of the wound along the lines shown in Box 3.10.1.

Antibiotics are necessary only in wounds involving joints, tendons, nerves, vessels, significant crush injury or if they are due to human or animal bites.[14]

Box 3.10.1 Preliminary wound preparation procedure instructions for nurses

Explain the procedure to the patient.
Identify any allergies, especially to iodine-like products and adhesive tapes.
Medicate the patient prior to the irrigation as needed for pain control.
Protect patient's clothing from soiling by the irrigation solution or wound drainage.
Position the patient so that the irrigating solution can be collected in a basin, depending on the wound's location.
Maintain a sterile field during the irrigation procedure as appropriate.
Irrigate wound with appropriate solution, using a large irrigating syringe and set-up (see Fig. 3.10.1).
Instil the irrigation solution at 8 psi (55 kPa), reaching all areas.
Avoid aspirating the solution back into the syringe.
Cleanse from cleanest to dirtiest areas of the wound.
Continue irrigating the wound until the prescribed volume is used or the solution returns clear.
Position the patient after the irrigation to facilitate drainage.
Cleanse and dry the area around the wound after the procedure.
Dispose of soiled dressing and supplies appropriately.
Lightly pack the wound with well-wrung-out, saline-soaked, lint-free sterile gauze or an alginate dressing.
Apply a sterile dressing as appropriate until repair has been performed.

Tetanus prophylaxis

The risk of tetanus is greatest in the very young and the very old, with an overall death rate of 1:10 in Australia,[15] so prevention is all-important. An average of 10 cases per year occur in Australia,[13] usually in older adults who have not been immunized or who have allowed immunization to lapse. The anaerobic bacterium *Clostridium tetani* is present in soil and animal faeces. After incubation of 3 to 21 days following inoculation into a wound, the toxin produced by the bacteria causes severe muscle spasm and convulsions. Death occurs commonly as a result of respiratory failure. The types of wound at risk are listed in Box 3.10.2, but tetanus may occur after apparently trivial wounds.

Tetanus immunoglobulin is given into the opposite limb to the tetanus toxoid in patients with inadequate protection against tetanus (Table 3.10.2), thus providing passive protection.

Box 3.10.2 Wounds that are prone to tetanus (defined as all wounds except clean minor wounds)

Compound fractures
Deep penetrating wounds
Wounds containing foreign bodies (e.g. wood splinters, thorns)
Crush injuries or wounds with extensive tissue damage (e.g. burns)
Wounds contaminated with soil or horse manure
Wound cleansing delayed more than 3–6 h

Wound-healing mechanisms

Wounds never gain more than 80% of the strength of intact skin.[16]

There are three phases of healing. Days 1 to 5 are the initial lag phase (inflammatory), where there is no gain in the strength of the wound. Days 5 to 14 are a period of rapid increase in wound strength, associated with fibroplasia and epithelialization. The wound has only 7% of its final strength at day 5. Wound maturation progresses from day 14 onwards, with the production, cross-linking and remodelling of collagen.

The surgical maxim that wounds heal from side to side is only partly true: if left to heal by itself, the entire wound will contract around its margin prior to epithelialization. This has been termed secondary closure or healing by second intention. Allowing the wound to close without intervention relies on healing up from the base and from the edges and often results in unsightly scars. Primary closure involves the apposition of wound edges, preferably within 6 hours of injury, with sutures, staples, tissue adhesive glue, etc. After a delay of 6 hours or more, the chance of infection increases. Delayed primary closure is performed 4 to 5 days after injury, when it is clear that there is no infection. This approach may be used for contaminated wounds that present more than 6 hours post-injury.

Factors that affect the rate of wound healing include

- technical factors of the repair.
- anatomic factors (intrinsic blood supply, etc.).
- drugs (steroids, cytotoxics, etc.).

Table 3.10.2 Tetanus vaccination schedule for acute wound management

History of tetanus vaccination		*Type of wound*	*DTPa, DT(ADT)[a] or dTpa as appropriate*	*Tetanus immunoglobulin*
3 doses or more	If less than 5 years since last dose	Clean minor wounds	No	No
		All other wounds	No	No+
	If 5–10 years since last dose	Clean minor wounds	No	No
		All other wounds	Yes	No[b]
	If more than 10 years since last dose	Clean minor wounds	Yes	No
		All other wounds	Yes	No[b]
Uncertain or less than 3 doses[c]		Clean minor wounds	Yes	No
		All other wounds	Yes	Yes

[a] *ADT*, Adult Diptheria Tetanus; *DTPa*, Diphtheria, tetanus, pertussis for children before 10th birthday; child diphtheria tetanus *(CDT)* if pertussis is contraindicated; adult dTpa for children after their 10th birthday and adults; *TIG* is Tetanus Immunoglobulin. This has substantially lower amounts of diphtheria toxoid and pertussis antigens.
[b] Individuals with a humoral immune deficiency (including HIV-infected persons who have immunodeficiency) should be given TIG if they have received a tetanus-prone injury, regardless of the time since their last dose of tetanus-containing vaccine.
[c] Persons who have no documented history of a primary vaccination course (3 doses) with a tetanus toxoid–containing vaccine should receive all missing doses and must receive TIG.
(Adapted with permission from *The Australian Immunisation Handbook*. 10th ed. 2017.)

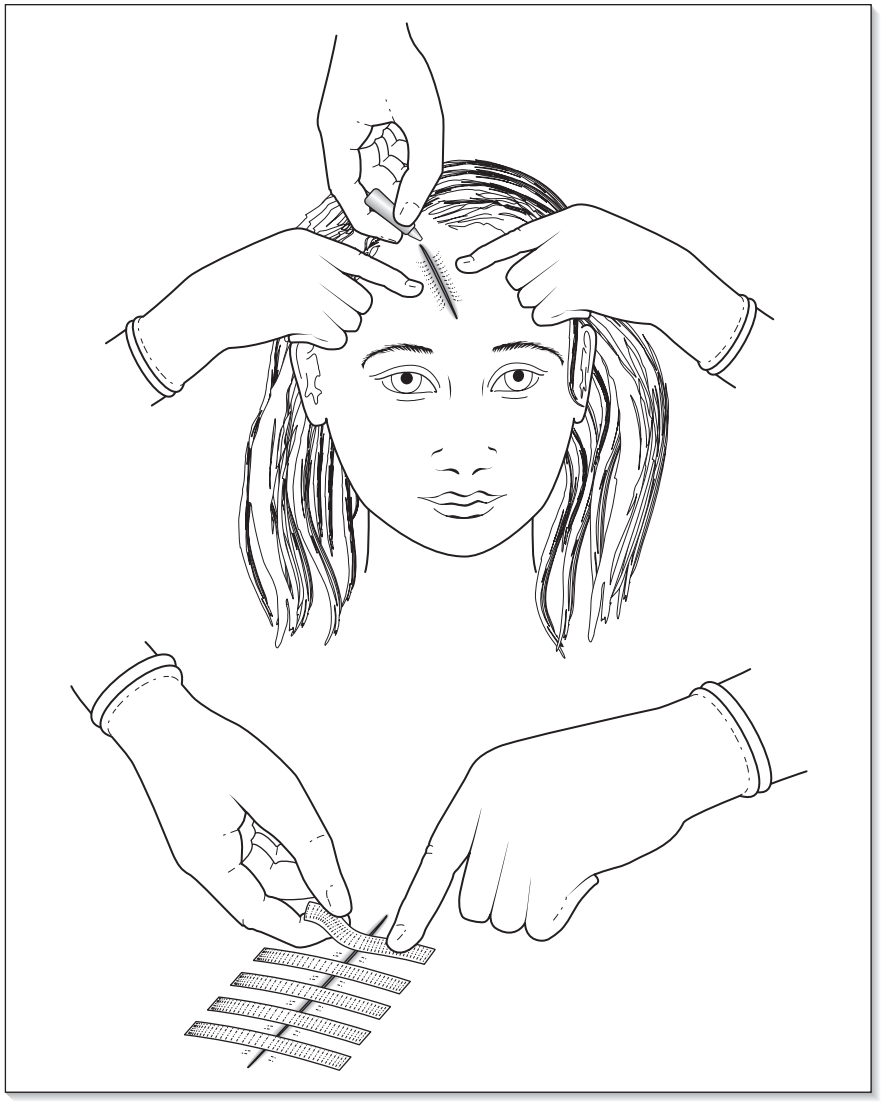

FIG. 3.10.2 Steri-Strips and glue are typically used for children in most simple split lacerations, thereby avoiding the use of needles. (From an original drawing by Elaine Wheildon.)

- associated conditions and diseases (diabetes, vitamin C, zinc deficiency, etc.).
- the general nutritional state of the patient.

Suture types

Wounds may be closed with tape, staples, sutures or tissue adhesive.

Purpose-made commercial tapes reinforced with rayon provide an excellent means of closure. The adherence of tapes (Fig. 3.10.2) may be improved by the application of adhesive adjuncts, such as tincture of benzoin or gum mastic paint.[17] These adhesives must not be allowed to enter the wound,[18] as they potentiate infection and cause intense pain. The rates of infection with tapes and staples are lower than with conventional sutures.[19]

Staples have the advantage of rapid insertion and wound closure, particularly for extensive wounds. They are applied using a staple gun and must be removed using the appropriate device, which may be a problem with follow-up arrangements.

From horsehair in World War II[20] to today's soluble monofilament plastics with prolonged tensile strength, necessity has seen the development of many different suture materials (Fig. 3.10.3) of different grades and using different types of needles. The ideal suture would be monofilament, which causes no tissue reaction, does not promote infection, is completely absorbed and yet has a tensile strength and secure knots that last until tissue strength has equalled that of the suture. It should stretch to accommodate wound oedema, recoil to its original length and be inexpensive. However, as yet no such suture exists.

A key factor in choosing absorbable suture is the length of time over which it retains adequate strength. The inflammatory phase of healing lasts for 7 days. Catgut prolongs this phase and is removed by enzymatic action, whereas absorbable plastics simply hydrolyse. Braided sutures produce greater tissue reaction than monofilaments. Braided and catgut sutures should be avoided in contaminated wounds,[21] as the interstices provide a haven for bacteria from phagocytes. Traditional absorbable sutures have included Vicryl and Dexon, both braided multifilament. Extensive studies have shown that new monofilament absorbable sutures have superior strength both initially and at 4 weeks. They cause less interference with bacterial clearance; enable more secure knots, requiring fewer throws; and involve lower drag forces through tissue compared with the braided absorbable types.[22]

Tissue adhesive agents such as Histoacryl (enbucrilate; B. Braun Surgical GmbH)—'superglue'—have been developed particularly with the minor superficial paediatric wound in mind. The results can be excellent provided that good wound-edge apposition is achieved prior to application of the glue on the surface (see Fig. 3.10.2).

In the future, biological tissue adhesive agents, such as fibrin sealant,[20] for use in the wound may replace sutures as the means of wound closure. As yet these are experimental in sterile, surgically created wounds.

Needles

Early surgical needles had eyes like traditional sewing needles and caused tissue trauma as the bulk of folded-back thread and needle passed through the tissues. The first swaged needles were invented over 100 years ago, and modern disposable swaged needles have largely replaced the reusable eyed needles. There are three parts to a needle: the swage, the body and the point (Fig. 3.10.4).

Advances in metallurgy have allowed the production of nickel stainless steel wire, from which needles are cut. They may be straight or curved in arcs of varying degrees to produce portions of a circle, such as 90-, 135-, 180- and 225-degree parts. A compound curved needle comprises two different arcs, limiting the amount of supination necessary to pass it through tissue. Skin repair usually requires half-circle needles. The points of surgical needles may be tapered, cutting or a combination. Taper-point needles are generally round or oval-bodied and are not suitable for skin, as they are difficult to pass through the tightly bundled collagen fibres of the dermis. Their role is in the repair of soft tissues such as fascia, blood vessels and bowel, etc. Cutting needles are for skin and have a triangular point with sharp cutting edges to facilitate tissue penetration. Conventional cutting needles have the apex of the triangle towards the concavity of the curved needle (see Fig. 3.10.4). Reverse cutting needles have the apex on the convexity of the needle. This style of needle and suture will not cut out when the needle is passed through tissue or once the knotted suture is resting against a block of tissue rather than a cut. Such needles are structurally

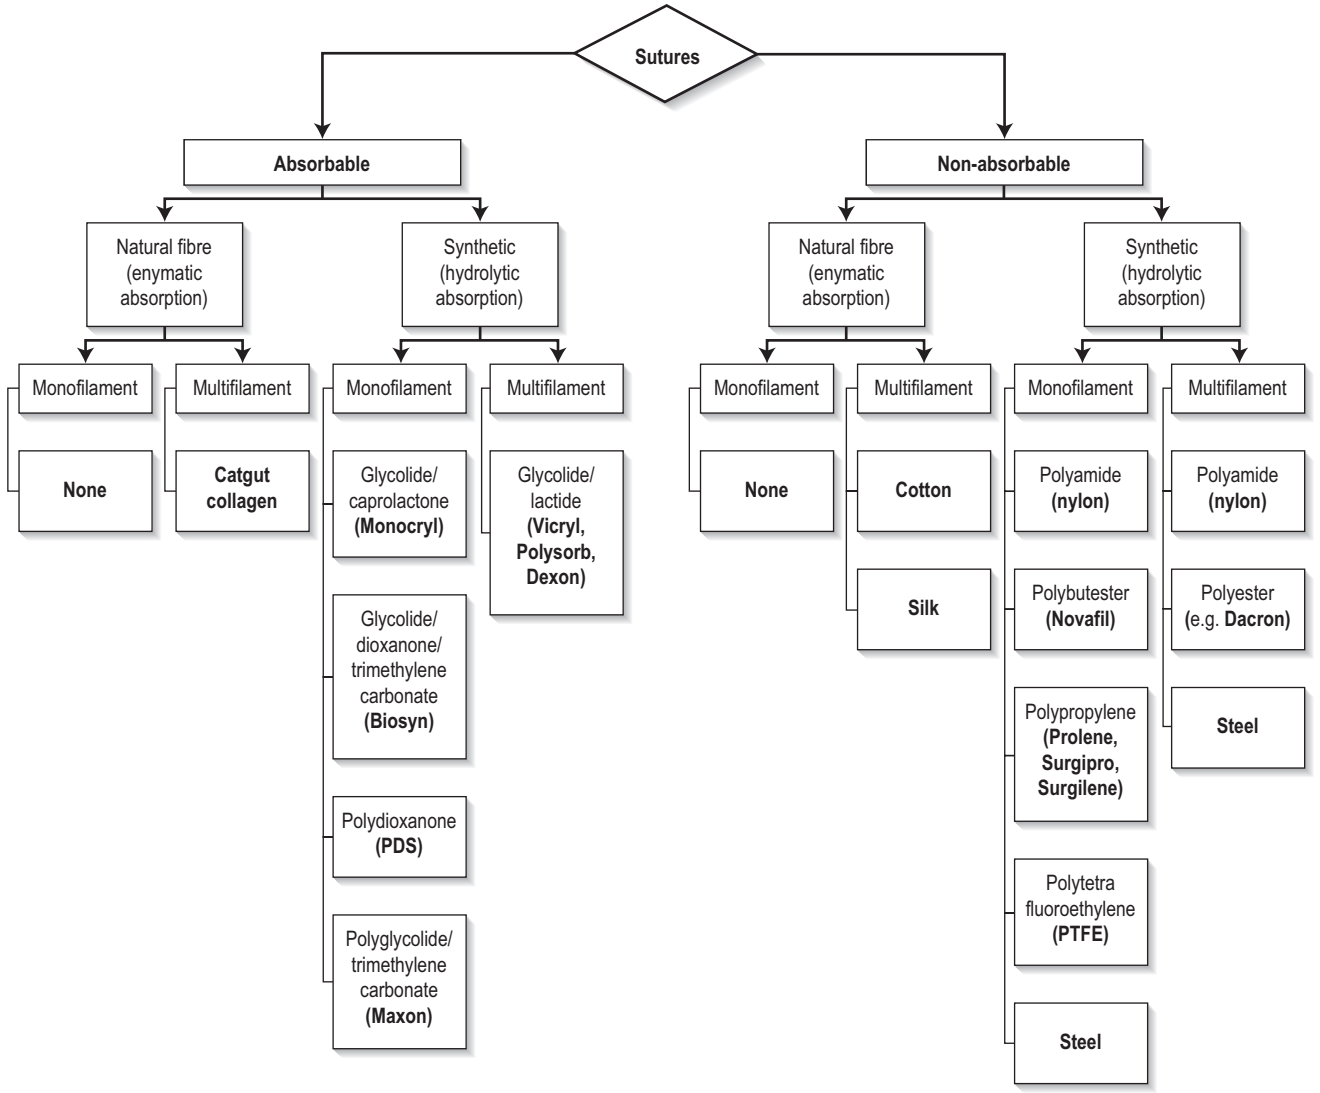

FIG. 3.10.3 A Simple Classification of Suture Types in Current Usage. (Adapted with permission from van Winkle W Jr, Hastings JC. Considerations in the choice of suture material for various tissues. *Surg Gynecol Obstet*. 1972;135:113–126.)

stronger.[23] Needles with combination cutting at the point and taper for the remainder of the body are for slightly denser tissues, such as tendon or aponeurosis. Needle holders are generally used with curved needles, and straight needles are handheld. The risk of needle-stick injuries with handheld needles makes their use hazardous.

Basic suture technique

Prior to closure, prophylactic antibiotics (see Chapter 9.9) should be given intravenously if required. This ensures that any haematoma that collects in the wound after or during closure will contain antibiotic.

Having prepared a sterile field with the contents of a suture tray (Box 3.10.3) laid out, the wound anaesthetized and cleaned and the sterile drapes placed around the wound, repair can begin. A very contaminated wound should be anaesthetized, lavaged and cleansed before re-preparing with antiseptic and draping for formal debridement, further lavage and repair.

One should choose the thinnest possible suture that will tolerate the tissue tensions and provide adequate strength. The needle holder must grasp the needle in the body, usually two-thirds of the length from the tip of the needle, rather than over the swage, where the metal is relatively weak. Stretching the suture in the hands and supporting it at the needle swage will remove its 'memory', making handling easier. The needle holder should be held in the palm of the hand and controlled with the index finger, using a supination/pronation action in the arc of the needle (Fig. 3.10.5). The placement of the first suture varies with the wound: in a small linear wound, it may be convenient simply to suture from one end to the other. In longer wounds without good corresponding landmarks on either side, it is helpful to subdivide the wound serially so as to ensure that one does not finish up with a 'dog-ear'. If an assistant is available, stretching the wound is helpful (Fig. 3.10.5). In more irregular complex wounds, it is helpful to approximate corresponding landmarks first: for example, the apex of a flap is best stitched first (Fig. 3.10.6).

After wound contraction has occurred, the wound edge has a natural tendency to inversion, resulting in a shallow crater. To prevent this, the edges must be everted at closure. This is done by depressing the skin near the wound edge (Fig. 3.10.7) or lifting it with a skin hook or forceps so that the needle enters and exits perpendicularly to the skin in both running and interrupted sutures. The sutures so placed may be interrupted with separate tied closed loops or continuous loops passing through tissue and tied at either end. Vertical mattress sutures (Fig. 3.10.8) and horizontal mattress sutures (Fig. 3.10.9) are designed to evert

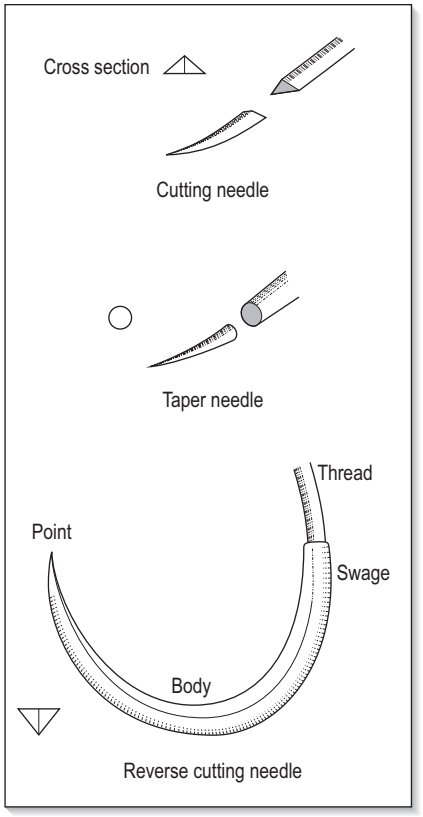

FIG. 3.10.4 Characteristics and Types of Surgical Needles. (From an original drawing by Elaine Wheildon.)

Box 3.10.3 Surgical instruments required for wound repair

Contents of a typical simple suture tray

1 × Nelson Hegar needle holder, 6.5 in
1 × Curved artery forceps
1 × Gillies dissectors
1 × McIndoe dissectors
2 × Small bowls
1 × Kidney dish autoplas, 255 mm
1 × Fenestrated drape
1 × Huck towel
1 × McIndoe dissectors
1 × Adson dissectors
1 × Gillies toothed dissectors
2 × Skin hooks
2 × Catspaw refractors
1 × Bard-Parker handle no. 3
1 × Bard-Parker handle no. 4
1 × Vein hook Alcot
1 × Rampley sponge holder
3 × Gallipots
1 × Kidney dish
3 × Towel clips
4 × Huck towel

Contents of a typical 'plastics' suture tray

2 × Mosquito forceps curved
2 × Mosquito forceps straight
1 × Hegar needle holder, 5.5 in
1 × Gillies needle holder
1 × Straight Mayo scissors
1 × Curved Mayo scissors
1 × Vein straight scissors
1 × Vein curved scissors

wound edges that are difficult to maintain in eversion with simple sutures.

Knots are the weakest link in the suture, particularly for continuous sutures, where the failure of a knot will release the whole suture along the length of the wound. The knots may be tied with instruments or by hand. When using instrument ties, one must be careful not to damage the suture by either crushing it with the serrated jaws of a needle holder or tearing on the edges of the jaws. A reef knot with a snug third throw produces the best results for nylon or polypropylene. Synthetic monofilament sutures require several twists in the first and second throws to prevent unknotting (see Fig. 3.10.5). It is important that the wound be closed without excessive tension on the sutures.

Interrupted sutures have the advantage of individual removal to allow drainage of an infected wound or, for cosmetic reasons, to limit the time a suture stays in while retaining some sutures for wound strength; however, there is a trade-off in the time it takes to close a wound using multiple knots. Sutures tied too tightly, exacerbated by oedema in the wound and from the trauma created by the needle's passage, will cause suture marks due to local ischaemia on the skin surface. An individual suture that is strangling tissue will continue to do so until it is cut. One way to avoid tissue strangulation is to use a loop throw in an interrupted suture (Fig. 3.10.10).[16]

Studies have shown no increase in wound infection or reduction in wound strength with the use of continuous sutures,[24] which may be placed rapidly in long linear wounds, thus distributing tension evenly. However, if one knot fails or the stitch is cut, the sutures will loosen along the length of the wound. Continuous sutures may be percutaneous or intradermal (subcuticular). If intradermal, they should surface every 3 cm to facilitate removal.[25]

Intradermal sutures are most appropriate for surgical wounds. Monofilament polypropylene has a very low surface coefficient of friction and is thus easiest to remove in the setting of continuous percutaneous or subcuticular closure.[26] One should ensure that the suture glides easily through each segment and is not looped, otherwise removal may become very difficult. Recently absorbable monofilament, such as glycolide caprolactone (Monocryl, Ethicon Inc.), has supplanted polypropylene for continuous subcuticular suture, as it does not have to be removed.

Historically, Halstead[27] considered it important to 'obliterate with the greatest care all of the dead spaces of a wound'. In 1974, it was demonstrated that suture closure of dead space increases the incidence of infection secondary to the foreign body (the suture) in the wound, thereby eliminating the benefits of dead-space closure.[28] Some authors[16] stress the importance of using buried sutures to obtain wound-edge eversion and dead-space closure. Modern hydrolysable monofilament sutures allow this. The long-term maintenance of dermal edge apposition, either with or without deep sutures, is the key to obtaining the narrowest possible scar. Techniques have been developed to encourage this and to avoid leaving buried sutures, with their attendant risk of wound infection. Some creative methods have been devised to allow the removal of a deep space-obliterating suture without disrupting the wound (Fig. 3.10.11).[29]

Wounds that slice obliquely through thick skin, as on the back, can be trimmed with a scalpel blade perpendicular to the skin or sutured with a vertical mattress to prevent one bevelled edge sliding over the other. If necessary to prevent a wound edge step, adjustments in the height of the wound edges can be achieved by exiting the needle superficially on the high side and deeper on the low side, using either continuous or interrupted sutures.[16]

Special sites and situations

Scalp lacerations may be closed using the 'hair braiding' technique,[30,31] either on its own or combined with tissue adhesive. In this technique, four to five strands of hair from opposite sides are brought together, twisted once and covered with tissue adhesive.

The face, particularly with dirty wounds such as bites, requires early repair to achieve good cosmesis. Delay for up to 24 hours is acceptable prior to definitive debridement and repair in the operating theatre provided that interim wound care is of a good standard. To enable adequate cleansing, local nerve blocks should be used.

A field block is generally required for ears. Ear cartilage must be aligned and skin coverage achieved to prevent perichondritis.

Injuries involving the eyelid need a good examination of the underlying globe to exclude scleral and conjunctival lacerations; also, canaliculi may be torn. A lacerated canaliculus should be microsurgically repaired and stented within 24 hours. Accurate apposition of eyebrows and vermilion border is essential. Never shave an eyebrow.

Damaged facial muscle must be repaired in the interests of facial symmetry. In cheek injuries, the facial nerve and parotid duct must be checked for intactness. The nerves are generally deep in the

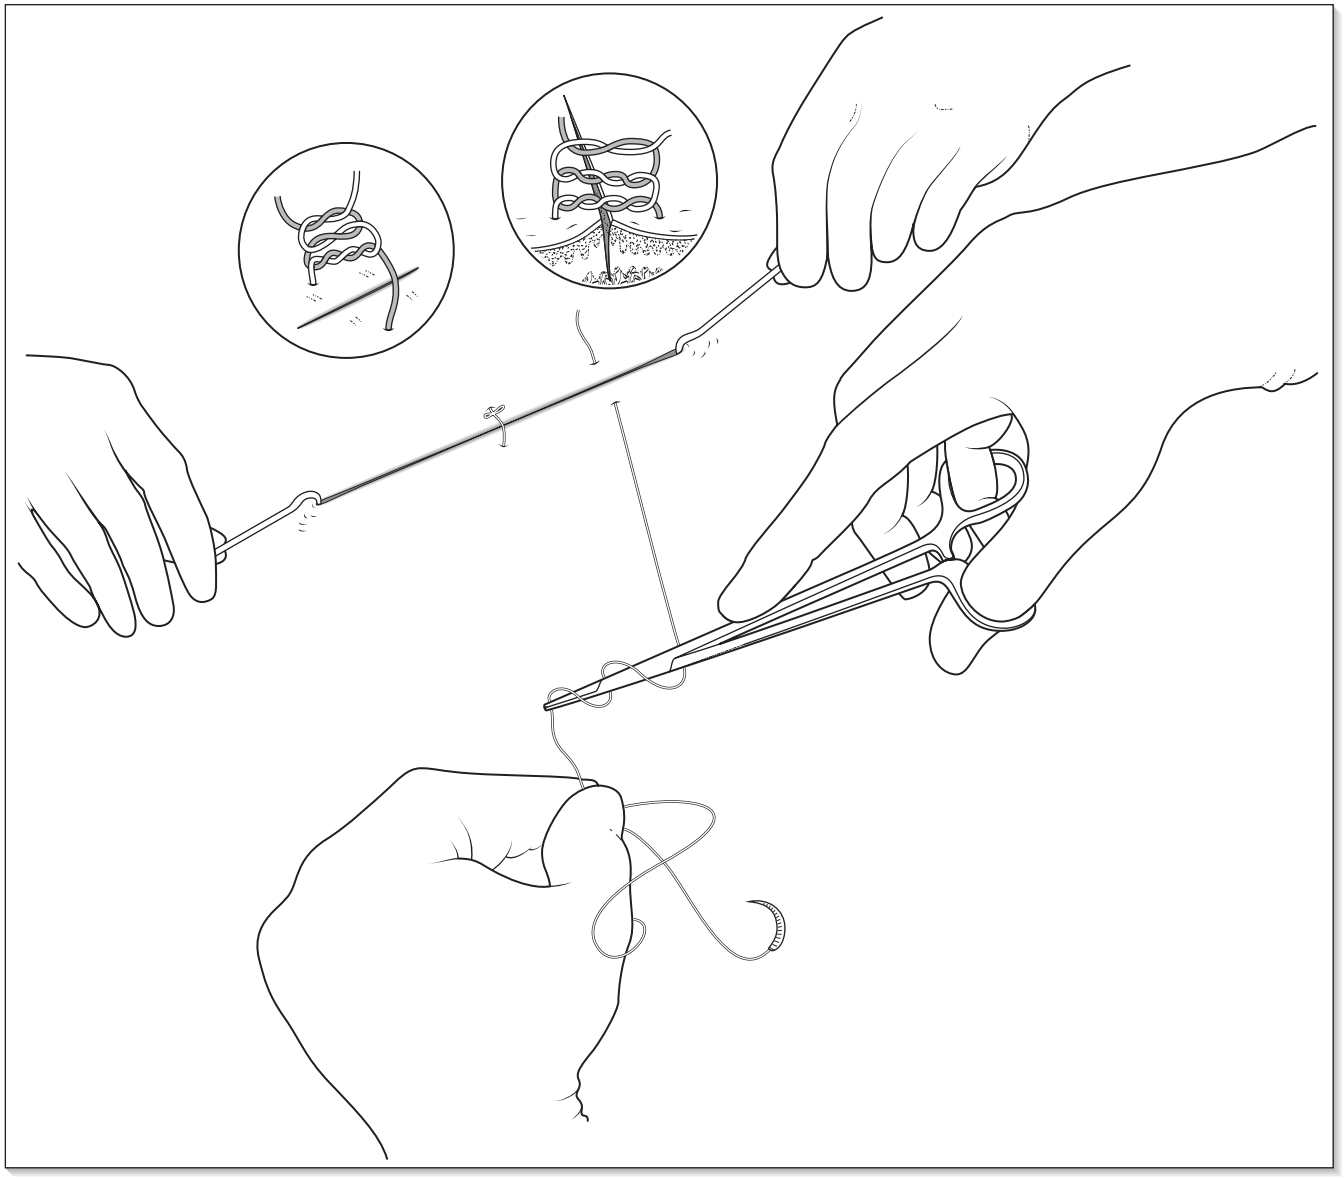

FIG. 3.10.5 The basic technique of how to hold a needle driver, put the wound on the stretch and suture a long wound in halves using surgical knots. For synthetic sutures, the reef knot with the third throw requires several twists, as illustrated, to prevent loosening. (From an original drawing by Elaine Wheildon.)

cheek. Terminal repair of nerves medial to the midpupillary line is unnecessary.

Tattooing should be removed within 12 hours to avoid tissue fixation. Use a sterile brush and magnification and be meticulous. It is useful to have sterile toothbrushes available in the ED for this. After 12 hours, a formal dermabrasion and/or debridement may be needed.

Complications of facial wounds are numerous and pose some special problems (Table 3.10.3).

Special suture techniques

Techniques for relieving the tension in a wound include limited undermining and the use of horizontal mattress sutures (see Fig. 3.10.9). Very rarely should skin flaps be raised in acute trauma. These may be advancement (e.g. V–Y advancement), rotation or transposition in design. It is usually better to apply a split skin graft to heal the wound primarily and perform later scar revision or reconstruction. In some settings, V–Y flaps can be advanced or retreated, depending on the direction of tension (Fig. 3.10.12).

The 'dog-ear'

The term 'dog-ear' refers to a conical pucker of redundant skin that may collect at the end of a wound towards the end of closure (Fig. 3.10.13), particularly in wounds with an elliptical area of skin defect. In order to avoid a 'dog-ear', the wound should be sutured in halves, placing each new stitch between the previous ones (see Fig. 3.10.5). There are several ways to remove a dog-ear[32]:

- The direct overlap excision technique involves drawing the redundant skin from one side across the wound and excising along the line of the wound. Any remaining redundant skin is drawn across the wound from the other side and excised along the line of the wound (see Fig. 3.10.13).
- Unilateral dog-ears are best removed by elevating the redundant skin with a skin hook in the centre, followed by incising along the edge of the fold and then allowing the created flap to fall back along the line of the sutures, where it is trimmed off. This results in a J-shaped repair (see Fig. 3.10.13).

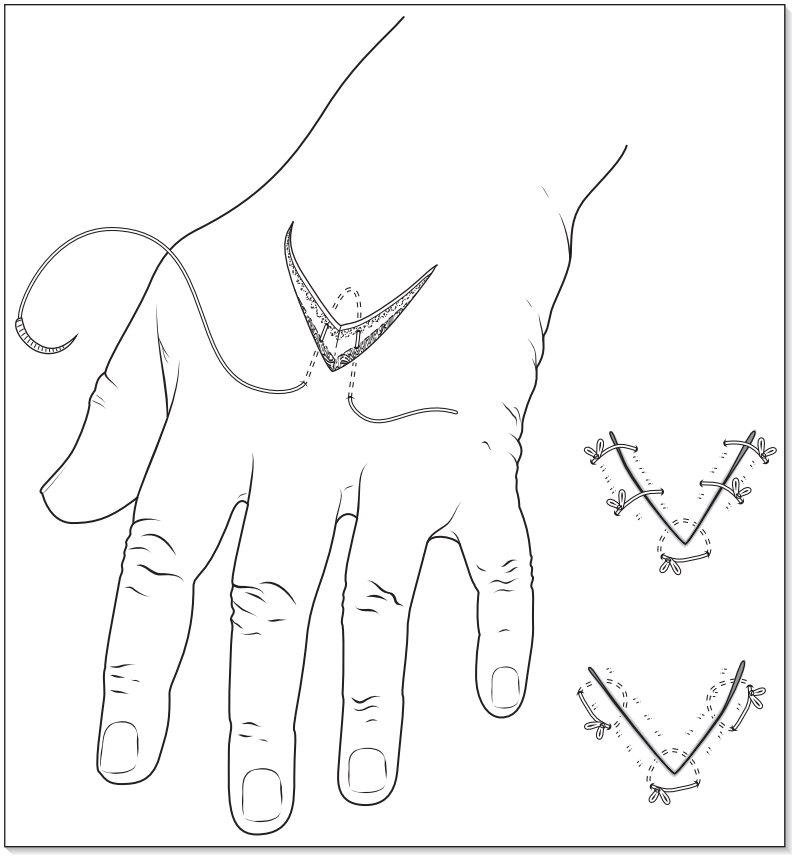

FIG. 3.10.6 Closure of a flap requires an initial suture of the apex, after which either simple or horizontal mattress sutures may be used. (From an original drawing by Elaine Wheildon.)

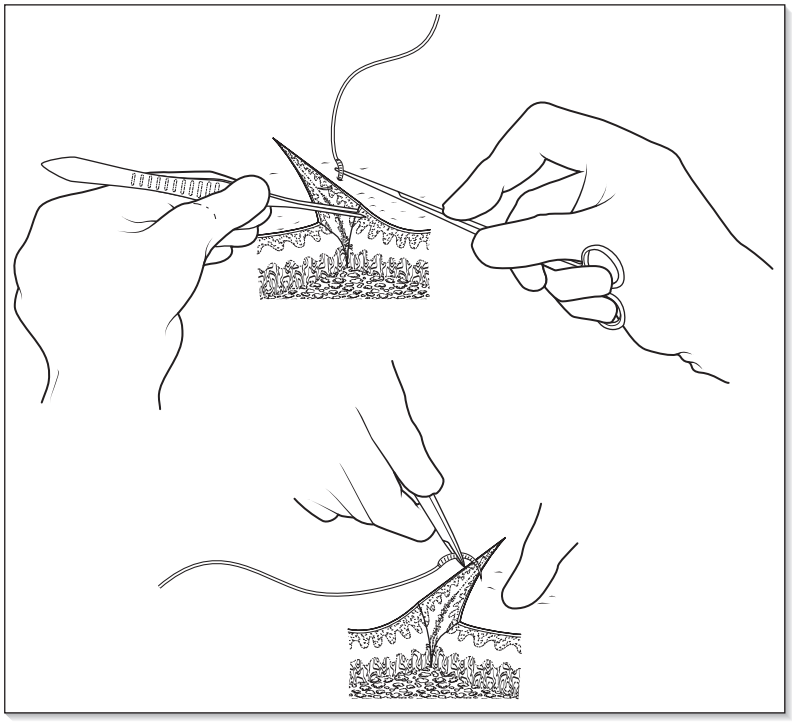

FIG. 3.10.7 When placing a suture, everting the wound edge using Gillies tissue forceps or digital pressure improves the cosmetic result. (From an original drawing by Elaine Wheildon.)

- An elliptical excision of the dog-ear in line with the closure can excise the defect (see Fig. 3.10.13), but this also lengthens the wound.
- In very large dog-ears, a V–Y excision and closure will provide good closure.
- Thick dog-ears that are aligned perpendicularly to the original closure can be excised and closed in a T repair (see Fig. 3.10.13).

Wound drainage

Fluid trapped within the closed wound predisposes to infection by

- progressive loss of opsonins.
- interfering with access of phagocytes to bacteria.
- providing a nutrient medium for bacterial growth.
- putting pressure on adjacent vasculature, thus compromising blood supply.

Fluid also prevents the apposition of healing tissues. The build-up of fluid can be prevented by immobilization, preventing shearing forces between tissue planes, firm but not tight dressings and drainage. The indications for drainage are as follows:

- Dead-space elimination to prevent fluid accumulation (with an active suction drain or a compressive dressing with a passive drain)
- Removal of established fluid collections.

Suction drains are superior to passive drains, which rely on gravity; however, blockage of drain holes and of the drain tube lumen can be a problem. There are many commercial closed suction systems on the market. A simple suction drain can be constructed from a 'butterfly' cannula and a vacuum blood specimen tube (Fig. 3.10.14)[7] by cutting off the syringe adapter and fenestrating the tubing prior to placement through a stab incision into the wound. The vacuum tube can be changed as necessary. Clamp the tube before changing it to prevent the ingress of contaminants into the wound via the drain. Patients with drains will need regular review, either in the ED or by the local doctor. Drains are generally removed at 48 hours unless they are draining copiously.

Dressings

It has long been recognized that the dressing and subsequent wound care are as important as the operative technique.[33] The depths of the wound must be moist for healing, but the skin surface must not become macerated.

The appropriate style of dressing for abrasions is still debated. The 'moist' versus 'dry' debate revolves around saline packs, sterile paraffin, Solugel, seaweed preparations, occlusive plastic film dressings and various foam preparations.

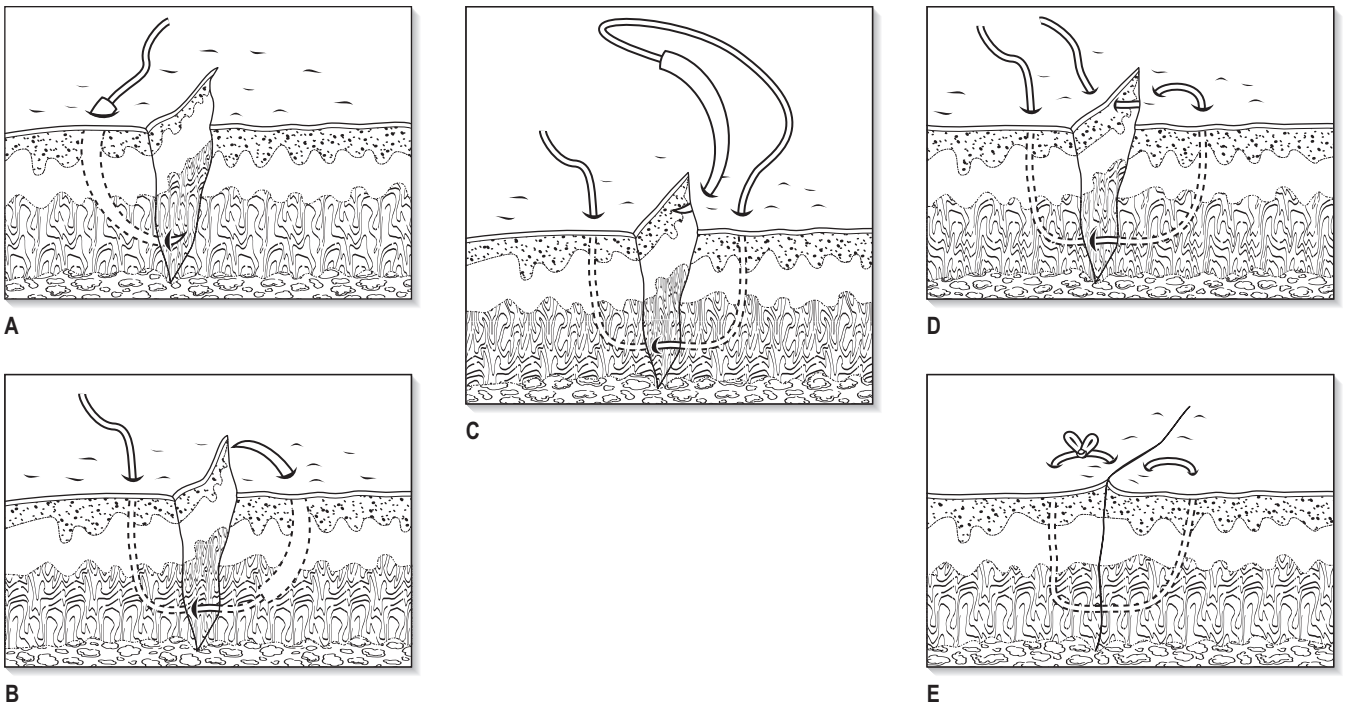

FIG. 3.10.8 (A–E) The vertical mattress suture technique is useful to evert wound edges that have a natural tendency to roll inward despite correctly placed simple sutures. (From an original drawing by Elaine Wheildon.)

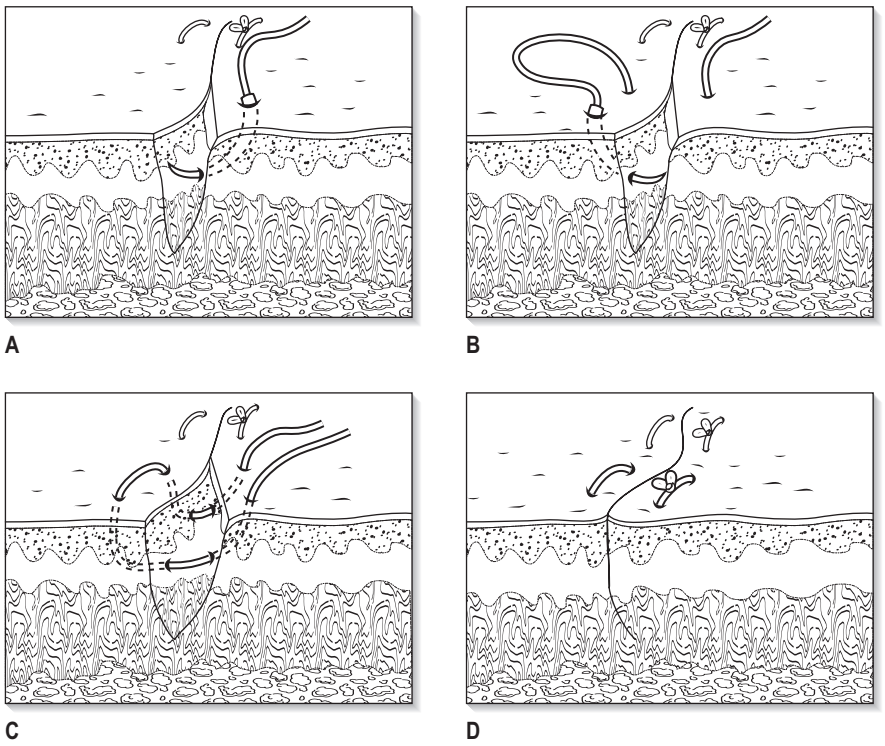

FIG. 3.10.9 (A–D) The horizontal mattress suture redistributes tension and everts wound edges. (From an original drawing by Elaine Wheildon.)

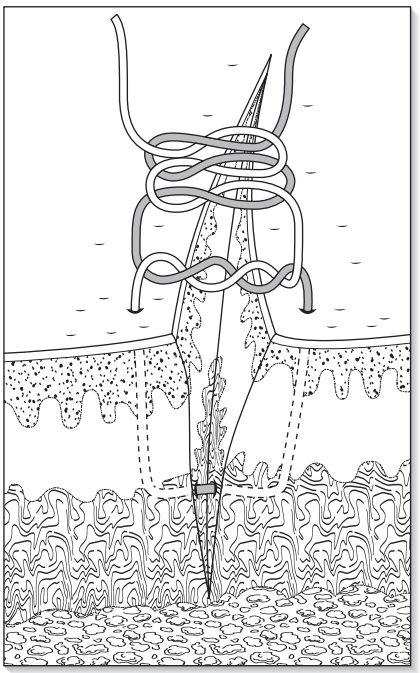

FIG. 3.10.10 The Loop Suture Method of Avoiding Excessive Tension on a Stitch.[16] (From an original drawing by Elaine Wheildon.)

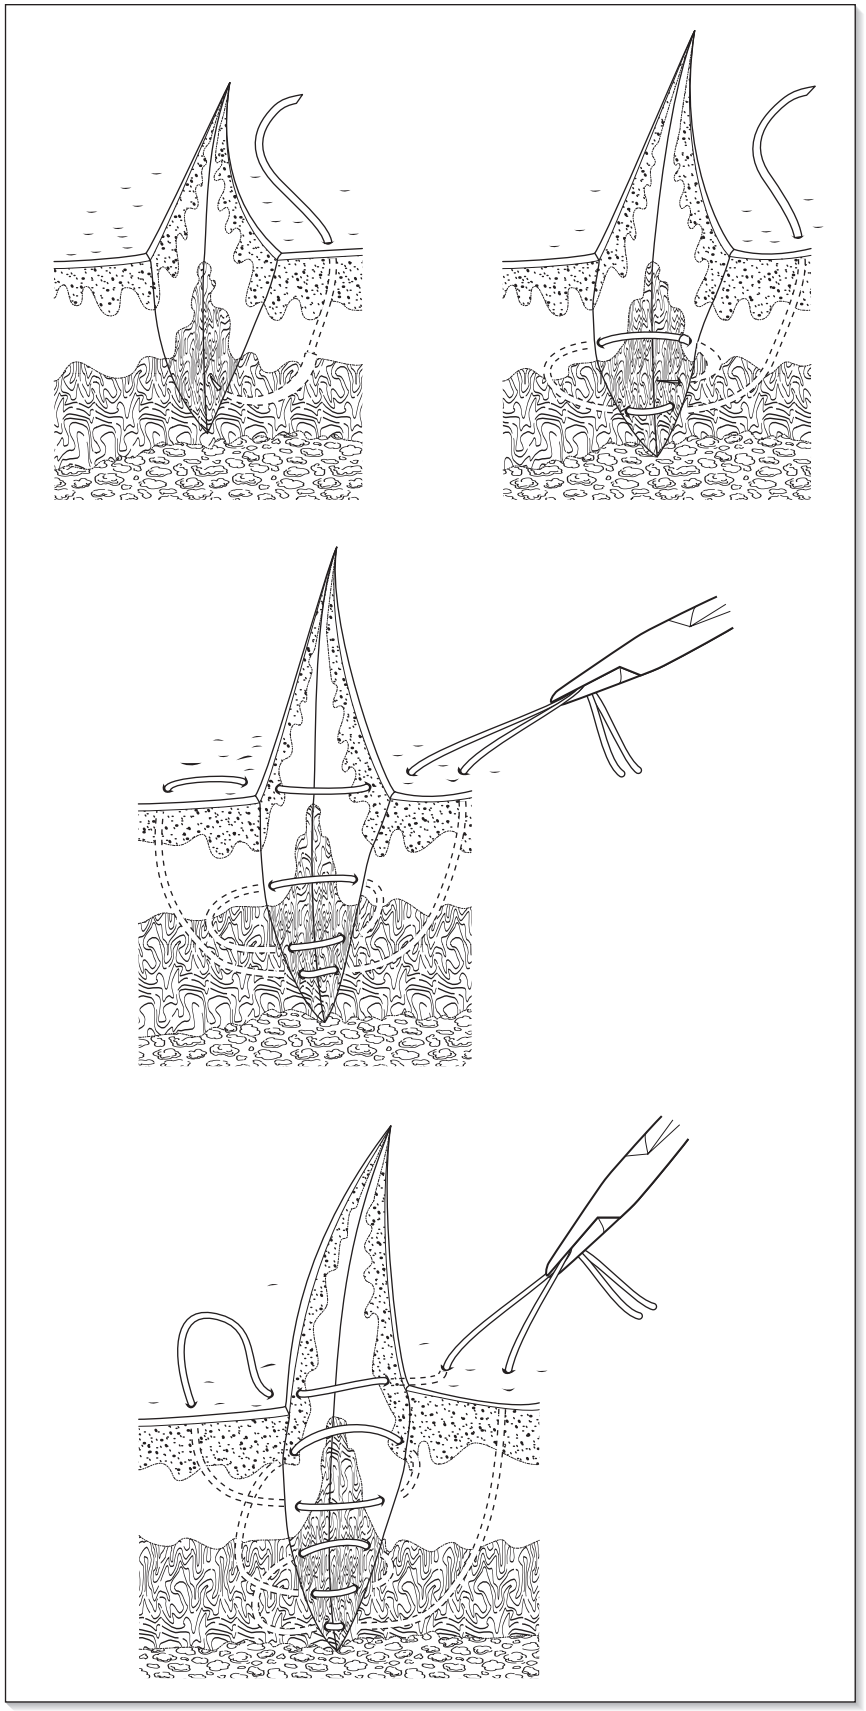

FIG. 3.10.11 A deep closure method utilizing a variable number of loops, modified from a Mayo Clinic stitch.[29] (From an original drawing by Elaine Wheildon.)

Table 3.10.3 Complications of facial wounds

Complications	*Notes*
Infection with the brain	Potentially fatal owing to the valveless venous communication
Arteriovenous fistulae	Due to profuse vascularity—uncommon
Scarring	Producing facial asymmetry and cosmetic implications
Deformity	Due to unrecognized fractures, such as of the nose or malar bone
Facial palsy	Due to damaged facial nerves
Epiphora damage	With tissue loss or scarring everting the lower lid, or canaliculus
Salivary fistula	After disruption of the parotid duct
Drooling	With tissue loss, scar contracture or local nerve damage
Corneal exposure	With tissue loss, scar contracture or local nerve damage

In covering the sutured wound, the dressing aims to keep the primarily apposed skin edges dry, wicking away any ooze, haemorrhage or exudate. It should be changed only if its capacity to absorb fluid is exceeded; ideally, it should stay on until the time of suture removal. Where this is not possible, the wound may be bathed or showered 24 hours after closure provided that it is thoroughly dabbed dry and not immersed and soaked in water. In the case of scalp wounds, this allows showering and hair washing and avoids the problem of fixing a dressing to hairy skin. Wounds that are contaminated and at high risk of infection need review and re-dressing at 48 hours.

Immobilization

Wounds that traverse joints or occur on highly mobile skin, such as in the hand, require immobilization. Splinting with plaster slabs is a cheap, traditional and reliable method. Apart from protecting and stabilizing the wound to allow healing, the splint also reduces the likelihood of infection. If practicable, potentially infected wounds of the upper limbs should be in a sling and elevated to reduce oedema. Lower limbs may be rested using crutches and elevated whenever possible.

Disposal/removal

Despite an apparently good cosmetic result at the time of suture removal (5 to 14 days) (Table 3.10.4), there is evidence of a poor correlation

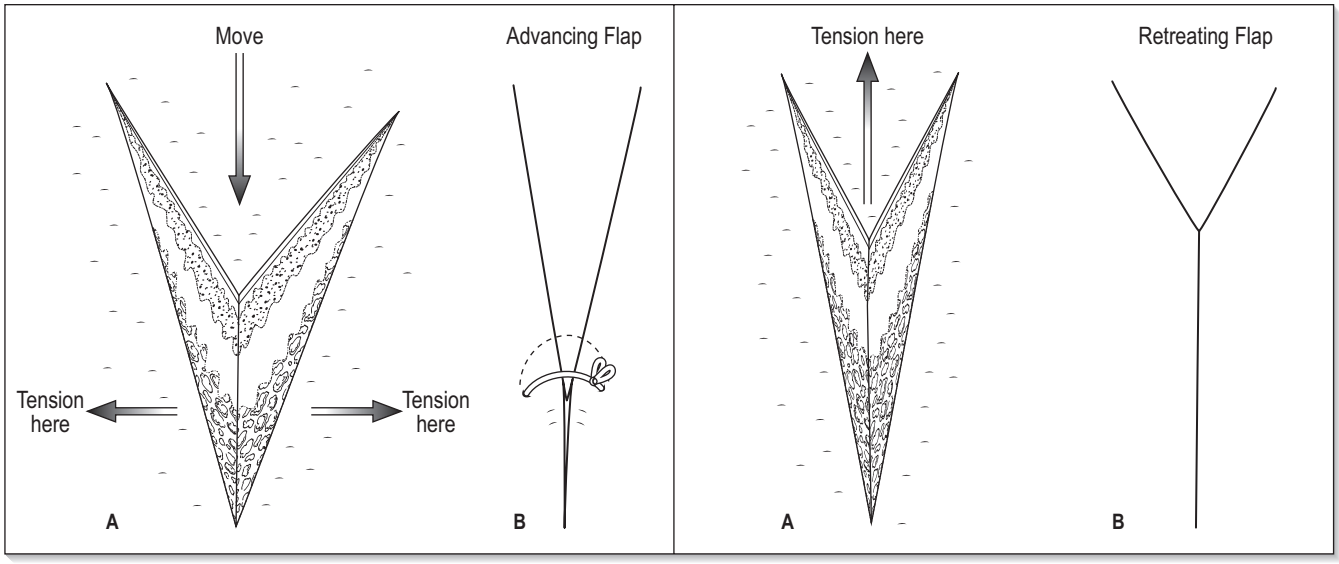

FIG. 3.10.12 The V–Y flap advancement or retreat is useful to redistribute and reduce tension across a wound. (From an original drawing by Elaine Wheildon.)

with wound appearance 6 to 9 months later in head and neck wounds.[34] The degree to which different factors—such as wounding mechanism, wound repair technique and patient host factors—have a role remains to be determined. Keloid or hypertrophic scarring is more common in negroid and Asian races and in wounds located over the deltoid muscle or sternum.

All percutaneous stitches will cause needle marks if left in situ longer than 8 days, as epithelium migrates down the needle track. Removal too early predisposes to wound

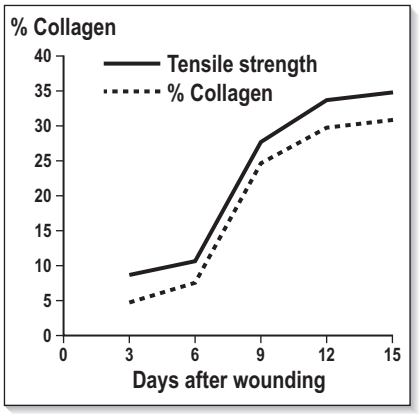

FIG. 3.10.15 The Relationship Between Tensile Strength and Collagen Deposition. (From an original drawing by Elaine Wheildon.)

dehiscence (Fig. 3.10.15); however, the wound may be supported by skin tapes. If tapes were the primary method of closure, they may be left on for at least 10 days or until they fall off provided that the skin is not sensitive to the adhesive, as evidenced by erythema or bulla formation.

Suture removal technique is also important. To avoid tissue trauma and additional scarring, stitches should be cut at the knots with iris scissors after gentle washing with saline to remove the eschar and the suture gently pulled through. So-called suture scissors are actually too big for the task.

CONTROVERSIES

- Drainage will remove fluid and haematoma that potentiate infection, but the drain itself may predispose to infection. This is less the case with suction drains.
- Interrupted dermal sutures will close dead space, thereby reducing haematoma and wound infection, but they may lead to infection in contaminated wounds. Their major role is to reduce skin tension, and they should be used in large clean wounds.
- The degree of debridement required for a dirty wound has moved from radical to conservative but meticulous, with an emphasis on preservation of viable skin to improve cosmesis.
- Povidone-iodine packs, which are tissue-toxic, are used by some surgeons in the setting of open wounds over compound fractures while the patient awaits transfer to the operating theatre for definitive repair.
- Opinions as to the appropriate dressings for abrasions vary, ranging from moist, such as plastic film, to dry, such as mercurochrome paint and dry gauze.

Inelastic paper tape can be used to support a wound and help stop the scar from stretching until such time as the collagen is near maturation, beyond 3 months. Paper tape is also useful in the setting of keloid scarring in an attempt to provide pressure and encourage remodelling. In some cases, silicone gel pads and even pressure garments are required to control keloid scarring.

If the wound suppurates, then the sutures will have to be removed, either partly or completely, to allow the egress of pus.

Likely developments over the next 5 to 10 years

A lot of work is being done on knotless wound-closure devices, which will speed up suturing by eliminating the need for knot tying.

With surgical wounds, there are new developments with absorbable staples and fast-setting cyanoacrylate.

3.11 Burns

Gerard O'Reilly • Biswadev Mitra

ESSENTIALS

1 **Effective triage and advances in the treatment of severely burned patients, including judicious fluid resuscitation, control of sepsis, early excision and use of skin substitutes, have made previously lethal burns survivable.**

2 **Signs of impending or developed laryngeal oedema should prompt early intubation.**

3 **Burn resuscitation formulae should be considered as a guide only.**

4 **Meta-analysis of previous studies suggests that resuscitation with colloid as compared with crystalloid does not improve survival.**

5 **Extensive or complicated burns should be managed in a specialised burns unit.**

6 **Chemical burns, after decontamination and specific antidotes, are treated in a similar fashion to thermal burns.**

Introduction

Advances in burn management over the last three decades have significantly reduced mortality and improved quality of life for victims. As a result of appropriate fluid resuscitation, early debridement and the appropriate use of antibiotics, hypovolaemia and sepsis are no longer the major contributors to mortality in burns. Multiorgan failure is the most likely event leading to death, whereas age, burn surface area, inhalation injury and female sex are the major contributors to a poor outcome.[1,2]

Pathophysiology

The skin is the largest organ of the body. Its most important functions are

- to act as a vapour barrier, preventing water loss from the body.
- to serve as the body's major barrier against infection.
- to regulate temperature.

The skin consists of two main layers, epidermis and dermis. The epidermis comprises stratified squamous epithelium that acts as the major barrier to passive water loss from the body. The dermis contains the adnexal structures – namely sweat glands, hair follicles and sebaceous glands – as well as pain and pressure receptors and the cutaneous blood vessels, which play a major role in temperature regulation by controlling the loss of radiant heat (Fig. 3.11.1).

The adnexae are embryologic down-growths of the epidermis. Following burn injury, the epithelial cells of these structures undergo metaplastic change to stratified squamous epithelium; they proliferate and gradually cover the wound. Thus burns that partially or completely spare these structures will usually heal without scarring. Deeper burns involve greater loss of adnexal cells, resulting in poorer epithelial coverage and hence greater scarring.

Burned skin undergoes coagulative necrosis, with three distinct zones of injury. A central zone of coagulation, in which irreversible cell death occurs, is surrounded by a zone of stasis, in which vasoconstriction and intravascular coagulation contribute to local ischaemia. A zone of hyperaemia surrounds the wound. In the early stages of the burn, evolution of these zones results in a progressive deepening of the wound, which may be minimized by appropriate early treatment.[3]

Classification

Burns are classified as either epidermal, partial thickness (with sub-categories of superficial, mid-dermal and deep) and full thickness.[4] Superficial burns involve only the epidermis. Pain and swelling usually subside within 48 hours, and the superficial epidermis peels off within a few days. Healing occurs by the proliferation of undamaged cells of the germinal layer of the epidermis and is usually complete within 7 days.

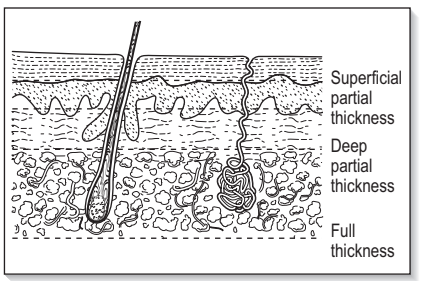

FIG. 3.11.1 Diagram of the Layers of the Skin.

Partial-thickness burns involve destruction of the epidermis and superficial dermis. They are characterized by blister formation and may be further classified into superficial, mid-dermal and deep. Healing is dependent on the amount of intact epithelium in the adnexae. Wounds of mid-dermal burn depth are by definition difficult to assess in the first few days following injury; even experienced clinicians are correct only 67% of the time.[5]

Superficial partial-thickness burns are typically bright red with a moist surface, are exquisitely sensitive to stimulus and heal in 2 to 3 weeks, generally with minimal scarring. Deep partial-thickness burns are typically dark red or yellow-white and take longer than 3 weeks to heal, as few epithelial elements survive. Hypertrophic scarring usually occurs.

Full-thickness burns involve the epidermis and dermis, including the epidermal appendages. Clinically they appear charred or pearly white in appearance and are usually insensate. Because loss of epidermal adnexae is complete, full-thickness burns heal only by scarring or skin grafting.

THERMAL BURNS

Presentation

History

History may be obtained from the patient, from witnesses and from fire or ambulance personnel. Details of the nature of the injury are important, especially the nature of the burning materials, duration of exposure, whether the patient was trapped in an enclosed space or lost consciousness or whether there was an associated fall, vehicular accident or blast injury.

A history of altered consciousness or confinement in a burning environment suggests the likelihood of carbon-monoxide poisoning. Past medical history, current medications, allergies and tetanus status should also be obtained.

Examination

The initial examination should be directed to identifying signs suggestive of airway burns as well as the presence of other injuries. Early

haemodynamic compromise is rarely due to burn injury alone and should prompt a search for other causes.

Facial and oral burns, singed nasal hairs, carbonaceous sputum, tachypnoea and wheeze are clinical signs suggesting an increased risk of inhalation injury; however, in the absence of laryngeal oedema, inhalation injury may not become clinically evident for 12 to 24 hours.[6]

Signs of laryngeal oedema—hoarseness, brassy cough or stridor—indicate the need for early endotracheal intubation, as oedema formation may rapidly distort the anatomy, necessitating a surgical airway.

The adequacy of the peripheral circulation should be assessed, particularly in the setting of circumferential limb burns.

Evaluation of burn area

The extent and depth of the burn must be assessed as accurately as possible. Representation of the burn area diagrammatically on a body chart aids assessment. The simplest method is the 'rule of nines', where the adult body is divided into anatomical regions that represent 9% of the total body surface area.

In infants and young children, the Lund and Browder chart is used to correct for proportional variation at different ages: for instance, the surface area of the head of a 1-year-old child is approximately 18% of the total body surface area, compared with 9% in an adult (Fig. 3.11.2).

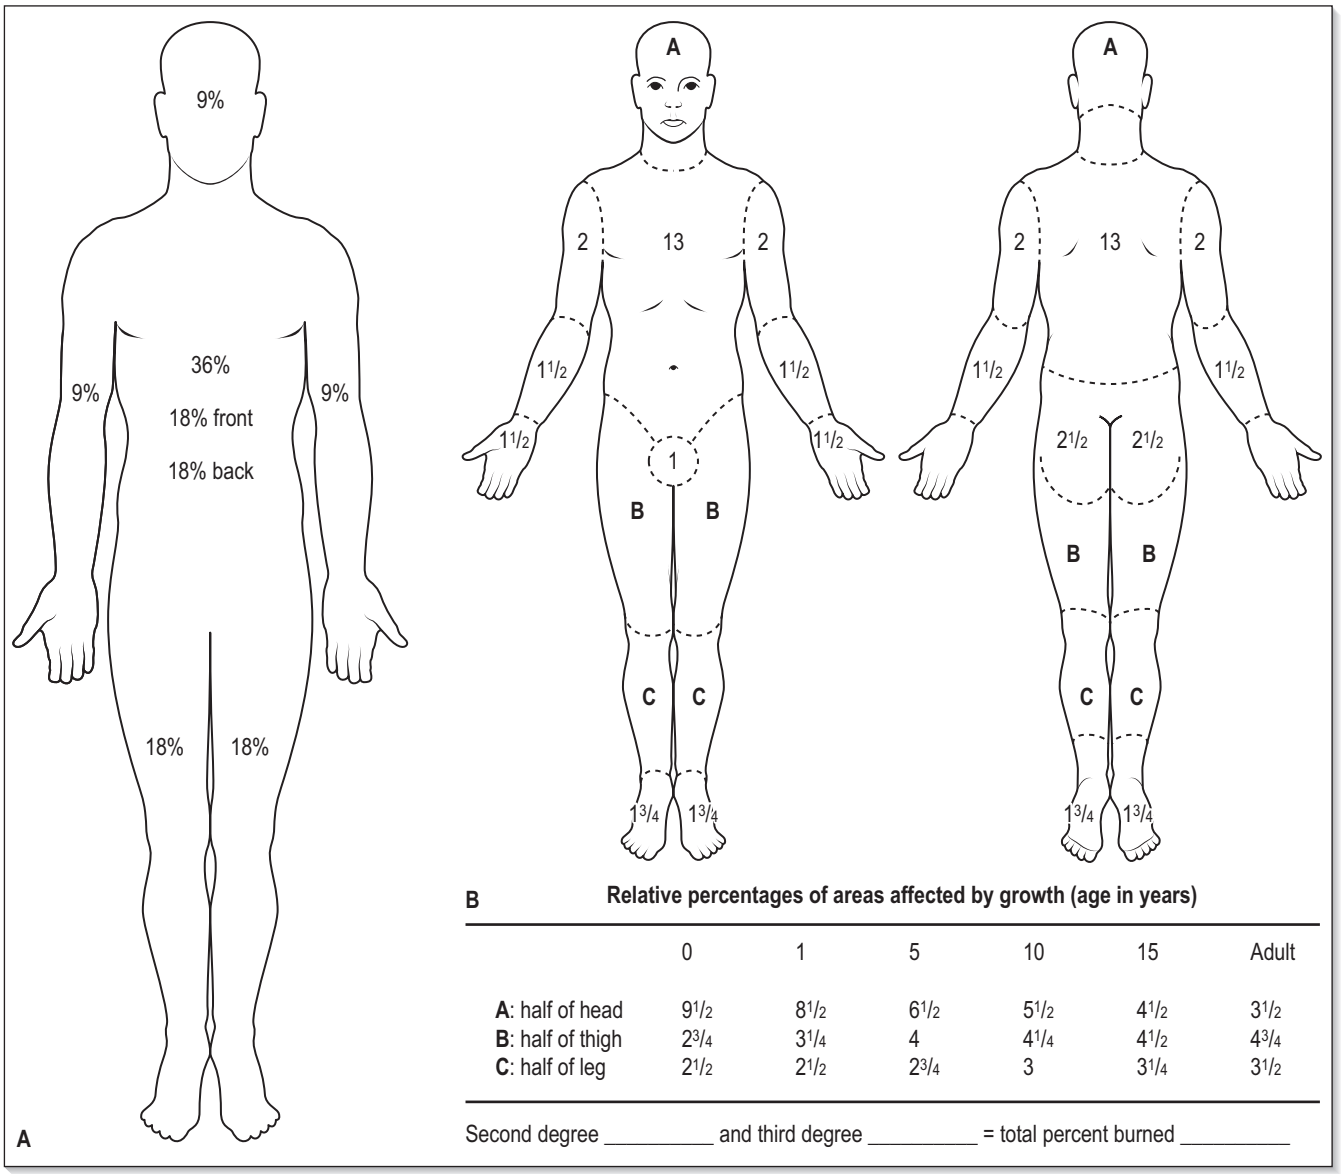
The palmar method can be used to estimate the size of smaller burns, where the palm of the patient (not the examiner) is equal to 1% of the total body surface area (TBSA).

Management

Pre-hospital

Pre-hospital care of the burned patient should be directed at stopping the burning process, assessing and stabilizing the airway, breathing and circulation and rapidly transferring the patient to hospital. Where possible, major burns should be triaged to a burn centre (Table 3.11.1).

If practical, 20 minutes of cool running water is most beneficial for partial thickness burns. En route to hospital, recent burns should be covered with a clean dry dressing or plastic cling film wrap so as to limit the depth of burn by dissipation of



B **Relative percentages of areas affected by growth (age in years)**

	0	1	5	10	15	Adult
A: half of head	9 1/2	8 1/2	6 1/2	5 1/2	4 1/2	3 1/2

C: half of leg	2 1/2	2 1/2	2 3/4	3	3 1/4	3 1/2

Second degree _____ and third degree _____ = total percent burned _____

FIG. 3.11.2 (A) 'Rule of nines' diagram. (B) Lund and Browder chart.

Table 3.11.1 Patients who fulfill the following criteria should be considered for transfer to a specialist burns unit

Partial-thickness burns >20% in all age groups or >10% in the <10 and >50 age groups
Full-thickness burns >5% in any age group
Burns involving face, eyes, ears, hands, feet, genitalia, perineum or a major joint
Inhalation burns
Electrical burns, including lightning injury
Burns associated with other significant injuries
Smaller burns in patients with pre-existing disease that could complicate management

heat. Prolonged exposure to cool water should be avoided and ice should never be applied directly to the wound as it may increase the depth of the burn.

The patient should be kept warm, supplemental oxygen administered and, where prolonged transport times are anticipated, intravenous fluid therapy instituted.

Emergency department

Initial management

Supplemental oxygen should be administered and cardiac and oxygen saturation monitoring instituted.

Stabilization of the airway and treatment of life-threatening injuries take priority over management of the burn wound itself. Burns to the face, neck and airways result in massive fluid shifts from the circulating plasma into the interstitial space, causing oedema and potentially resulting in rapid upper airway obstruction. Immediate intubation is indicated in apnoea or obstruction. Other indications for immediate intubation are the same as for any critically injured patient, including actual or impending cardiac arrest, impending respiratory failure and a decreased level of consciousness with inability to protect the airway.

Early intubation is indicated in burns to the face and neck where it is anticipated that oedema will make intubation difficult in the future or to facilitate initial pain and operative management. The nasal route is preferable in the presence of friable burnt oral tissue but requires a spontaneously breathing patient. The choice of an inducing agent is varied, with thiopentone or propofol appropriate in haemodynamically stable patients. Succinylcholine may be used in the first 24 hours, but in later periods it has been associated with catastrophic potassium release leading to possible cardiac arrest and is best avoided. Non-depolarizing muscle relaxants are preferred; however, the dose required may increase to 3 to 5 times normal. Uncut endotracheal tubes should be used and meticulously secured.[7]

Airway patency alone does not guarantee adequate ventilation. Fumes and minute particles produced by the fire may cause bronchospasm, which can be treated with inhaled bronchodilators. Smoke particles also cause inflammation, hypersecretion and mucosal sloughing, resulting in airway obstruction and atelectasis. Carbon monoxide (CO) poisoning should be suspected in anyone with a history of smoke exposure, an extended length of time in the fire or burns in an enclosed space. The features of CO poisoning include tachypnoea, tachycardia, vomiting, confusion and irritability, cherry-red colour of the mucous membranes, a reduced conscious state and syncope. Oxygen saturation measured by pulse oximetry is not helpful in diagnosing CO toxicity, although recently developed oximetry devices display carboxyhaemoglobin levels. Blood gases and carboxyhaemoglobin levels aid in diagnosis. An admission carboxyhaemoglobin level greater than 15% suggests significant smoke inhalation. The affinity of CO for haemoglobin is substantially more than that for oxygen, with a slow dissociation half-life of 3 to 4 hours. Administration of high concentrations of oxygen can decrease the dissociation half-life to 50 minutes.

Cyanide poisoning can result from thermal decomposition of natural fibres, such as wool and silk, and manifests as persistent lactic acidosis with a high anion gap. Cyanide levels may help to confirm the diagnosis in retrospect but are not useful in the acute setting due to long turnaround times in most hospital laboratories. Cyanide antidotes commonly available include the following[8]:

- Dicobalt edetate and hydroxocobalamin (this combination should be used if severe cyanide poisoning is suspected due to toxic adverse effects of the cobalt salt).
- Hydroxocobalamin and thiosulfate, but not in the same infusion.
- Methaemoglobin generators, but these are contraindicated in the setting of smoke inhalation.

Where hydroxocobalamin is not available, sodium thiosulfate with oxygen may be sufficient for mild to moderate cases Ventilation difficulties due to lung parenchymal damage from burns share a similar pathophysiology to the development of acute respiratory distress syndrome (ARDS). The onset is generally slow, and this may be an issue in delayed presentations. An exception is blast injury, which can cause lung contusions and alveolar trauma leading to ARDS. The most effective initial treatment is the application of positive end-expiration pressure (PEEP). The mechanism by which PEEP improves oxygenation is linked to the increase in residual functional capacity (RFC) obtained both by increasing the volume of partially collapsed alveoli and by reopening totally collapsed alveoli.

Fluid Resuscitation[7]

Intravenous fluid resuscitation with crystalloid solution, as outlined further on, should be started in any patient with burns of more than 20% TBSA. There are many formulae for the fluid resuscitation of burns victims. Although considerable debate continues, the general principles of fluid resuscitation are as follows:

- In the first 24 hours, isotonic salt solution should be used to replace the large volumes lost to tissue oedema, with about half the fluid given in the first 8 hours after injury, coincident with the period of most rapid oedema formation.
- The administration of colloid is unnecessary for patients with burns of less than 40% TBSA and during the first 8 hours.
- Fluid resuscitation formulae are a guide only; the patient's haemodynamic status must be monitored by cardiovascular parameters and hourly urine volume measurement. Increased resuscitation fluid volume (per kilogram) is required in children weighing less than 30 kg, in high-voltage electrical injuries, if resuscitation is delayed and in the presence of inhalation injury.

The initial goal of fluid resuscitation is the restoration of cardiac output and tissue perfusion. Multiple formulae estimating the initial fluid requirement in patients with major burns have been proposed, including the Brooke, modified Brooke, Parkland, Evans, Massachusetts General Hospital (MGH) and Monafo regimens. These formulae use the patient's weight and the percentage of body surface area burnt to estimate fluid requirements. The percentage of body surface area burnt can be easily estimated using a Lund and Browder chart. Weight should be measured, if possible, or estimated from collateral history. The Parkland formula allows for 4 mL/kg over 24 hours per percent of TBSA burned, with half the total fluid requirement to be given in the first 8 hours. In children under 30 kg, this fluid should be given in addition to calculated maintenance fluid.

The proposed formula of *weight in kg × %TBSA mL* of fluid in the first 2 hours post-injury is approximately double that estimated by the Parkland formula and leads to maintenance of resuscitation end points without obvious adverse events. This strategy has also been adopted in the pre-hospital phase and must be followed by goal-directed management to maintain adequate resuscitation.[9] Haemodynamic status may be difficult to evaluate in the severely burned patient. In patients with severe burns, the insertion of a central venous catheter allows the measurements of preload, tissue oxygenation via central venous oxygen levels, contractility and coronary

perfusion pressure and may facilitate the measurement of afterload. Additional measures of tissue oxygenation are obtained by serial serum lactate measurements and monitoring urine output via an indwelling catheter. Inserting a urinary catheter with an electronic temperature probe will assist in monitoring core temperature.

Hypertonic saline solution may be useful in patients with limited cardiopulmonary reserve and in those with severe burns; however, there is considerable debate over the safety of this technique and, again, there is limited evidence of outcome benefit compared to isotonic solution.[10]

Subsequent management

Having stabilized the patient and initiated fluid resuscitation, a careful secondary survey should be performed looking for associated injuries.

Adequate analgesia is an important facet of management. Small burns may be managed with a combination of cool compresses and oral analgesia; larger burns will require parenteral analgesia. Opiates will generally be the first option; an infusion of ketamine can be useful for continuous analgesia where there are extensive burns.

Burn patients lose heat quickly. Wrapping the patient in blankets, foil or external warming devices may prevent hypothermia.

Simple initial management of the wound with cling-wrap is adequate in providing analgesia, protection from the environment and allowing visualization of pathological appearance (E-Fig. 3.11.1). Early definitive surgical therapy with excision and autologous skin grafting is currently widely practised for deep burns and constricting eschars. Tangential escharectomies remove much of the necrotic tissue while leaving behind healthy tissue. Peripheries with circumferential burns are at a high risk of ischaemic necrosis and warrant urgent escharotomy. Such procedures can be undertaken in the emergency department when pulses are absent. In circumferential chest burns, escharotomy may be necessary to relieve chest wall restriction and improve ventilation. Routine fluorescein staining and examination of the eye in cases of facial burns result in the early diagnosis and treatment of corneal burns.

Tetanus following burn injury has been previously reported. A tetanus vaccine booster is recommended for all patients with no history of tetanus vaccination in the last 10 years. Tetanus immunoglobulin should be considered in wounds grossly contaminated with soil. Systemic prophylactic antibiotics are not indicated. Although there have been some suggestions of administering antibiotics to prevent toxic shock syndrome, its incidence is low and routine prophylaxis for all burnt patients is not warranted. Antibiotics in the immunocompromised patient should be considered on an individual basis.

Burn shock

The pathophysiology of burn shock is complex and involves a combination of haemodynamic and local tissue factors.

The early post-burn period (i.e. within the first 8 hours) is marked by the rapid formation of tissue oedema, predominantly in the wound itself but also in non-burned tissue. Factors contributing to this fluid accumulation are not fully understood but include local release of inflammatory mediators, particularly prostaglandins and leukotrienes. These increase capillary permeability both locally and systemically in addition to increasing regional blood flow. Increased interstitial osmotic pressure in burned tissue due to the release of osmotically active cellular components and the partial degradation of collagen also contributes to tissue oedema. The combination of tissue injury, shock and dilution of coagulation factors through exogenous fluid administration leads to coagulopathy in about one-third of the victims of major burns.

Major evaporative loss from burned skin due to loss of epithelial integrity significantly adds to fluid losses. In addition to the fluid shifts, cardiac output may fall by 30% to 50% in major burns, possibly due to a circulating myocardial depressant factor.

Inhalation injury

The presence of inhalation injury has a considerable negative impact on prognosis in the burn patient. Direct thermal trauma below the larynx is rare except in the case of steam inhalation.

Pulmonary complications are largely due to the inhalation of toxic products of combustion, particularly in house or vehicular fires. Smoke consists of a particulate fraction – predominantly carbon – and a gaseous fraction, which may include carbon dioxide, carbon monoxide, oxides of nitrogen and sulphur, hydrogen cyanide and polyvinyl chloride, depending on the materials being burnt. These agents adhere to the moist respiratory mucosa, forming corrosive compounds that cause inflammation, hypersecretion and mucosal sloughing, a process leading to airway obstruction and atelectasis. Smoke inhalation also triggers the release of thromboxane, resulting in increased pulmonary artery pressures.

Disposition

Patients with major burns should be managed in a specialist burns unit as outlined in Table 3.11.1. The patient should be discussed with the receiving unit prior to transfer, so that appropriate measures may be undertaken to stabilize him or her. Plastic cling wrap applied directly over the burn for inter-hospital transfer provides a good non-adherent dressing that will reduce the loss of heat and fluid. As noted previously, silver sulphadiazine (SSD) cream should not be applied to these burns as it interferes with subsequent evaluation. Modern wound care products have changed considerably over the past years and there are many different ones that are suitable for treating minor burn wounds. There is no high-quality evidence that identifies one particular dressing as better than other, and it is not possible to draw any strong conclusions of the efficacy of one dressing over another. The choice of dressing for minor burn wounds should be guided by local guidelines.

Current management of full- and deep partial-thickness burns involves early excision and autologous skin grafting. In extensive burns, excision and autologous grafting may need to be staged, allowing time for sufficient skin to regenerate.

Less extensive burns (i.e. not meeting the criteria for burns centre transfer) may be admitted to a general or plastic surgery service. Loose skin and broken blisters should always be debrided. Blisters may otherwise be initially left intact, although some would advocate that all blisters be deroofed.

Superficial or partial-thickness burns involving less than 10% TBSA may be suitable for outpatient management subject to the criteria in Table 3.11.1 and depending on the social and psychological status of the patient. The choice of dressings for outpatient management depends on the depth of the burn, the extent and size of blisters and the amount of exudate from the burn surface.[4,7]

Superficial burns can also be covered with a moist ointment (e.g. paraffin-based Dermeze) or moist dressing (e.g. Burnaid, which contains melaleuca-derived local anaesthetic properties). Superficial partial-thickness burns involve loss of epithelium with considerable exudate and hence are prone to infection. These patients will need to be reviewed the next day, at which time the dressing will be changed. Silicone dressings allow removal without trauma to the surrounding skin but are non-absorbent. Foam dressings present an alternative and can absorb water while maintaining a moist interface at the wound surface. Alginate dressings are highly absorbent, biodegradable products derived from seaweed that are used to absorb wound exudate. Gel dressings are predominantly made of water and are designed to donate moisture to the wound. They are useful for dry wounds. Hydrocolloid dressings are self-adhering wafer-style dressings that can absorb exudate and maintain a moist wound-healing environment; they are useful for lightly to moderately exuding wounds.

Epithelialization commences at 7 to 10 days, by which time the burn surface should be drying out. At this stage, the more convenient hydrocolloid or film dressings may be used until epithelialization is complete.

If healing is not well established by 10 to 14 days, the patient should be referred for specialist opinion, as excision and grafting may be required.

Chemical burns

A wide range of products available in both the industrial and domestic environments can lead to burns. Although the mechanism is different, chemical burns demonstrate a similar spectrum of injury to thermal burns. Superficial burns are associated with itching, burning or pain; partial-thickness burns are associated with tissue oedema and the formation of bullae; and full-thickness burns are associated with damage extending through the dermis. The extent of tissue damage in chemical burns is determined by the nature and concentration of the chemical as well as the extent and duration of contact.

In addition to the burn itself, toxicity may occur as a result of systemic absorption.

The majority of chemical burns are caused by acids and alkalis. Acids cause coagulation, with the formation of a tough eschar that may limit further tissue damage. Alkalis cause liquefactive necrosis, allowing deeper penetration. There are many types of chemical that cause burns, but distinguishing between them by mechanism of action is not relevant to the clinician, as their management, apart from a few exceptions, is similar.

General principles

Chemical agents continue to damage tissue until they are removed or inactivated. Therapy then is directed to decontamination and, where appropriate, the use of specific antidotes as well as recognition and treatment of systemic toxicity.

Adequate protection of medical personnel to prevent secondary contamination is essential. Copious irrigation is the cornerstone of therapy, but contaminated garments should be removed and dry chemical particles brushed away before irrigation commences. Adherent or oily compounds may need to be removed with mild soap and a scrubbing brush; nails, hair and intertriginous areas should be carefully checked.

The duration of irrigation depends on the agent. Alkali burns in particular may require prolonged lavage owing to its tissue penetration. The use of litmus paper to determine wound pH may guide the duration of irrigation in acid and alkali burns.

Other than decontamination and treatment of systemic toxicity, management is similar to that of thermal burns.

Disposition

Most patients with chemical burns can be treated on an outpatient basis. Indications for admission include

- partial-thickness burns >15% TBSA.
- all full-thickness burns.
- burns involving hands, feet, eyes, ears or perineum.
- evidence of or potential for systemic toxicity.
- significant associated injuries or complicating medical conditions.

3.12 Massive transfusion

Biswadev Mitra

ESSENTIALS

1 Early prediction of massive transfusion and activation of massive transfusion guidelines can ease some of challenges of resuscitation.

2 Systems should be instituted for effective prenotification of patients at risk of massive transfusion and a team-based approach to resuscitation planned, with the emergency physician as the team leader.

3 Laboratory tests may require a considerable amount of time to provide results and are not always reliable in the setting of acidosis, hypothermia and ongoing bleeding.

4 It is recommended that massive transfusion guidelines be developed and followed in all centres expected to receive haemorrhaging patients.

5 Patients with coagulopathy in the setting of massive transfusion have been shown to be four times more likely to die than those without.

What is a massive transfusion?

A 70-kg male has an average circulating volume of 5 L of whole blood. Assuming a haematocrit of 0.40 to 0.50, this approximates to a red cell volume of just over 2 to 2.5 L. A leucocyte-depleted unit of red blood cells, as distributed by the Australian Red Cross Blood Service, has a volume of 250 to 300 mL with a haematocrit of 0.50 to 0.70. The traditional definition of massive transfusion (MT) of at least 10 units of packed red blood cells (PRBCs) transfused in the first 24 hours was approximated from the total red cell volume in a 70-kg man. More recently, this definition has been challenged as being under-representative of patients during the acute resuscitative phase,[1,2] as patients who die prior to receiving 10 units

E-FIG. 3.11.1 Simple Pre-hospital Dressing of Major Burns.

of red cells are excluded (mortality bias), as are patients whose transfusion requirements may not reach 10 units, while including patients who may not require transfusion during the acute resuscitative phase but are transfused later, secondary to surgical procedures or complications of management. Definitions using lower volumes of PRBCs in shorter times, such as at least 5 units in 4 hours or greater than 10 units in 6 hours, have also been used.[3,4]

The definition of MT can be used to alert the clinician and blood bank to a massively haemorrhaging patient. A secondary use of the definition of 'massive' *transfusion* lies in transfusion research for selecting patients for prospective or retrospective studies to establish the guidelines for MT and has little use in clinical practice. Some prospective studies on MT have appropriately selected patients based on perceived need rather than a predetermined definition.[5,6] However, most retrospective studies of the components of a MT guideline have used the traditional definition of MT as the inclusion criterion. For these guidelines to be useful, a clinician must anticipate the patients who are likely to suffer with a certain level of blood loss over a specified time frame.

The volume of red blood cells transfused is associated with the rate of mortality.[7] There are a number of clinical and ethical reasons for reducing the volume of blood transfusions during resuscitation. Blood is a scarce resource and significant costs are associated with the administration of blood banks. Transfusion of blood has also been associated with multiple adverse effects. Independent of shock severity, blood transfusion is a risk factor for mortality. Blood transfusions are independently associated with an increased incidence of acute respiratory distress syndrome (ARDS), and the volume of transfusion has a dose response with the later development of multi-organ failure. Rarer risks associated with transfusions include minor allergic reaction, blood-borne viral infections, bacterial infection, anaphylactic shock, clinically significant immunosuppression and graft-versus-host disease.

The adverse clinical risks of transfusion and the limited supply of blood have resulted in a trend in modern resuscitation protocols to limit the volume of blood transfused. Appropriate use of blood in the reception and resuscitation of the massively haemorrhaging patient can be achieved by the early definitive control of haemorrhage, restrictive transfusion practice in select patients, external warming and correction of coagulopathy.

Predicting massive transfusion

MT post-injury is relatively infrequent but presents major challenges to emergency departments (EDs) and blood banks. It is important to note that the most common indication for MT in the ED in non-trauma centres is for patients with gastrointestinal haemorrhage. In the hectic phase of reception and resuscitation of patients with critical bleeding, in addition to diagnosis and management of the underlying pathology, the complex processes of rapid checking and delivery of blood products, monitoring of accurate ratios and, later, goal-directed management of coagulopathy must occur. Early prediction of MT and activation of MT protocols can ease some of these challenges, leading to the formulation of several predictive scoring tools (Table 3.12.1).

The primary utility of current predictors of MT is in situations involving mass casualties or combat, although in those scenarios it might result in directing limited resources away from patients with higher scores, just the opposite of its purpose in civilian trauma care. When MT is used clinically, the primary benefit in scoring is the ability to select accurately patients who will receive transfusions because of the high specificity of their scores. This makes it possible for blood and products to be supplied with minimal wastage. However, owing to the current low sensitivity of the scores, a high clinical suspicion must be maintained for all patients and MT protocols promptly activated where clinically indicated.

Table 3.12.1 Examples of scores to predict massive transfusion

PWH score		*ABC score*		*TASH score*	
Criteria	***Score***	***Criteria***	***Score***	***Criteria***	***Score***
SBP ≥90 mmHg	3	Penetrating mechanism	1	Hb <7 g/dL	8
GCS ≤8	1	SBP <90 mmHg	1	Hb <9 g/dL	6
HR ≥120 beats/min	1	HR >120 beats/min	1	Hb <10 g/dL	4
Displaced pelvic fracture	1	Positive FAST	1	Hb <11 g/dL	3
CT scan or FAST positive	2			Hb <12 g/dL	2
BD >5 mmol/L	1			Base excess <−10	4
Hb <7 g/dL	10[a]			Base excess <−6	3
Hb 7.0–10 g/dL	1			Base excess <−2	1
				HR >120 beats/min	2
				Free abdominal fluid	3
				Clinically unstable pelvic fracture	6
				Open or dislocated femur fracture	3
				Male gender	1
Maximum score	10	Maximal score	4	Maximal score	29
Cutoff	≥6	Cutoff	≥2	Cutoff	≥18

[a]Maximum score.

Preparation

Systems should be instituted for effective prenotification of patients at risk for MT. Prehospital staff should be encouraged to contact receiving hospitals as early as possible. Upon notification, relevant staff should be informed. The most senior emergency physician should assume the role of team leader in all cases. Medical and nursing roles should be allocated for management of the airway, breathing and circulation, ensuring flexibility at the discretion of the team leader to reallocate according to patient needs. The role of transfusion specialists to monitor blood and blood-product administration has been reported but has current limited availability. The blood bank, surgical, radiological and theatre staff should be notified. Allied health staff should be on standby to aid in the transport of blood products and equipment, transport of patient and to cater to the needs of relatives.

Reception

On reception, the patient should be managed in a trauma or resuscitation cubicle with full physiological monitoring. The principles of reception of all critically ill patients apply and have been discussed previously. The team leader must prepare the team for specific procedures to assist in the diagnosis and management of the severely haemorrhaging patient. Where relevant, focused assessment with sonography for trauma (FAST) should be performed by staff trained and credentialled in its use. FAST screening in the haemodynamically unstable population has a higher sensitivity and specificity as compared with the stable population.[8] The likelihood ratio for presence of haemorrhage given a positive FAST is about 12.0. Where delays to the operating theatre are expected, preparation should be made for thoracotomy or laparotomy in the ED for appropriate indications.

History

History of haemorrhage should be obtained from the patient or collateral history from paramedics or family members if present. Essential items on history should include the following:

- Age, gender, mechanism of injury or bleeding
- History of external bleeding
- Previous sources of bleeding (e.g. oesophageal varices, angiodysplasias)
- Bleeding disorders and coagulopathies
- Previous (e.g. associated with liver disease) use of antiplatelet and anticoagulant agents
- Acquired (e.g. dilutional) through massive fluid administration or pre-hospital blood cell transfusion
- Pre-hospital management, including transfusions, fluid administration, use of procoagulant (or antiplatelet) medications
- If available, history of previous transfusions, blood typing and previous transfusion reactions
- Family history as well as the possible intake of medicinal herbs, including homeopathy

Consent for transfusions should be obtained as early as possible. If the clinician is unable to obtain consent from a patient, alternate sources, such as the next of kin, should be approached. However, transfusion in life-threatening situations should not be delayed where consent cannot be obtained.

Examination

Clinically assessed blood loss when the patient is awake using advanced trauma life support (ATLS) guidelines of shock classes is outdated and rarely useful in the clinical setting. Significant haemorrhage should be suspected when signs such as tachycardia, hypotension, oliguria, deficient peripheral perfusion, venous collapse and pulmonary capillary bed collapse (increase of dead space with low end tidal [ET] CO_2 and hypercapnia), are observed along with base deficit and increased lactate levels.

Observation of the wound for clot formation can sometimes be enough to diagnose the coagulopathic sequelae of a massive haemorrhage. A thorough secondary survey will usually locate its source.

Investigations

Investigations should initially be directed towards accurately determining the source of bleeding and then facilitating transfusion management. In the setting of haemodynamic instability, investigations for accurate diagnosis may have to be delayed in preference to explorative surgery. Where available, radiological investigations, such as red cell scans or angiograms, may assist in diagnosis while also facilitating management through embolization.

Laboratory tests may require a considerable amount of time to provide results, and they are not always reliable when there is acidosis, hypothermia and ongoing bleeding. Blood samples should be taken to identify blood group and rhesus status, perform cross-match compatibility tests, implement a full blood examination (including platelet count) and to determine acid-base balance and lactate. Standard coagulation tests do not identify the pathophysiological mechanisms of haemorrhage. Prolongation of the activated partial thromboplastin time (aPTT) can be due to a deficiency of intrinsic factors of coagulation, fibrinogen deficit, hypothermia, blood heparinization or increased fibrinolysis. Each requires a different approach and tests usually do not help to choose the appropriate therapy. Finally, common laboratory tests (international normalized ratio [INR] and aPTT) are carried out at 37°C without platelets and red blood cells; therefore they cannot determine the presence of coagulopathy associated with hypothermia and the platelet dysfunction of fibrinolysis.

However, testing of coagulation status may have a prognostic value. A prolonged aPTT greater than 1.8 times the normal value is related to significant haemorrhage and has been associated with an increase of more than 300% in the mortality rate among injured patients.[9] The INR is a predictive factor independent of mortality in traumatized patients when it reaches more than 1.5 to 1.8.

Normal quantitative values do not ensure platelet function in patients with anaemia, hypothermia, hypocalcaemia or hypomagnesaemia. A decreased number of platelets is a phenomenon with high individual variability and is not predictive of mortality in injured patients.

There has been renewed interest in the use of near-patient functional tests of coagulation, such as thromboelastometry for the diagnosis of coagulopathy. These devices (e.g. rotational thromboelastometry [ROTEM], thromboelastography [TEG]) may be suitable for EDs. They are in routine use in some elective surgery settings, such as cardiac and liver transplant surgery. TEG and ROTEM are representative of a total coagulation process as well as thrombus formation and lysis. Blood samples are processed at the patient's temperature, including hypothermia in the dysfunction analysis. These procedures are easy to use and interpret and results are available within 15 minutes. Blood tests should be repeated every 30 minutes depending on the clinical condition.

Circulatory management

The goal of blood replacement is to maintain tissue perfusion and cellular oxygenation so as to avoid multi-organ failure from shock. In the setting of concomitant brain injury (traumatic and atraumatic) and in the elderly, it is recommended that during active bleeding arterial pressure be kept to minimal safe values (mean arterial pressure 60–70 mmHg) to maintain perfusion of vital organs (kidney, heart and central nervous system). In patients with traumatic brain injury, a cerebral perfusion pressure should be maintained despite increased intracranial pressure

by optimizing mean arterial pressure to ensure a cerebral perfusion pressure of 60 mmHg. This may require the use of vasoconstrictors and inotropic drugs and may worsen bleeding if that has not previously been controlled surgically.

Permissive hypotension in the setting of blunt trauma resuscitation has recently been advocated, but level I evidence for the practice exists only for patients with penetrating truncal trauma. In other situations the risks of reduced tissue perfusion must be weighed against potential benefits of preserving clot strength.

The specific goals of circulatory management are as follows:

- Surgical control of bleeding
- Replacement of intravenous fluids (maintaining circulatory volume and oxygen transport)
- Correction of normothermia, acidosis and hypocalcaemia
- Avoidance of hyperventilation and excessive positive end expiratory pressure

These goals are interactive and corrections should be performed simultaneously. The end point of resuscitation may be reached when vital signs are normal or even hyperdynamic as measured by cardiac output, arterial pressure, central venous pressure, haematocrit (stable between 20% and 30%, according to patient's physical condition) and the normalization of coagulation test results.

Group O Rhesus-negative red blood cells may be used while awaiting results of testing for blood group. If the group O-Rh-negative supply becomes compromised, the patient should be maintained with group O-positive until such time as his or her blood group can be determined. It is recommended to switch to the patient's specific group unless the patient's group cannot be determined. Group AB plasma may be used if necessary while awaiting results of the group. It is recommended that MT guidelines be developed at all centres expected to receive haemorrhaging patients and that such guidelines be followed.

Massive transfusion guidelines

A guideline is defined as 'a systematically developed statement that assists in decision making about appropriate health care for specific clinical situations'. Owing to the varied levels of evidence on the management of the massively haemorrhaging patient, these guidelines remain largely variable across different regions. The following section discusses the key components that are likely to be uniform across most guidelines.

Fresh frozen plasma

Fresh frozen plasma (FFP) is a key component in MT protocols, and most of the evidence for its use has been gleaned from resuscitation post-trauma. The landmark study to suggest high-dose FFP was completed in 2006 by Borgman et al. Combat casualties (n = 246) admitted to a combat hospital in Baghdad, Iraq, who were given ≥10 units of PRBCs or fresh whole blood in the first 24 hours were divided into three groups and analysed according to low (1:12–1:5), intermediate (1:3.0–1:2.3) and high (1:1.7–1:1.2) ratios of FPP:PRBC units. Overall mortality was 28%, but mortality in patients receiving a high ratio was significantly lower, at 19%. This study was limited by being retrospective in design and included fresh whole blood, which was viewed as 1:1:1 PRBCs:FFP:platelets (PLTs). Furthermore, the military setting was unlikely to be generalizable to a community setting with a high degree of penetrating trauma and pre-hospital care with short transit times involving standardized regimental care. There was a significantly higher incidence of thoracic trauma in the low-ratio group with more severe injuries as well as lower initial haemoglobin levels in those who died early.[10]

There have been multiple retrospective reviews on this topic to date, with similar weaknesses and with survival bias poorly controlled. Studies have provided inadequate evidence to support or refute the use of a high FFP:PRBC ratio in patients with severe trauma. It could be that the benefits accorded to the 1:1 strategy are solely due to survival. Specifically, those patients who survive injury are simply able to receive more plasma transfusions as opposed to those who die immediately from overwhelming injury and acute haemorrhagic shock.

In the setting of massive haemorrhage, early treatment with thawed FFP is recommended, with an initial dose of 10 to 15 mL/kg. Further doses should be guided by coagulation monitoring and the quantity of other blood products administered. In patients with an ongoing RBC requirement, the best current evidence supports a ratio of at least 1:2 FFP:PRBC.

Platelets

The role of early platelet transfusion in the setting of haemorrhagic shock also continues to be debated. Platelets are obtained by two methods: (1) an apheresis machine separates anticoagulated blood into components with retention of the platelets and a portion of plasma to create a standard adult dose of platelets. The remaining elements may be returned to the donor. The platelet apheresis unit is then divided into four packs of equal volume to produce a paediatric platelet component. This is done in order to reduce donor exposure for small paediatric transfusions and to minimize product wastage. (2) An adult dose of platelets is derived from whole blood from ABO-identical donors and resuspended in a nutrient additive solution to produce a platelet-pooled leucocyte-depleted component. Leucocyte depletion is performed during or soon after collection to remove most leucocytes.

In Australia, platelets obtained by both apheresis and pooling are irradiated before release from the Australian Red Cross Blood Service unless other specific arrangements have been made with the receiving laboratory/institution. As with FFP, recent military reports have promoted the routine administration of apheresis platelets to the injured patient. However, a similar survival bias has been suggested to explain the apparent benefit of early platelet administration.

Studies from more than two decades ago evaluating clotting factor and platelet counts in MT patients concluded that a platelet count of 100,000/mm^3 is the threshold for diffuse bleeding and that thrombocytopaenia was not a clinically significant problem until transfusions exceeded 15 to 20 units of blood. Specifically, patients with a platelet count greater than 50,000/mm^3 had only a 4% likelihood of developing diffuse bleeding. Although the classic threshold for platelet transfusion has been 50,000/mm^3, a higher target level of 100,000/mm^3 has been suggested for multiply injured patients and patients with massive haemorrhage. However, the relationship of platelet count to haemostasis and the contribution of platelets to the formation of a stable clot in the injured patient remain largely unknown. Furthermore, platelet function, irrespective of number, is also of crucial importance. The complex relationship of thrombin generation to platelet activation requires dynamic evaluation of clot function. Accordingly, at this time there is inadequate evidence to support an absolute trigger for platelet transfusions during resuscitation. Best evidence suggests a low threshold for transfusion without specific defined levels.

Cryoprecipitate

The evidence for cryoprecipitate use during resuscitation remains similarly scant. It has been suggested that cryoprecipitate can rapidly increase the concentrations of fibrinogen and von Willebrand factor, but the advantages of higher-than-normal concentrations remain speculative. Cryoprecipitate administration is recommended at a fibrinogen count below 1.0 g/L.

Calcium

Calcium in the extracellular plasma exists either in a free ionized state (45%) or bound to proteins and other molecules in a biologically inactive state (55%). The normal concentration of the ionized form ranges from 1.1 to 1.3 mmol/L and is influenced by the pH. A 0.1 unit increase in

pH decreases the ionized calcium concentration by approximately 0.05 mmol/L. The availability of ionized calcium is essential for the timely formation and stabilization of fibrin polymerization sites, and a decrease in cytosolic calcium concentration precipitates a decrease in all platelet-related activities. In addition, contractility of the heart and systemic vascular resistance are compromised at low levels of ionized calcium. Combining beneficial cardiovascular and coagulation effects, the level for ionized calcium concentration should therefore be maintained above 0.9 mmol/L.[11] Early hypocalcaemia following haemorrhage shows a significant correlation with the amount of infused colloids but not with crystalloids and may be attributable to colloid-induced haemodilution.[12] Also, hypocalcaemia develops during MT as a result of the citrate employed as an anticoagulant in blood products and is rare prior to the start of transfusion. The anticoagulant activity of citrate is exerted by the binding of ionized calcium, causing hypocalcemia. This is most commonly seen with FFP and platelet transfusions because these products have high citrate concentrations. Citrate undergoes rapid hepatic metabolism and hypocalcaemia is generally transient during standard transfusion procedures. Citrate metabolism may be dramatically impaired by hypoperfusion states, hypothermia and in patients with hepatic insufficiency.

There are currently no evidence-based guidelines on calcium management during MT. It is recommended that ionized calcium levels be monitored during MT and that calcium chloride be administered during MT if ionized calcium levels are low or electrocardiographic changes suggest hypocalcaemia.

Synthetic agents

Pharmacological interventions that inhibit fibrinolysis (aprotonin, e-aminocaproic acid, tranexamic acid [TXA]) or increase von Willebrand factor release (desmopressin) have been used to decrease bleeding and reduce blood-product usage in selected settings. Agents that have shown promise in randomized controlled trials for the bleeding patient are recombinant activated factor VII (rFVIIa) and TXA.

rFVIIa is approved for treatment of bleeding in haemophilia patients with inhibitors to factors VIII and IX. It has also been used during surgery to control haemorrhage and been shown to be safe in these settings. To date, no effect of rFVIIa on mortality or thromboembolism has been demonstrated in the trauma population, but a significant reduction in blood usage and ARDS has been found. The use of rFVIIa should be considered only in the setting of continuing bleeding refractory to routine management.[13]

Tranexamic acid (TXA) is an antifibrinolytic agent that inhibits both plasminogen activation and plasmin activity, thus preventing clot breakdown rather than promoting new clot formation. TXA is a small molecule (molecular weight 157.2). It occupies the lysine-binding sites on plasminogen, thus preventing its binding to lysine residues on fibrin. This reduces plasminogen activation to plasmin. Similarly, blockade of lysine-binding sites on circulating plasmin prevents binding to fibrin and thus prevents clot breakdown. TXA is 10 times more potent in vitro than aminocaproic acid, an older drug of the same class. At therapeutically relevant concentrations, TXA does not affect platelet count, aggregation or coagulation parameters. It is excreted largely unchanged in urine and has a half-life of about 2 hours in circulation.

CRASH-2 was a landmark study in the use of TXA for trauma.[14] The authors also reported a reduction in relative risk (RR) of death as a result of bleeding as 15% (4.9% vs 5.7%; RR, 0.85; CI, 0.76 to 0.96; $P = .0077$). Similarly, they reported an RR reduction in death as a result of bleeding on the day of randomization of 20% (2.8% vs 3.5%; RR, 0.80; CI, 0.68 to 0.93; $P = .0036$). The generalizability of the results of CRASH-2 to severely injured patients in mature trauma systems has been questioned. It is likely that patients most severely injured and those with acute traumatic coagulopathy (ATC) were excluded from the study. Trauma mortality in mature trauma systems is also significantly lower than reported in CRASH-2. Together with advanced trauma reception, resuscitation, intensive care and rehabilitation in mature trauma systems, any additional benefits of TXA as a routine agent in this setting is debatable.[15] There may be some benefit in the pre-hospital phase, where the management of ATC is minimal; trials are underway to evaluate this question.

Prothrombin complex concentrates are indicated for bleeding in the setting of vitamin K–dependent oral anticoagulants (warfarin). There is no evidence for the routine use of desmopressin, but it may be considered in patients with refractory bleeding who are using antiplatelet agents. Antithrombin III should be avoided until further studies on its safety profile have been conducted.

Acute traumatic coagulopathy

ATC is a unique entity defined by coagulation disorders precipitated by tissue injury and shock. It has been shown that nearly 25% of major trauma patients arrive in the ED with a clinically significant coagulopathy. The existence of this early coagulopathy has been verified, with remarkably similar results, despite subtle differences in the definition of coagulopathy.

The key measures used in defining ATC are as follows:

- Prothrombin time (PT): a measure of the extrinsic pathway of coagulation. PT measures function of factors I, II, V, VII and X. The reference range for PT is usually around 10 to 13 seconds. The PT is most commonly measured using blood plasma. Blood is drawn into a test tube containing liquid citrate, which acts as an anticoagulant by binding the calcium in a sample. The plasma is analysed at 37°C and excess of calcium is added (thereby reversing the effects of citrate), which enables the blood to clot again. Tissue factor (also known as factor III) is added and the time the sample takes to clot is measured optically. The PT was described by Quick in 1935 and the test is sometimes referred to as the 'Quick test'.
- Prothrombin ratio (PTr): the prothrombin ratio is the PT for a patient divided by the result for control plasma.
- The INR: the result (in seconds) for a PT performed on a normal individual will vary according to the type of analytical system employed. This is due to the variations between different batches of manufacturer's tissue factor used in the reagent to perform the test. The INR was devised to standardize the results. Each manufacturer assigns an ISI value (International Sensitivity Index) for any tissue factor they manufacture. The ISI value indicates how a particular batch of tissue factor compares with an international reference tissue factor. The ISI is usually between 1.0 and 2.0. The INR is the ratio of a patient's PT to a normal (control) sample, raised to the power of the ISI value for the analytic system used.
- Activated partial thromboplastin time: the partial thromboplastin time (PTT) and aPTT or APTT are performance indicators of both the intrinsic and common coagulation pathways. Blood samples are collected in tubes with oxalate or citrate to arrest coagulation by binding calcium. In order to activate the intrinsic pathway, phospholipid, an activator (such as silica, celite, kaolin, ellagic acid) and calcium (to reverse the anticoagulant effect of the oxalate) are mixed into the plasma sample. The time is measured until a thrombus forms. The test is termed 'partial' owing to the absence of tissue factor from the reaction mixture.

ATC has been associated with the presence of combined tissue injury and shock. Its incidence appears to be very low when one of these two factors is present without the other. Patients with this acute coagulopathy from trauma have been shown to be four times more likely to die than those without. It should also be remembered that up to 30% of coagulopathic patients do not receive MTs and therefore may not be amenable to MT guidelines. With no other guidelines to manage the acute coagulopathy resulting from

tissue injury and shock, these patients potentially have delayed management of their coagulopathy.

Future directions

The varied nature of MT guidelines and the low level of evidence for their components have been barriers to adequately powered outcome studies. Future clinical trials are required to focus on improvements in the quality of supporting evidence for these agents.

The benefits of high volumes of FFP and the limitations of a relatively low levels of evidence to guide this practice were highlighted earlier. Despite randomized controlled trials, the trials of rFVIIa and TXA suffered from deficiencies in design and the known difficulties of performing research in critical care environments. Uncertainties about these trials have led to a lack of consensus. Associated with the agents already mentioned, fibrinogen may be the key element of blood coagulation and is the first element to reach critically low levels. In addition to tissue injury, fibrin polymerization can be compromised by colloids, but it has been shown that this form of blood coagulation compromise can be reversed by the administration of fibrinogen. Fibrinogen quantity and function in vitro can be improved by multiple agents, including direct administration of fibrinogen concentrate; this should be a key measure in future studies examining improvements in the management of the acutely haemorrhaging patient.

SECTION 4

ORTHOPAEDIC EMERGENCIES

Edited by *Conor Deasy*

4.1 Injuries of the shoulder

Crispijn van den Brand

ESSENTIALS

1 **Most clavicular fractures heal despite displacement; therefore reduction is not necessary.**

2 **Injuries to the shoulder region may also involve injury to local neurovascular structures.**

3 **Acromioclavicular joint injuries and fractures of the scapula are usually treated conservatively.**

4 **Posterior sternoclavicular dislocations require reduction.**

5 **In dislocation of the shoulder, careful examination of the axillary (circumflex) nerve, brachial plexus and axillary artery is mandatory both before and after reduction.**

6 **In anterior dislocation of the shoulder, surgical repair of the capsule is recommended for recurrent dislocators and first-time dislocators who are young and engaged in high-risk sports.**

Fractures of the clavicle

Fractures of the clavicle account for 2.6% to 5% of all fractures and usually result from a direct blow to the point of the shoulder, but they may also be due to a fall on the outstretched hand. The most common site of fracture is the middle third of the clavicle, which accounts for 69% to 82% of clavicular fractures. Most other clavicular fractures are in the outer third. There are varying degrees of displacement of the fracture ends, with overlapping fragments and shortening being common. Owing to the strategic location of the clavicle, injury to the pleura, axillary vessels and/or brachial plexus is possible, but fortunately these complications are rare. They should be excluded by directed examination.

The clinical signs of clavicular fracture are a patient supporting the weight of the arm at the elbow coupled with local pain and tenderness, often accompanied by deformity.

In non-displaced or minimally displaced fractures, treatment consists of an elbow-supporting sling (e.g. broad arm sling) for 2 to 3 weeks. For comfort, this may be worn under clothing for the first few days. The sling may be discarded when local tenderness has subsided. Note that clinical union usually precedes radiological union by weeks. Early shoulder movement should be encouraged within the limits of pain and immobilization should be discontinued if clinical union has occurred, even if there is not yet radiological union. Non-union is rare.

Midshaft fractures with complete displacement or comminution or fractures in the elderly or women with osteoporosis have a higher rate of non-union and poorer functional outcome. Recent evidence suggests that this group may benefit from surgical stabilization with either plate-and-screw fixation or intramedullary devices.

Fractures of the outer third of the clavicle may involve the coracoclavicular ligaments (CC). These fractures are generally displaced. If so, surgical management should be considered, because these fractures have a high incidence of non-union (30%). Displaced fractures of the medial third of the clavicle are often associated with other serious injuries and warrant further examination. Early orthopaedic consultation is recommended for all (displaced) fractures of the medial and outer third of the clavicle.

Late complications of clavicular fractures include shoulder stiffness and a local lump at the site of fracture healing, which is rarely of cosmetic significance.

Acromioclavicular joint injuries

AC joint injuries usually result from a fall where the patient rolls onto his or her shoulder. The degree of the injury relates to the number of ligaments damaged; about two-thirds of AC injuries are incomplete and involve only part of the AC and CC ligaments (types I and II).

AC dislocations are classified according to the Tossy-Rockwood classification system (Fig. 4.1.1):

- Type I: partial tear of the AC ligament, CC ligament intact. Tenderness over the AC joint, no deformity.
- Type II: complete tear of the AC ligament, partial tear of CC ligament. Radiographs show partial elevation of the distal clavicle.
- Type III: complete tear of the AC and CC ligaments. Radiographs show substantial elevation of the distal clavicle and increased CC distance.
- Type IV: complete tear of the AC and CC ligaments with dislocation of the distal clavicle posteriorly into or through the trapezius muscle.
- Type V: complete tear of the AC and CC ligaments along with disruption of the muscular attachments of the distal clavicle.
- Type VI: complete disruption of the AC and CC ligaments and muscular support. The distal clavicle is forced behind the tendons of the biceps and coracobrachialis.

On clinical examination of the standing patient, the outer end of the affected clavicle may be prominent and there will be local tenderness over the AC joint. The degree of damage can be ascertained by taking standing x-rays of both shoulders with the patient holding weights in both hands (stress x-rays) and by ultrasound. Stress x-rays may be normal in mild strains, but dynamic ultrasonographic techniques may better define the injury.

Treatment is with a broad arm sling. For minor injuries (Rockwood type I–II) 1 to 2 weeks is usually sufficient. For type II injuries, heavy lifting and contact sports should be avoided for 4 to 6 weeks to avoid conversion to a type III injury. The treatment of type III injuries is controversial, with some authors recommending conservative treatment and others surgery. Type IV to VI injuries are usually treated surgically.

Sternoclavicular subluxation and dislocation

Sternoclavicular dislocations are uncommon and usually due to a direct, high-velocity blow to the medial clavicle or to medial compression of the shoulder girdle. Subluxation is more common than dislocation, with the affected medial end of the clavicle displaced forwards and downwards. Dislocations may be anterior or, rarely, posterior. In the latter case, the great vessels or trachea may be damaged.

Clinical features include local tenderness and asymmetry of the medial ends of the clavicles. The diagnosis is essentially clinical. X-rays are difficult to interpret and are not necessary for subluxations. For dislocations, contrast enhanced computed tomography (CT) scanning should be obtained.

Subluxations should be treated in a broad arm sling for 2 to 3 weeks. Anterior sternoclavicular joint instability should also be treated conservatively; however, there is a significant risk of ongoing instability; this is usually well tolerated and of little if any functional consequence. For patients with posterior dislocations, expeditious diagnosis and treatment are important. Closed reduction performed under general anaesthesia is usually stable, and the joint can then be managed in a brace or sling for 4 to 6 weeks. Operative stabilization is required if closed reduction is unsuccessful or there is persistent instability.

Fractures of the scapula

Fractures of the scapula are uncommon, accounting for less than 1% of all fractures. They typically occur after high-energy trauma. Up to 90% of patients have other associated injuries.

Fractures of the blade of the scapula are most common and are usually due to direct violence. Clinical features are local tenderness, sometimes with marked swelling. Healing is usually rapid,

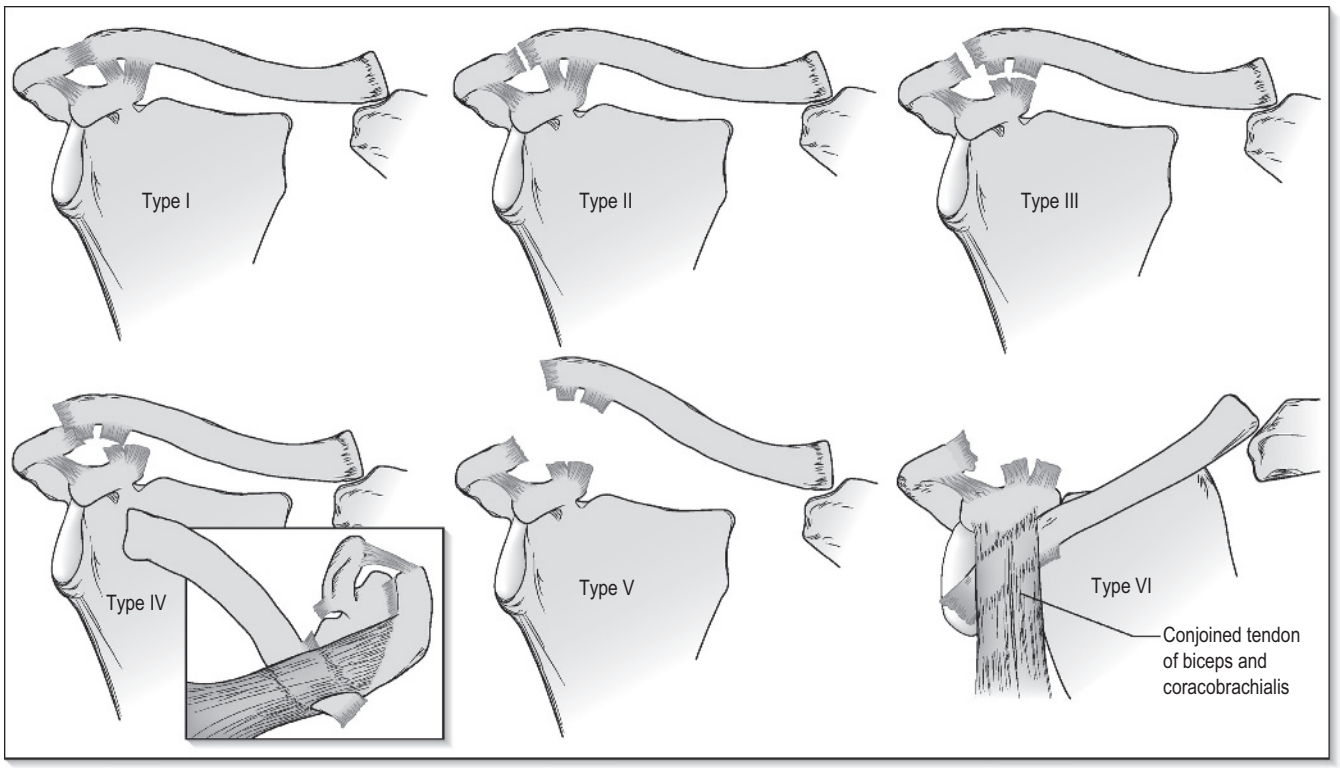

FIG. 4.1.1 The Tossy-Rockwood Classification System of Acromioclavicular Dislocations.

even in the presence of comminution and displacement, with an excellent functional outcome. Treatment is usually non-operative, with a broad arm sling and early mobilization. There is growing acceptance of surgical treatment for highly displaced fractures. However, there is no evidence comparing outcome for surgical versus non-surgical treatment.

Fractures of the scapular neck are often comminuted and may involve the glenoid. Swelling and bruising of the shoulder may be marked. Clinical examination and x-rays should ensure that the humeral head is enlocated. CT scans may be useful in defining the anatomy and the degree of involvement of the glenoid, including any steps in the articular surface. Surgery is often indicated for fractures involving the scapular neck or glenoid.

The 'floating shoulder' is an uncommon injury pattern. Although it is usually defined as an ipsilateral fracture of the clavicle and scapular neck, recent studies suggest that ligamentous disruption associated with a scapular neck fracture can give the functional equivalent of this injury pattern, with or without an associated clavicle fracture. Because the degree of ligament disruption is difficult to assess, indications for non-surgical versus surgical management are not well defined. Minimally displaced fractures typically do well with conservative management. The degree of fracture displacement and ligament disruption that results in poor outcome with conservative management is not well defined and the indications for surgery are controversial, as is choice of surgical technique. Options include fixation of the clavicular fracture, which often indirectly reduces the scapular fracture, or fixation of both fractures.

Supraspinatus tendon injuries

Rotator cuff tears most commonly affect the supraspinatus tendon and become more common with advancing age, as degeneration weakens the cuff. Indeed, the presence of asymptomatic partial or complete tears identified on ultrasound or magnetic resonance imaging (MRI) may be as high as 40% in patients above 50 years of age.

Symptomatic injuries may follow minor trauma or the sudden application of traction to the arm. Many are acute or chronic in nature rather than truly acute. This can be defined with ultrasound or MRI if required.

The clinical features of a strain include a painful arc of abduction centred at 90 degrees of abduction, weakness in external rotation and tenderness under the acromion. If the tear is complete, no abduction at the glenohumeral joint will occur, although some abduction to 45% to 60% is possible by scapular rotation. In both partial and complete injuries, there is a full passive range of abduction. Another useful test to isolate the supraspinatus and test its integrity is the 'empty can' test. The patient abducts the arm to 30 degrees with 30 degrees of forward flexion and full internal rotation (i.e. thumb pointed down) and is then asked to forward flex the shoulder first without and then against resistance. Pain or weakness against resistance suggests supraspinatus injury.

The goals of emergency care for rotator cuff injuries are to provide pain relief and prevent further disability. For the acute symptoms, an arm sling can provide support, but prolonged immobilization should be avoided. Treatment of supraspinatus tears is controversial, with no clear evidence guiding the choice of operative versus non-operative therapy or the components or duration of non-operative treatments. Most experts would still recommend a trial of non-operative therapy before considering surgery. An exception to this may be the patient with a previously asymptomatic shoulder who sustains trauma with resultant weakness (after the pain from the injury subsides) in whom imaging studies indicate an acute full-thickness tear.

Dislocation of the shoulder

Dislocation of the shoulder results in the humeral head lying anterior, posterior or inferior to the glenoid. Of these, anterior dislocation is the most common.

Anterior dislocation

Anterior glenohumeral dislocation is most often due to a fall resulting in external rotation of the shoulder—for example, the body rotating internally over a fixed arm. It is most common in young adults, often being related to sports. There is inevitable damage to the joint capsule (stretching or tearing) and there may be associated damage to the subscapularis.

Anterior dislocations are associated with several fractures including Hill-Sachs deformities, (bony) Bankart lesions and greater tuberosity fractures. A Hill-Sachs deformity is an impression fracture of the humeral head caused by the glenoid and is present in 35% to 100% of all anterior dislocations. It is unclear if this is prognostically important. Bony Bankart lesions are caused by a disruption of the glenoid labrum with an avulsion of the glenoid. These occur in about 5% of patients. Another common fracture is of the greater tuberosity of the humerus. Other complications may include damage to the axillary (circumflex) nerve (resulting in inability to contract the deltoid and numbness over the insertion of deltoid) and, rarely, the axillary vessels and the brachial plexus.

Clinical features include severe pain, reluctance to move the shoulder and the affected arm being supported at the elbow, often in slight abduction. The contour of the shoulder is 'flattened off' and there is a palpable gap just under the acromion, where the humeral head usually lies. The displaced humeral head may be palpable anteriorly in the hollow behind the pectoral muscles.

Dislocation is confirmed by x-ray. The dislocation may be evident on the Anteroposterior (AP) film but cannot be ruled out on a single view. Additional views (e.g. an axial lateral, translateral, tangential lateral) are required. These may reveal an associated fracture of the greater trochanter, but this does not influence initial management.

The principles of management are the provision of adequate analgesia as soon as possible, reduction of the dislocation and immobilization followed by physiotherapy. There are more than 20 described methods for the reduction of anterior dislocations, with reported success rates ranging from 60% to 100%. These include the FARES (Fast, reliable and safe) technique, the Spaso technique, the modified Kocher manoeuvre, the Milch technique and scapular rotation techniques (www.youtube.com/watch?v=NXFPWxSTK5c). There is no high-quality evidence to assist in selecting the most effective method. That said, the Hippocratic method is not recommended as the traction involved may damage neurovascular structures. Gravitational traction (the Stimson technique), having the patient lie face down with a weight strapped to the limb, is occasionally successful and may be worthwhile if there will be a delay until reduction by another method. All reduction methods require adequate analgesia. Intra-articular local anaesthesia may also be useful. Sedation, in an appropriately controlled environment, may be of assistance in augmenting analgesia and providing a degree of muscle relaxation and amnesia, but it is not required in most cases. Failure of reduction under analgesia/sedation is rare and mandates reduction under general anaesthesia.

If there is an associated fracture of the greater trochanter, it usually reduces when the shoulder is reduced. If it remains displaced, open reduction and internal fixation may be required.

Post-reduction x-rays confirm reduction, and neurovascular status must be rechecked. Post-reduction care includes immobilization in a broad arm sling followed by physiotherapy. Available evidence suggests that there is no benefit from immobilization for more than 1 week. It has been suggested that bracing in external rotation might reduce the incidence of recurrent dislocation, but this has not been borne out in validation studies.

Primary surgery, usually by arthroscopic techniques, is recommended for patients having suffered recurrent dislocations and should be considered for first-time dislocators, especially

those who are young, as surgery has been shown to significantly reduce the risk of recurrent dislocation.

Recurrence is rare in the elderly but is common (64% to 68%) in young patients.

Reduction techniques

Most anterior glenohumeral dislocations can be reduced without anaesthesia or procedural sedation, although appropriate analgesia and a patient, gentle technique is required. Intra-articular lignocaine (lidocaine) has been shown to be a safe, effective alternative to procedural sedation for reduction of dislocated shoulders.

FARES technique

The patient may be in the supine or prone position. Hold the patient's wrist and apply traction to the affected limb in a neutral position. Move the limb anteriorly and posteriorly in small oscillating movements (about 5 to 10 cm) while continuing to apply traction and slowly abducting the limb. Once the limb has been abducted to 90 degrees, externally rotate the limb at the shoulder, with ongoing traction and oscillating antero-posterior (AP) movements. Continue slowly to abduct the limb past this position. Reduction is usually achieved once the limb has been abducted to about 120 degrees. A success rate of the order of 89% has been reported.

Spaso technique

The patient is placed in the supine position. The affected arm is held by the forearm or wrist and gently lifted vertically, applying traction. While maintaining vertical traction, the shoulder is then externally rotated, resulting in reduction. If necessary, countertraction by downward pressure over the shoulder joint may be applied. A success rate of the order of 75% has been reported.

Modified Kocher manoeuvre

While applying traction to the arm by holding it at the elbow, the shoulder is slowly externally rotated, pausing if there is muscle spasm or resistance. External rotation to about 90 degrees should be possible, and reduction often occurs during this process. The elbow is then adducted until it starts to cross the chest and then is internally rotated until the hand lies near the opposite shoulder.

Scapular rotation

This technique is traditionally performed with the patient prone, but it can be performed on a seated patient. For both variations, the scapula is manipulated by adducting (medially displacing) the inferior tip using thumb pressure while stabilizing the superior aspect with the other hand.

Posterior dislocation

Posterior dislocation is frequently mentioned in medicolegal reports as it is easy to miss, especially in the unconscious patient. It may result from a fall on the outstretched or internally rotated hand or from a blow from the front. It is also associated with seizures and electrocution injuries, where it is not uncommonly bilateral. The dislocation is usually not apparent on an AP film, so additional views are required. Reduction is performed by traction on the limb in the position of 90 degrees abduction, followed by external rotation. Aftercare is the same as for anterior dislocation.

Posterior dislocation is prone to recurrence. Good functional outcomes are associated with early detection and treatment, a small osseous defect and stability following closed reduction. Poor prognostic factors include late diagnosis, a large anterior defect in the humeral head, deformity or arthrosis of the humeral head, an associated fracture of the proximal part of the humerus and the need for an arthroplasty. The indications for surgery are controversial.

Inferior dislocation (luxatio erecta)

This type of dislocation is rare and usually obvious, as the arm is held in abduction. Neurovascular compromise is a significant risk, requiring careful examination and prompt reduction. Reduction is by traction in abduction followed by swinging the arm into adduction. Aftercare is the same as for anterior dislocation.

CONTROVERSIES

- What is the role for surgery in midshaft clavicular fractures
- What is optimal treatment for Rockwell type III AC joint disruptions
- What is surgical treatment of scapular fractures
- What is the preferred immobilization method after reduction of dislocation of the shoulder
- What is the best technique for reduction of anterior dislocation of the shoulder
- In which patients is surgery indicated after first time shoulder dislocation?

4.2 Dislocations of the elbow

Timothy H. Rainer • Raymond Chi Hung Cheng

ESSENTIALS

1 Elbow dislocations are the third most common large joint dislocations.

2 Surgical intervention is rarely required for simple elbow dislocations.

3 Surgical intervention may be required when fractures of the radius, ulna and humerus are associated with elbow dislocation or when neurovascular injury occurs.

4 The commonest neurovascular complication involves the ulnar nerve.

5 After reducing elbow dislocations, it is important to reassess joint stability and potential neurovascular complications.

Introduction

Elbow dislocation, along with glenohumeral and patellofemoral joint dislocations, is one of the three most common large joint dislocations. It is also the second most common site for non-prosthetic joint dislocation. The elbow joint is a hinge-like articulation involving the distal humerus and proximal radius and ulna. Owing to its strong muscular and ligamentous supports, the joint is normally quite stable and rarely requires operative intervention, even for acute instability after dislocation.

Elbow dislocations can be classified as either anterior or posterior. Posterior dislocation is the most common type and can be further divided into postero-medial and postero-lateral. It usually results from a fall on the outstretched hand with some degree of flexion or hyperextension at the elbow. The radius and ulna commonly dislocate together. Similarly, anterior dislocation can also be divided into anteromedial or anterolateral. This type is less common and is usually due to a direct blow to the dorsal side of the elbow.

Uncommonly, the radius or ulna alone may dislocate at the elbow. In such cases there is always a fracture of the other bone. One common example is the Monteggia fracture, where anterior or posterior radio-humeral dislocation occurs alongside a fracture of the proximal third of the ulnar shaft (Fig. 4.3.1). A rarer example is a posterior ulnar-humeral dislocation with fracture of the radial shaft. There is a specific type of injury of the elbow, the 'terrible triad', characterized by elbow dislocation, radial head or neck fracture and coronoid fracture. Therefore although elbow dislocations may appear to be isolated, it is essential to look for associated intra-articular or shaft fractures.

Clinical assessment

History and examination

Patients typically present holding the lower arm at 45 degrees to the upper arm and there is swelling, tenderness and deformity of the elbow joint. The three-point anatomical triangle of olecranon, medial and lateral epicondyles should be assessed for abnormal alignment, as this strongly suggests dislocation.

The commonest neurovascular injury involves the ulnar nerve, reported in 10% to 15% of elbow dislocations; but the median and radial nerves and the brachial artery may also be affected.

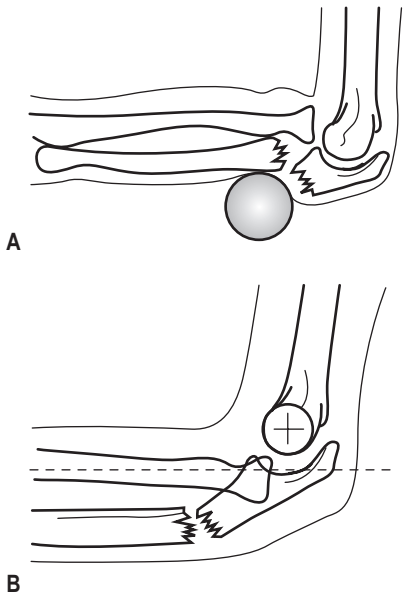

FIG. 4.2.1 Monteggia Fracture Dislocation. Fracture of the ulnar shaft may be associated with (A) anterior radio-humeral dislocation or (B) posterior radio-humeral dislocation.

The differential diagnosis is a complex distal humerus fracture that, in a swollen elbow, may be hard to differentiate clinically from an elbow dislocation.

Clinical investigations

Antero-posterior and lateral radiographic views should be obtained and scrutinized for associated fractures of the coronoid process, radial head, capitellum and olecranon. If in doubt, computed tomography gives a better evaluation of coronoid process fracture and is also useful for pre-operative planning. Magnetic resonance imaging characterizes bony injury more accurately than radiography in children with elbow injuries, but its potential role for diagnosis and guiding management in adults has not been well evaluated. Duplex Doppler ultrasound can be used to identify early brachial artery injury.

Treatment

Simple dislocation can be reduced using a closed method. With adequate sedation, gentle traction and counter-traction, the joint relocates quite easily. Medial and posterolateral dislocations may also require sideways correction. Dislocation of the stable elbow joint produces severe soft-tissue injury and resultant instability; therefore after reduction, signs and symptoms of compartment syndrome should be sought.

Joint instability should be tested by valgus and varus testing and by the lateral pivot-shift test. The reduced elbow joint should move smoothly. Any crepitation or resistance, particularly during the mid-range, suggests incongruent reduction or soft tissue interposition, which is commonly associated with coronoid process or epicondylar fractures. Inability to fully flex or extend the elbow suggests a loose bone, cartilaginous fragment or capsular tear.

Post-reduction films should be assessed, not only for correct joint relocation but also for associated fractures. After successful reduction, the elbow should be placed in a posterior plaster slab in 90 degrees of flexion. Cylinder casts are contraindicated because of the likelihood of severe soft-tissue swelling.

There is little evidence that surgical intervention improves outcome in patients with medial or lateral elbow instability after dislocation. A systematic review found that there is no difference in outcome between surgical repair of the ligament and plaster immobilization for simple elbow dislocation. Patients with early mobilization have a better range of movement, less pain, better functional scores,

shorter disability and shorter treatment time when compared with those who have had plaster immobilization. The management of a Monteggia fracture-dislocation is discussed in Chapter 4.4. Compound fracture dislocation should be reduced by the open method. Patients with irreducible dislocations, neurovascular complications, associated fractures or open dislocations require orthopaedic intervention.

Ulnar nerve injuries can occur both before and after closed reduction. The reported rate varies between 10% and 15%. Most are neuropraxic and recover with conservative measures. The most sensitive sign and symptoms are numbness over the little fingers.

Disposition

Current practice is that most patients may be discharged from the emergency department with analgesia, a pressure bandage for stable joints and plaster immobilization for unstable joints. A broad arm sling with appropriate follow-up should be arranged after reduction.

A recent prospective randomized study suggested that early mobilization is superior to plaster immobilization in terms of functional recovery without any increased instability or a recurrence of dislocation for patients with uncomplicated posterior dislocations. The duration of immobilization should not be longer than 14 days to prevent joint stiffness. Patients with irreducible dislocations, neurovascular complications, associated fractures or open dislocations require admission.

CONTROVERSIES

- There are no large-scale randomized studies comparing operative and non-operative management of elbow dislocation. It is therefore unclear whether one method may produce better outcomes than another.
- Early mobilization may be superior to prolonged plaster immobilization after reduction of uncomplicated posterior dislocations.
- The epidemiology of elbow injury, including dislocation in patients presenting to emergency departments, has not been well described and requires further studies.
- The roles of computed tomography and magnetic resonance imaging in evaluating acute elbow injury and influencing management require further study.

4.3 Fractures of the humerus

Raymond Chi Hung Cheng • Timothy H. Rainer

ESSENTIALS

1 **Fractures of the proximal humerus occur primarily in the elderly, whereas distal humeral fractures occur more often in children.**

2 **Falls producing fractures in elderly patients are often precipitated by an underlying medical problem that should be sought for and managed.**

3 **Most proximal humeral fractures do not require surgical intervention.**

4 **The aim of treatment is to minimize pain, maximize the return of normal function as soon as possible and achieve acceptable cosmesis.**

5 **Humeral shaft fractures, displaced distal humeral fractures and fractures associated with neurovascular compromise require early orthopaedic review.**

6 **Low-force fractures, especially in the elderly, suggest the presence of osteoporosis. At-risk patients not already identified as having osteoporosis should be referred for bone density scans, vitamin D testing and treatment.**

Introduction

The function of the upper limb depends on an intact shoulder girdle; this is, in turn, affected by the integrity of muscles, tendons and ligaments, bones, joints, blood vessels and nerves. Fractures of the humerus severely limit efficient function of the upper limb; that can be divided into proximal (proximal to the surgical neck), middle (shaft) and distal (supracondylar) segments.

Fractures of the proximal humerus

Patterns of injury

Fractures of the proximal humerus represent 5% of all fractures presenting to emergency departments (EDs) and 25% of all humeral fractures. The fracture typically occurs as a result of an indirect mechanism in elderly, osteoporotic patients who fall on an outstretched hand with an extended elbow. The fractures are female-predominant. The majority do not require surgical intervention and may initially be treated in the ED. A subset with a non-viable humeral head requires early surgical intervention; it is therefore important to identify this group. Fractures of the humerus may also occur in patients with multiple injuries or in the elderly with associated fractures of the neck of femur.

Clinical assessment

Patients typically present soon after injury, holding the arm adducted. They complain of pain and exhibit swelling and tenderness of the shoulder and upper arm. Although crepitus and bruising may occur, the former should not be elicited because it causes excessive and unnecessary

pain. Bruising is usually delayed, occurring several days after injury. It appears around the lower arm rather than at the fracture site as a result of gravity and blood tracking distally.

A neurovascular examination is essential, as the axillary nerve, brachial plexus and/or axillary artery may be damaged. The axillary nerve is the most commonly injured and presents with altered sensation over the badge area (insertion of the deltoid) and reduced deltoid muscle contraction (which may be hard to assess because of pain). The axillary artery is the commonest vessel to be injured and may present with any combination of limb pain, pallor, paraesthesia, pulselessness and paralysis.

As these injuries frequently occur in elderly patients, careful attention must be paid to the reason for the fall, as an underlying acute medical condition may have precipitated the event and may require management in its own right.

Clinical Investigations

Three radiographic views—antero-posterior, lateral and axillary—will allow most proximal humeral fractures to be correctly diagnosed.

Fracture classification

Although the majority of these fractures are easily managed in the ED, the challenge is to differentiate them from the minority that require orthopaedic intervention.

Neer classification system

In this system, fractures are classified first according to the number of the four anatomic sites (humeral head, humeral shaft, greater and lesser tuberosities) that were involved in the injury; second, the degree of fracture displacement is determined, defined as 1 cm separation or more than 45 degrees of angulation (Figs 4.3.1 and 4.3.2).

One-part fracture. These account for 80% of proximal humeral fractures. Any number of fracture lines may exist but none are significantly displaced.

Two-part fracture. These account for 10% of proximal humeral fractures, and one fragment is significantly displaced or angulated. Two-part fractures of the humerus may involve the anatomical neck (see Fig. 4.3.1A), the surgical neck (see Fig. 4.3.1B), the greater tuberosity (see Fig. 4.3.1C) or the lesser tuberosity (see Fig. 4.3.1D).

Three- and four-part fractures. These account for the remaining 10% of proximal humeral fractures, with two or three significantly displaced or angulated fragments (see Fig. 4.3.2A–C).

Treatment

One- and two-part fractures can be treated with a collar-and-cuff sling, adequate analgesia and

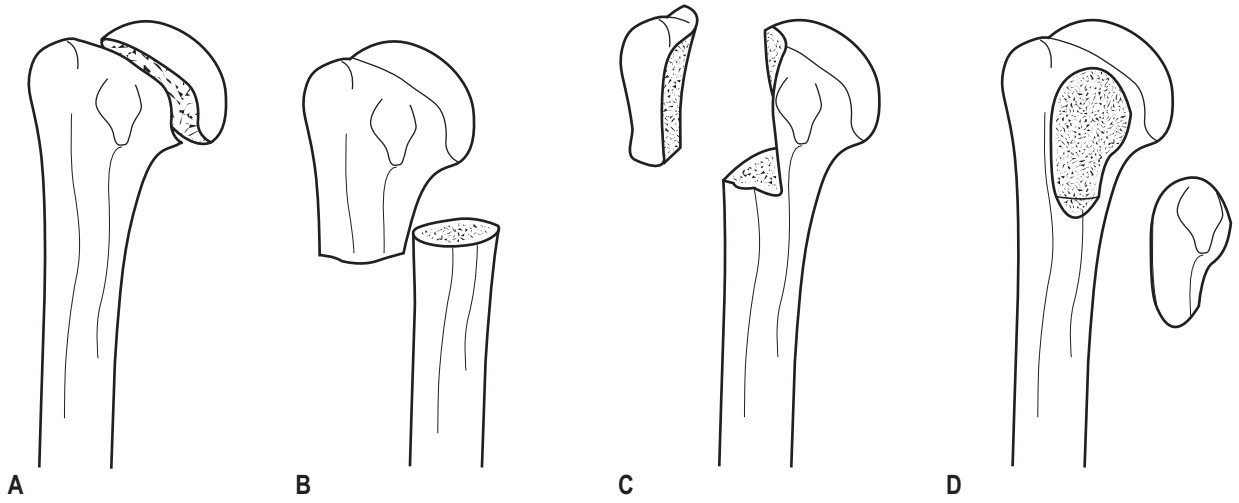

FIG. 4.3.1 Neer classification of two-part fractures with (A) the anatomical neck, (B) the surgical neck, (C) the greater tuberosity and (D) the lesser tuberosity.

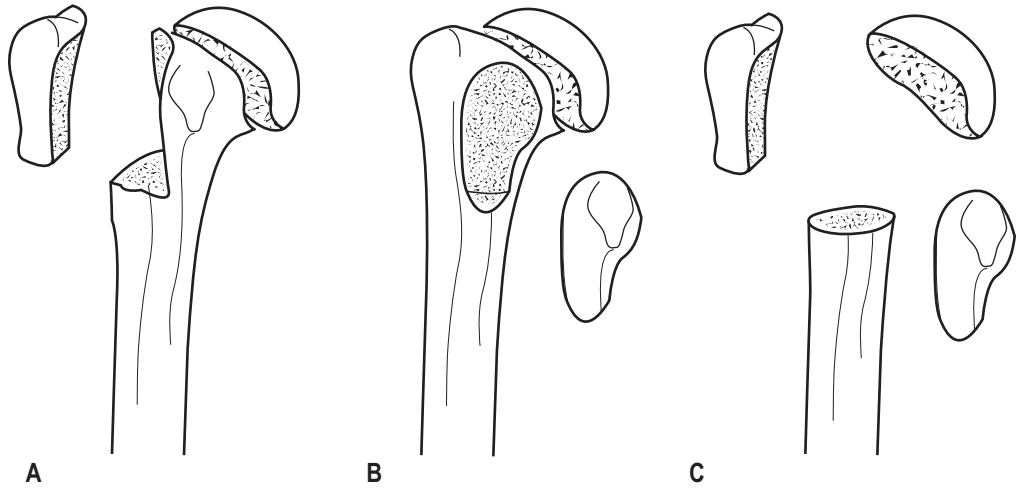

FIG. 4.3.2 Neer classification of three-part fractures with (A) the greater tuberosity and anatomical neck, (B) the lesser tuberosity and anatomical neck and (C) the four-part fracture involving the anatomical neck, greater tuberosity and lesser tuberosity.

follow-up. Early mobilization is important and the prognosis is good.

Definitive management of the displaced fragment in two-part fractures may include open or closed reduction, depending upon neurovascular injury, rotator cuff integrity, associated dislocations, likelihood of union and function. Early orthopaedic assessment is recommended.

For three- and four-part fractures, the consensus is for open reduction and internal fixation. However, a review has suggested that there is little evidence that surgery is superior to the non-operative approach, especially for elderly patients.

For displaced proximal humeral fractures, surgical management remains varied and controversial. A recent systematic review suggested that non-operative treatment of proximal humeral fractures has a high rate of radiological healing with good functional outcomes but a lower complication rate when compared with the operative approach. Small randomized controlled trials suggest that external fixation may confer some benefit over closed manipulation and that conservative treatment is better than tension-band osteosynthesis. Another study suggests that the decision should be made according to the viability of the humeral head. Locking-plate technology may also provide better outcomes in patients with unstable displaced humeral fractures having a viable humeral head. Other small-scale studies suggest that some bandaging styles may be better than others and that early physiotherapy may improve functional outcome.

Special cases

Fracture of the anatomical neck and articular surface

Fractures at these sites are uncommon but are important to recognize as they are associated with a high incidence of compromised blood supply to the articular segment, may result in avascular necrosis and may require a humeral hemiarthroplasty.

Fracture dislocations

Fractures of the greater tuberosity accompany 15% of anterior glenohumeral dislocations and may be associated with rotator cuff tears. Although the fracture may be grossly displaced, reduction of the dislocated shoulder usually also reduces the fracture. In patients who require the full range of motion of the shoulders, surgical repair of the cuff may be required.

Fractures of the lesser tuberosity are associated with posterior glenohumeral dislocations.

Disposition

Most patients with undisplaced one- and two-part fractures may be discharged from the ED with a collar-and-cuff sling, analgesia, early mobilization and appropriate follow-up. High-risk cases, including displaced three- and four-part fractures, all open fractures and the special proximal humeral fractures described earlier, require orthopaedic consultation and admission, as do those with underlying medical problems requiring investigation or treatment.

Low-energy fractures, especially in the elderly, suggest the presence of osteoporosis. At-risk patients not already identified as having osteoporosis should be referred for bone density scans, vitamin D testing and treatment.

Fractures of the shaft of humerus

Patterns of injury

Fractures of the humeral shaft commonly occur in the third decade (in active young men) and in the seventh decade of life (in osteoporotic elderly women). The commonest site is the middle third, which accounts for 60% of humeral shaft fractures. The close proximity of the fracture to the radial nerve and brachial artery commonly leads to neurovascular deficits.

Direct blows tend to produce transverse fractures, whereas falls on the outstretched hand produce torsion forces and hence spiral fractures. Combinations of the two mechanisms may produce a butterfly segment. Pathological fractures are also common, most resulting from metastatic breast cancer.

The angle and degree of displacement of the fracture depends on the site of injury and its relationship to the action and attachment of muscles on either side of the injury (Fig. 4.3.3).

Clinical assessment

Patients typically present complaining of pain and supporting the forearm of the injured limb, flexed at the elbow and held close to the chest wall. Examination of the limb reveals tenderness, swelling, shortening and possibly deformity. The skin should be assessed for tension or disruption and particular attention should be paid to the shoulder and elbow regions for associated fractures or dislocations. Initial and post-reduction

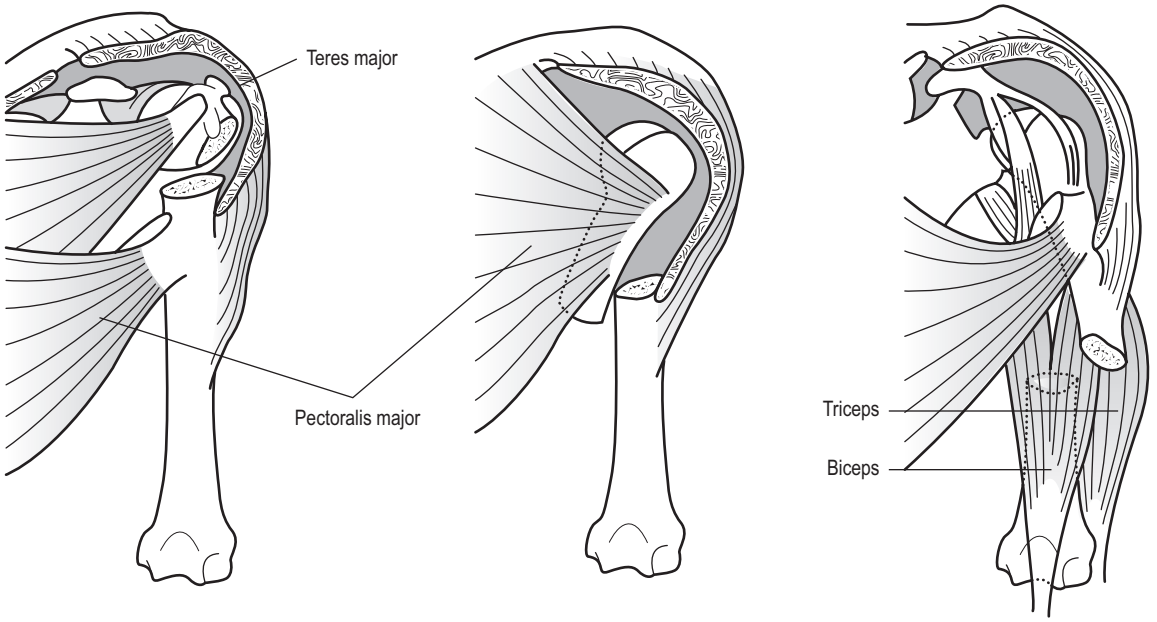

FIG. 4.3.3 Relationships between humeral fracture site and the actions of inserting muscles determine bony angulation and displacement.

assessments of the brachial artery and vein and ulnar, median and radial nerves are essential.

The commonest complication is radial nerve injury resulting either from the injury itself or reduction of the fracture; it is evidenced by wrist drop and altered sensation in the first dorsal web space. A recent systematic review reported that radial nerve injury occurs in 11% of mid-shaft humeral fractures.

Clinical investigations

Two radiographic views—antero-posterior and lateral—will enable the correct diagnosis in most cases.

Treatment and disposition

Uncomplicated closed fractures account for the majority of injuries and may be treated conservatively by immobilization and analgesia. Immobilization can be by a hanging cast, U-shaped cast or with functional bracing and a broad arm or collar-and-cuff sling. The acceptable deformity is 20 degrees of antero-posterior angulation and 30 degrees of varus-valgus deformity. The rate of fracture union is usually higher than 90%. Early specialist follow-up is recommended.

Some authors prefer a functional humeral brace rather than U-shaped plaster for immobilization, as the former may permit greater functional use without affecting healing or fracture alignment. For oblique or spiral fractures, some orthopaedic surgeons prefer an operative approach for a better functional outcome.

Open fractures and complications affecting the vessels require surgical repair. Although the majority of radial nerve injuries constitute neuropraxia and recover without surgical intervention, each case should be considered individually by an orthopaedic surgeon with a view to possible operative exploration.

Fractures of the distal humerus

Classification and patterns of injury

Unlike in children, fractures of the distal humerus in adults are very uncommon and patterns of injury tend to reflect the anatomical two-column construction (condyles) of the humerus. Several classification methods have been used, such as the Riseborough and Radin, Mehne and Matta classifications, but the simplest and most commonly used are the AO/ASIF AO (Arbeitsgemeinschaft für Osteosynthesefragen) or the Association of the Study of Internal Fixation (ASIF) classifications. These classify injuries into three categories: type A are extra-articular fractures, type B are partial articular fractures and type C are complete articular fractures. Practically, distal humeral fractures may be classified into supracondylar, intercondylar and other types. Supracondylar fractures lie transversely, whereas intercondylar T or Y fractures include an additional vertical extension between the condyles.

Mechanisms of injury usually involve a direct blow to the flexed or extended elbow. In the former, the olecranon is driven upwards, thereby either splitting the condyles apart and producing a 'T' or 'Y' pattern or shearing off one condyle.

Clinical assessment

Patients typically present with a swollen, tender, deformed elbow. As very little subcutaneous or other tissue separates the bone from skin, any disruption of the skin should be carefully examined for the possibility of a compound fracture. Distal neurological and vascular injury must be assessed carefully, as the possibility of nerve injury has been reported to be as high as 12% to 20%.

Clinical investigations

Two radiographic views—antero-posterior and lateral—should be obtained. Some authors suggest that an internal oblique view may improve diagnostic accuracy. Pain and inability to extend the elbow often result in poor-quality radiographs. Although high-quality radiographs are essential for operative planning, repeat films should not be attempted in the ED, as they rarely provide the desired result. When there is any suspicion of severe injury, either from the history or from gross soft tissue swelling, early computed tomography (CT) scanning should be considered to give better detail, especially of intra-articular fractures.

Undisplaced fractures may not be visible on radiography but may be suggested by posterior or anterior fat pad signs, which result from fat displaced by an underlying haemarthrosis. Ultrasonography, CT and magnetic resonance imaging may all improve diagnostic precision. They alter management and improve outcome in patients with occult fractures, mostly of the intra-articular type.

Treatment and disposition

Uncomplicated undisplaced closed fractures with minimal swelling should be immobilized for 3 weeks in 90 degrees flexion with an above-elbow cast and a broad arm sling, followed by active mobilization.

Patients with severe swelling, compound fractures, displaced fractures or neurovascular compromise require orthopaedic intervention.

CONTROVERSIES

- In humeral shaft fractures, it is unclear whether hanging plasters or functional braces are better than U-shaped plasters for fracture healing and position.
- Although the union rate of humeral shaft fractures treated with bracing is high, the functional outcomes after brace treatment are still under investigation.
- Low-intensity pulsed ultrasound may be useful in the treatment of non-union. Whether it might enhance normal fracture healing is not known.
- The role of magnetic resonance imaging in the diagnosis of bone bruising and humeral fracture has not been studied.

4.4 Fractures of the forearm and carpal bones

Crispijn van den Brand

ESSENTIALS

1 **Forearm fractures are among the most common fractures seen in the emergency department (ED).**

2 **When the need for or potential success of reduction is being assessed, the external appearance of the limb is a key feature.**

3 **Median nerve function must be assessed before and after reduction of all distal radial fractures.**

4 **Splinting or functional bracing may be sufficient for stable fractures. Early movement and load bearing aid functional recovery.**

5 **General indications for orthopaedic referral include fractures that are compound, unstable, associated with intra-articular or neurovascular injury and those that have failed reduction in the ED.**

6 **Displaced, isolated fractures of the ulna or radius may be associated with a dislocation of the radius or ulna, respectively (Monteggia and Galeazzi fracture dislocations). These should be carefully sought, as they pose a high risk of long-term disability.**

7 **Significant or persistent symptoms with the absence of a visible fracture on plain x-ray may be due to an undetected fracture or significant soft tissue injury. A high index of suspicion and early review are recommended. Further investigation with bone scintigraphy, computed tomography (CT) or magnetic resonance imaging (MRI) may be indicated.**

Fractures of the radial head

Clinical features

History

Radial head fractures occur frequently, usually as a result of a fall onto an outstretched hand or, less frequently, following a direct blow to the lateral side of the elbow. Radial head fractures present with pain and restricted movement at the elbow.

Examination

Usually there is swelling and tenderness over the radial head. Sometimes, with more subtle injuries, rotating the forearm while palpating the radial head may be necessary to elicit tenderness. Elbow extension and forearm rotation are usually limited. Severely comminuted fractures may involve proximal displacement of the radius, which can be associated with disruption of the interosseous membrane and subluxation of the distal radio-ulnar joint (Essex–Lopresti fracture dislocation).

Clinical investigations

Imaging

Standard anteroposterior (AP) and lateral x-rays of the elbow and, on indication, also of the wrist are required. A radio-capitellar view may be necessary if the fracture is subtle. The presence of an anterior fat pad sign alone on x-ray is associated with an underlying radial head or neck fracture in up to 50% of patients. In this case, a fracture should be assumed to be present if there is an appropriate mechanism and local signs. A follow-up x-ray or CT scan is indicated only in the presence or persistent pain, stiffness or locking.

Classification

Radial head fractures are usually classified according to the (modified) Mason classification (Fig. 4.4.1). About two-thirds of fractures are Mason type I.

The Mason classification is as follows:

- Mason type I, displaced less than 2 mm
- Mason type II, displacement more than 2 mm
- Mason type III, comminuted fractures of the entire radial head
- Mason type IV, radial head fracture with associated elbow dislocation

Treatment

All non-displaced (type I) radial head fractures and those type II fractures without mechanical block may be managed with a bandage and sling. Mobilization should be started as early as possible. If there is severe pain, a posterior splint may be useful, but it should not be applied for more than 2 days. Prognosis is good, but full extension may not be possible for many months.

Displaced or complex radial head fractures (type II or III) may be treated in the acute setting with a sling or posterior splint. These patients should have early orthopaedic review (within days). The treatment of displaced or complex radial head fractures remains controversial and should be determined by an orthopaedic surgeon.

Mechanical block can be difficult to assess acutely due to pain. Intra-articular injection of bupivacaine may assist early assessment or assessment may be deferred until pain has settled. Surgical options include open reduction and internal fixation and excision of the radial head with or without implantation of a prosthesis.

Radial neck fractures with up to 20-degree tilts can be managed conservatively. Fractures with more severe tilts can be reduced using intra-articular local anaesthesia. The forearm is pronated until the most prominent part of the radial head is felt. Then traction is applied to the forearm and pressure applied to the radial head. Open reduction is indicated if closed methods fail or displacement is severe.

Proximal radial fractures may be associated with rupture of the interosseous membrane and dislocation in the distal radioulnar joint (DRUJ) (Essex–Lopresti fracture). Pain in the wrist should give an index of suspicion; moreover, on the lateral x-ray of the pronated wrist, the distal part of the ulna is usually subluxated to dorsal.

Complications

Neurovascular complications and compartment syndrome are uncommon. Most complications relate to disturbance of the relationships of the proximal radio-ulnar and radio-capitellar articular surfaces, causing limitation of movement. This is uncommon with minor fractures.

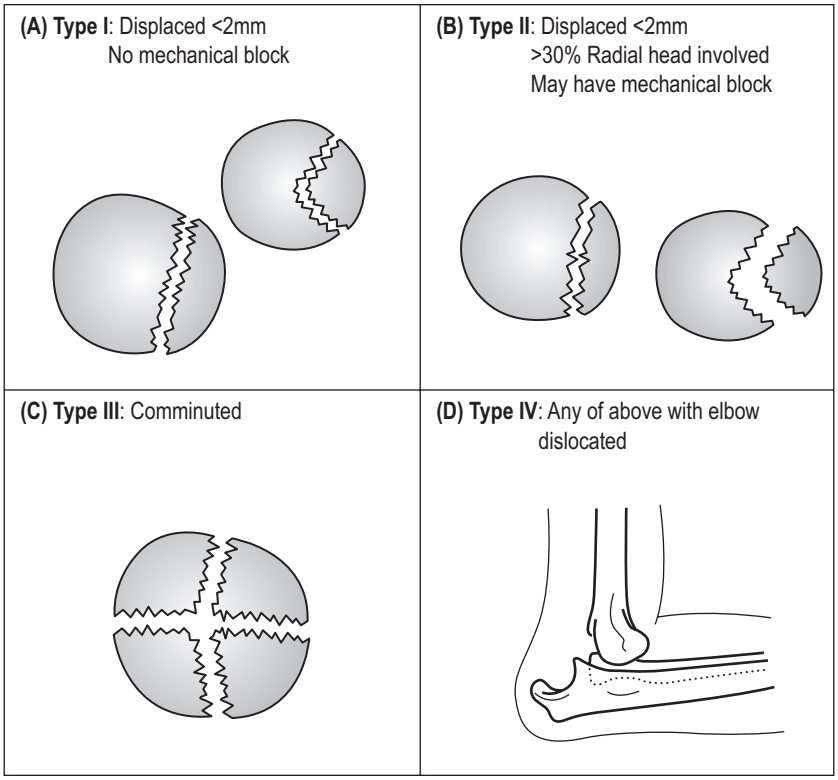

FIG. 4.4.1 (A–D) Mason-Hotchkiss classification of radial head fractures.

Shaft fractures

Clinical features

History

This type of injury requires great force, typically from a motor vehicle accident, a fall from a height or a direct blow. These fractures are commonly open and nearly always displaced.

Examination

The forearm is swollen and tender and may be angulated and rotated. Examination looking for an open wound, local neurovascular compromise, compartment syndrome or musculotendinous injury is required. Given the mechanism of injury, other injuries should also be sought.

Clinical investigations

Imaging

AP and lateral x-rays of the forearm, including the wrist and elbow joints, are needed. Displacement and angulation are easily determined, but torsional deformity may be subtle. Because the ulna and radius are rectangular in cross section rather than circular, a change in bone width at the fracture site indicates rotation. The radial and ulnar styloid processes normally point in opposite directions to the bicipital tuberosity and coronoid process, respectively. A change in this alignment also suggests torsion.

Treatment

Adult forearm fractures are less stable than those in children, and lack of remodelling limits tolerance to incomplete reduction. Undisplaced fractures may be managed with an above-elbow cast, but they must be reviewed at 1 week for displacement and angulation. Most fractures, however, are displaced and require open reduction and internal fixation.

Complications

Early complications include wound infection, osteomyelitis, neurovascular injury and compartment syndrome. Later, non-union, malunion, reduced forearm rotation and reflex sympathetic dystrophy are possible complications.

Specific fracture types

Isolated fracture of the ulnar shaft

These fractures are due to a direct blow to the ulna, often when raised in defence; hence they are also known as 'nightstick' fractures. Patients present with localized pain and swelling. AP and lateral x-rays delineate the location of the fracture and degree of angulation. Look for associated dislocation of the radial head if displacement is present (Monteggia fracture dislocation).

Treatment is often surgical; however, in fractures with less than 10 degrees of angulation and displaced less than 50% of the diameter of the ulna, conservative treatment can be considered.

Traditional treatment involves fixing the forearm in mid-pronation with a plaster cast extended above elbow.

Monteggia fracture dislocation

This is a rare fracture of the proximal ulna with dislocation of the radial head. It occurs either through a fall onto the outstretched hand with hyper-pronation or through a force applied to the posterior aspect of the proximal ulna. Patients present with pain, swelling and reduced elbow movement. The forearm may appear shortened and the radial head may be palpable in the antecubital fossa. Associated posterior interosseous nerve injury is common.

On x-ray, the fracture is obvious, but the dislocation is commonly missed. Check that a line through the radial shaft bisects the capitellum on both views. There are four types of Monteggia fracture, depending on displacement of the radial head (Bado classification). Dislocation is anterior in 60% (Bado type I), but it may be lateral or posterior.

All Monteggia fractures require open reduction and internal fixation. Common complications include malunion and non-union of the ulnar fracture and an unstable radial head.

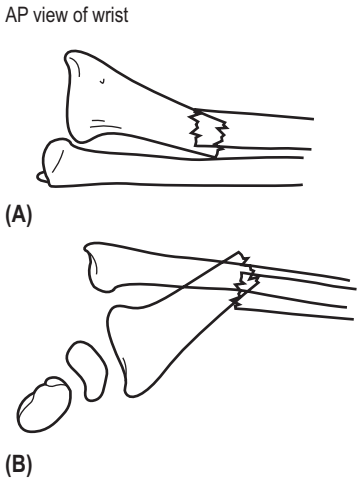

FIG. 4.4.2 The Galeazzi fracture dislocation. A, AP (anteroposterior view); B, lateral view.

Isolated radial shaft fracture

Isolated fractures of the proximal two-thirds of the radial shaft are uncommon and are usually displaced. Rare undisplaced fractures can be treated similarly to isolated ulnar shaft fractures. Displaced fractures require open reduction and internal fixation.

Galeazzi fracture dislocation

Fractures of the distal third of the radial shaft occur as a result of a fall onto the outstretched hand or a direct blow. There may be an associated subluxation or dislocation of the DRUJ, known as the Galeazzi fracture dislocation. Patients have pain and swelling at the radial fracture site. Those with a Galeazzi injury will also have pain and swelling at the DRUJ and a prominent ulnar head.

X-rays show the radial fracture, which is tilted ventro-laterally. Widening of the DRUJ space on the AP x-ray and dorsal displacement of the ulnar head on the lateral x-ray are seen (Fig. 4.4.2). An ulnar styloid fracture is seen in 60% of cases.

All Galeazzi fracture dislocations require surgical management. Complications include malunion or non-union of the radial fracture and subsequent instability of the DRUJ.

Fractures of the distal radius and ulna

Fractures of the distal radius and ulna are common, particularly in children and elderly women. Fractures in the latter group are indications for evaluation of bone-mineral density.

Clinical features

History and examination

Fractures usually occur after a fall onto the outstretched hand—resulting in bending, shearing or impaction forces being applied to the distal metaphysis—or from a direct blow. Patients present with pain, tenderness and variable degrees of swelling and deformity. It is important to examine for associated injuries to carpal bones, radial and ulnar shafts, elbow and shoulder joints as well as for median nerve injury, vascular compromise and for extensor tendon injury.

Clinical investigations

Imaging

Antero-posterior and lateral x-rays of the wrist demonstrate most injuries. For patients with significant symptoms or signs and a normal x-ray, consider an occult undisplaced fracture or ligamentous injury.

Although this chapter uses eponymous names, it is important to be aware that orthopaedic circles have moved to more formal classification systems for distal radial fractures. The several systems that have been proposed, however, are beyond the scope of this text. The author recommends being familiar with anatomical descriptions and fracture features associated with the need for reduction, instability of reduction and indications for operative intervention.

Treatment

Management

Prompt attention to analgesia, splinting and elevation is essential while x-rays are being awaited.

Reduction is indicated in the following circumstances to improve long-term function:

- Visible deformity of the wrist
- Loss of volar tilt of the distal radial articular surface beyond neutral
- Loss of more than 5 degrees of the radial inclination of the distal radius (normally approximately 20 degrees)
- Intra-articular step of more than 2 mm
- Radial shortening of more than 2 to 3 mm

Greater deformity can be accepted in elderly patients with limited wrist use.

Anaesthetic options for reduction include haematoma block, Bier block and procedural sedation. Reduction is traditionally maintained with an encircling plaster cast moulded to oppose displacement forces and extending from the volar metacarpal crease to the proximal forearm, to remain in place for 4 to 6 weeks. Displaced or comminuted fractures at high risk of swelling, especially in the elderly or coagulopathic patients, are immobilized with non-encircling splints.

Factors associated with instability of the distal fragment and failure to maintain reduction include the following:

- Presence of an intra-articular component (especially involving the distal radio-ulnar joint)
- Shearing fractures (Barton type, Hutchinson type)
- Palmarly displaced fractures (Smith type)
- Greater magnitude of the initial displacement or comminution

Weekly x-rays for 2 to 3 weeks with orthopaedic follow-up are recommended for all displaced fractures, those with intra-articular extension and potentially unstable fractures.

Stable, undisplaced, extra-articular fractures can be managed more conservatively with splinting and referral to a family doctor for early mobilization after 4 weeks.

Indications for operative management are debated and should take patients' characteristics into account. However, surgery should be considered for the following:

- Comminuted, displaced, intra-articular fractures
- Open fractures
- Associated carpal fractures
- Associated neurovascular or tendon injury
- Failed conservative treatment (failed reduction or instability after reduction)
- Bilateral fractures/impaired contralateral extremity

Complications

Median nerve injury may occur acutely due to the injury as a result of reduction or later due to pressure effects from the plaster. Median nerve function must be documented before and after reduction.

Loss of reduction may require delayed surgical intervention. Malunion with chronic wrist pain, arthritis and secondary radioulnar and radiocarpal instability are associated with intra-articular extension of the fracture.

Long-term complications include osteoarthritis, residual disability and complex regional pain syndrome (CRPS). The incidence of CRPS following fractures of the distal radius ranges in the literature from less than 1% to 22%. Prophylactic vitamin C may reduce the incidence of CRPS and should be considered; the advised dose is 500 mg/day for 50 days.

Specific fractures

Colles fracture

The Colles fracture is a metaphyseal bending fracture. The wrist has a classic 'dinner-fork' appearance, often with significant swelling of the soft tissues. This appearance is reflected in the radiographs (Fig. 4.4.3). There is often associated damage to the radio-ulnar fibro-cartilage. There may be comminution, commonly dorsally, which can extend into the radio-carpal or radio-ulnar joints.

The aim of reduction is to restore radial length, volar tilt and radial angulation. A minimum of 0 degrees tilt is acceptable if full reduction is not possible. Reduction is achieved by first disimpacting the fracture with traction in the line of

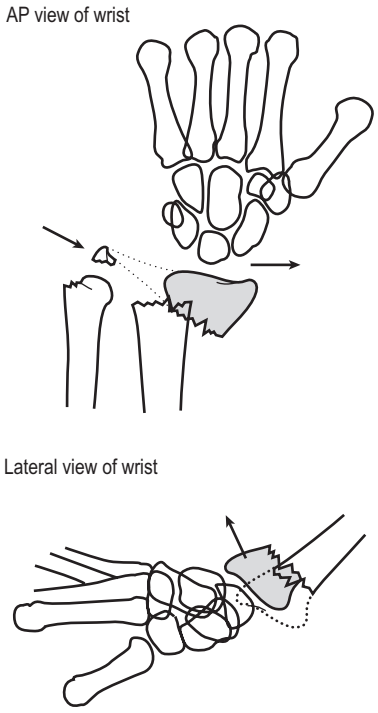

FIG. 4.4.3 Colles fracture: a fracture of the distal radial metaphysis with six classic deformities. The lateral view shows dorsal angulation, dorsal displacement and impaction. The anteroposterior *(AP)* view reveals radial displacement, ulnar angulation and an ulnar styloid fracture.

the forearm. If this fails, traction in extension or hyperextension should be tried. Volar tilt is then restored with volar pressure over the dorsum of the distal fragment while traction is maintained. After this, correct radial tilt and radial displacement with ulnar pressure over the radial side of the distal fragment. Reduction is successful in 87% of cases, but almost two-thirds lose reduction over 5 weeks, most of this occurring during cast immobilization.

The commonly accepted cast immobilization position is with the wrist joint in 15 degrees palmar flexion, 10 to 15 degrees of ulnar deviation and slight pronation. However, some evidence suggests that better outcomes are achieved with the wrist in dorsiflexion and mid-supination. The cast must be carefully moulded over the dorsum of the distal fragment and the anteromedial forearm. Functional bracing allowing wrist movement has also shown good outcomes.

Smith fracture

This metaphyseal bending fracture of the distal radius occurs through a direct blow or fall onto the back of the hand or a fall backward onto the outstretched hand in supination.

AP and lateral x-rays of the wrist show a 'reverse Colles' fracture' with a similar AP appearance, but with volar displacement and tilt on the lateral x-ray view.

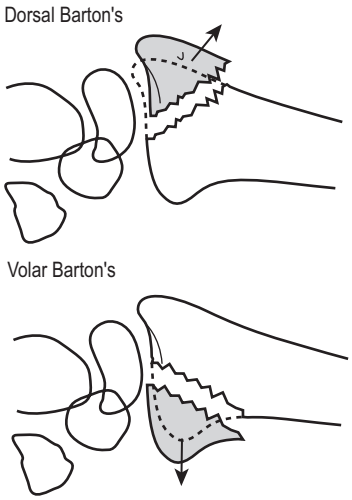

FIG. 4.4.4 Barton fractures demonstrated on lateral views of the wrist.

Closed reduction to achieve anatomical radial length and volar tilt should be attempted. Traction is first applied to restore length, followed by dorsal pressure over the volar surface of the distal radius to reverse displacement and angulation. A full above-elbow cast is applied with the wrist in supination and dorsiflexion to prevent loss of reduction. However, most Smith fractures are unstable and require operative management. Early orthopaedic follow-up is mandatory.

Barton fracture

Barton fractures are dorsal or volar intra-articular fractures of the distal radial rim (Fig. 4.4.4). The mechanisms of injury are similar to those seen with Colles and Smith fractures, respectively. There is often significant soft tissue injury and the carpus is usually dislocated or subluxated along with the distal fragment. These fractures are complicated by arthritis of the radiocarpal joints and carpal instability.

Minimally displaced fractures involving less than 50% of the joint surface and without carpal displacement may be reduced along the lines of a Colles or Smith fracture. Immobilization should occur with wrist flexed for dorsal Barton and extended for volar Barton. However, most fractures are unstable and potentially disabling, requiring early operative management, especially in younger patients. Early orthopaedic follow up is mandatory.

Radial styloid (Hutchison or chauffeur) fracture

This oblique intra-articular fracture of the radial styloid is caused by a direct blow or fall onto the hand. Displacement is associated with carpal instability and long-term arthritis. The fracture is seen best on AP x-rays of the wrist (Fig. 4.4.5). Undisplaced fractures can be treated with a cast

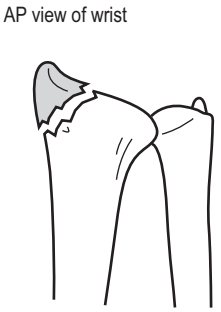

FIG. 4.4.5 Radial styloid (Hutchison or chauffeur) fracture. *AP*, Anteroposterior.

for 4 to 6 weeks. Displaced fractures should be referred to an orthopaedic surgeon for anatomic reduction and fixation.

Ulnar styloid fracture

An isolated fracture can occur through forced radial deviation, dorsiflexion, rotation or a direct blow. Avulsion fractures involving the lesser portion of the ulnar styloid are not associated with significant instability of the DRUJ. In contrast, fractures involving the base of the ulnar styloid disrupt the major stabilizing ligaments of the distal ulna and the triangular fibrocartilage complex (TFCC); they may lead to subsequent DRUJ instability. Fractures should be treated with a splint or cast with the wrist in mid-supination and ulnar deviation. Patients should be referred to an orthopaedic surgeon to assess DRUJ stability.

Carpal fractures and dislocations

Carpal fractures predominantly occur in young men. The bones in the proximal carpal row, especially scaphoid fractures, are more commonly involved, accounting for 82% to 89% of all carpal fractures. Most other isolated carpal fractures are triquetral fractures. Management depends on the degree of displacement, damage and instability. Generally undisplaced fractures with minimal comminution can be managed by cast immobilization. Given the importance of wrist function, early orthopaedic review should be sought for patients with displaced or comminuted fractures or where instability or an associated carpal dislocation is suspected.

Specific fractures

Scaphoid fracture

The most common mechanism of injury is a fall on the outstretched hand with the wrist in radial deviation. This mechanism also puts the distal radius and the scapho-lunate (SL) ligament at risk. Clinical features include wrist pain and local swelling and tenderness over the scaphoid palpated dorsally or via the anatomical snuffbox. Imaging with AP, lateral and scaphoid views will detect at most 70% of all scaphoid fractures.

Fractures of the scaphoid are classified by their location (proximal third, waist, distal third or tubercle) and by their stability. Stable fractures are undisplaced with little comminution and unstable fractures are displaced with considerable comminution. Stable fractures are generally treated with a below-elbow cast for 10 to 12 weeks. There is no evidence that cast immobilization with inclusion of the thumb leads to better outcome. Unstable fractures require surgical intervention. Complications include non-union and avascular necrosis of the proximal segment.

Some patients have clinical features suggestive of scaphoid fracture without confirmatory x-ray evidence. In the past, cast immobilization for 1 to 2 weeks followed by repeat x-ray was advocated. Although this is still advocated by some, it is not recommended. The additional sensitivity is low and scaphoid fractures are often missed. A number of alternative diagnostic approaches have been suggested, including bandaging with clinical review at 7 to 10 days followed by CT if clinical features persist or early primary CT, magnetic resonance imaging (MRI) or bone scintigraphy. All of these imaging modalities have their advantages and shortcomings.

Dislocations of the wrist

Dislocations involving the wrist usually result from high-energy falls on the outstretched hand (such as from a height) that result in forced hyperextension. The distal row of carpal bones is commonly displaced dorsal to the proximal row as a result of a scaphoid fracture, a scapho-lunate dislocation or a peri-lunate dislocation. Trans-scaphoid peri-lunate fracture dislocation is slightly more common than peri-lunate dislocation.

Clinical features

Clinical features include mechanism of injury, wrist pain, swelling and tenderness and possibly reduced grip strength.

Clinical investigations

Imaging requires PA and lateral x-rays. The normal PA view should show two rows of carpal bones in a normal anatomic position with uniform joint spaces of no more than 1 to 2 mm. No overlap should be seen between the carpal bones or between the distal ulna and the radius. On the lateral film, a longitudinal axis should align the radius, lunate, capitate and third metacarpal bone.

Radiographic features include the following:

- Lunate dislocation: on the usual PA image, the lunate has a triangular shape rather than its usual trapezoidal shape. On the lateral film, the lunate has a 'C-' or 'half-moon' shape. The rest of the carpal bones are in a normal anatomic position in relation to the radius.
- Perilunate dislocation: on the lateral film, the lunate is in a normal anatomical position with respect to the radius, with the rest of the carpal bones displaced dorsally. On the PA film, crowding is evident between the proximal and distal carpal bones.
- Scapholunate dislocation: on a PA radiograph, the scapholunate space is greater than 4 mm (also known as the Terry-Thomas sign). The scaphoid rotates, producing the classic signet-ring sign. Associated carpal fractures, especially of the scaphoid, may be evident.

Treatment All wrist dislocations require orthopaedic consultation and prompt reduction.

CONTROVERSIES

- Optimal management for Mason type II radial head fractures
- Optimal immobilization for distal radial fractures
- Operative versus non-operative management of distal radial fractures, particularly in the elderly
- Vitamin C for prevention of complex regional pain syndrome following distal radius fractures
- Optimal management strategy for suspected scaphoid fracture with normal initial x-rays

4.5 Hand injuries

Arthur Hennessy

ESSENTIALS

1 Hand injuries are common, and most, if treated early and competently, carry a good prognosis.

2 A comprehensive knowledge of hand anatomy and function is essential for appropriate management of the injured hand.

3 Aftercare and rehabilitation, ideally with specialized hand therapists, are essential for return to normal function.

Introduction

Hand injuries are common causes of presentation to emergency departments (EDs). The most common injuries are wounds (~50%), fractures (~15%), sprains (~8%), contusions (~8%).[1] Males injure their hands more often than females. The complex anatomy and tactile function of the hand mean that hand injuries can profoundly affect an individual's activities of daily life. The importance of the correct assessment and care of hand injuries cannot be overstated. Apart from the initial pain and trauma, occupational and psychological concerns play a major role in the aftermath of these injuries. Even a relatively minor fingertip injury can cause an individual being away from work for several days, with consequent loss of earnings and concerns for long-term function and appearance. A detailed knowledge of the anatomy of the hand and its common injuries is essential to proper diagnosis and management.[2] The role of ED management is as much about identifying cases that require specialist referral as it is about treating straightforward injuries.

Clinical features

History

Time taken eliciting a focused history of the mechanism of injury is essential in cases of hand injury. Key questions include the following:

- When did the injury occur?
- What was the position of the hand at the time?
- Was the hand injured with a sharp implement, such as glass, or crushed in a machine? Incised wounds caused by sharp implements tend to damage structures such as nerves and tendons, whereas crush injuries may cause fractures and lacerations.
- Was there brisk bleeding and does any part of the hand feel numb? These symptoms are important as, in the fingers, the digital nerves lie adjacent to the arteries.
- In what environment did the injury occur? Is it likely that the wound is contaminated or contains foreign material, such as glass?

The patient's hand dominance should be noted, as well as his or her occupation and key leisure activities. These details will have to be considered by the physician and patient when a management plan is being decided upon. Tetanus prophylaxis status should be determined.

Examination

The injured hand must be examined in a well-lit area. Overhead lighting and headlamps should be used if required. Temporary dressings may have to be soaked off if they have been allowed to dry out and become adherent. At triage, an initial moist dressing is preferred. Firm pressure and elevation will invariably arrest even brisk bleeding.

A standardized hand examination is recommended to ensure completeness.

Hand and finger injuries are painful; therefore suitable analgesia should be given prior to full examination. Local infiltration of a local anaesthetic without adrenaline around a wound or as a digital nerve block will allow examination of all aspects except sensation. It is imperative that sensation be tested and recorded prior to anaesthesia, as is palpating for specific areas of tenderness. A wrist block is useful when some or all of the hand must be anaesthetized (Fig. 4.5.1). In this instance, a longer-acting local anaesthetic is generally used to prolong the effect.

Inspection of the hand and comparing it with the other side will give information on local swelling and bruising, wounds and bleeding, deformity, misalignment, amputation. Discolouration may give information about perfusion of the tissues. The resting position of the hand may be a clue to tendon injury, as the normal uninjured position is held with the fingers in increasing flexion from the index to the little finger (Fig. 4.5.2A). A pointing finger may indicate a flexor tendon injury (see Fig. 4.5.2B). Obvious bone or joint deformity should be recorded.

Testing sensation is achieved by point touch in the distribution of the three main nerves that supply the hand (Fig. 4.5.3). Testing sensation of individual digits is necessary to elicit digital nerve injury. The median nerve supplies the palmar aspect of the thumb, index, middle and half of the ring finger, extending to supply the fingertip and nail bed. The ulnar nerve supplies both palmar and dorsal aspects of the other half of the ring finger and the little finger. The radial nerve supplies the radial dorsum of the hand, thumb, index, middle and radial aspects of the ring finger. If the patient is unable to describe sensation because he or she is too young or is unconscious, it is useful to remember that the digital nerves also carry the sympathetic supply to the fingers and that division will cause a dry finger in the distribution of the digital nerve. The motor components of median, ulnar and radial nerves are tested with resistance to thumb opposition, adduction and extension, respectively.

The metacarpals and phalanges are all easily palpable subcutaneously, and local tenderness or crepitus may indicate underlying fracture. Ligamentous stability should be tested with valgus and varus stress on the proximal interphalangeal (PIP), distal interphalangeal (DIP) and metacarpophalangeal joints (MCPJs). Gamekeeper's or skier's thumb (in which there is insufficiency of the ulnar collateral ligament of the thumb) is a common ligamentous injury.

Functional testing should be performed for all injured hands. Tendon integrity is tested by asking the patient to perform specific movements. Some tendon injuries may be obvious; however, two flexor tendons supply each finger, and simply asking the patient to flex the finger will not exclude a divided flexor digitorum superficialis tendon. The profundus tendon flexes the distal interphalangeal joint (DIPJ) and is tested by asking the patient to flex the tip of each finger in turn while the examiner holds the proximal interphalangeal joint (PIPJ) in extension. The superficialis flexor tendon is tested by asking the patient to flex each finger individually while the examiner holds the other fingers straight. The extensor tendons to the

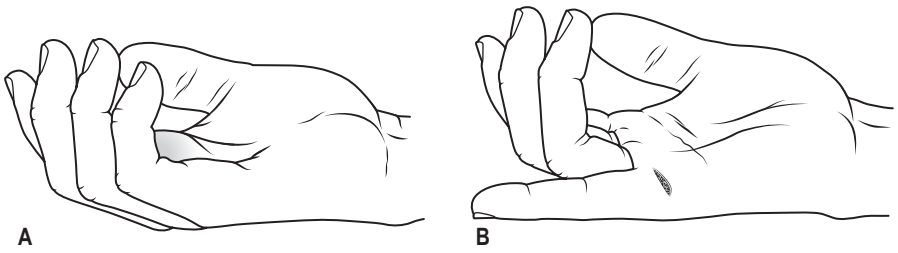

FIG. 4.5.2 (A) The normal resting hand. (B) The pointing finger. (Reproduced with permission from American Society for the Surgery of the Hand. *The Hand*. 2nd ed. Boston: Churchill Livingstone; 1990.)

fingers are tested by asking the patient to extend the fingers against resistance. It is important to remember that the broad interconnections between the extensor tendons make it possible to extend to near neutral in the presence of a divided tendon. Partial tendon injuries may still exist despite normal functioning of the fingers. A functioning hand should allow full extension of all fingers and comfortable flexion of the fingers into the palm.

Displaced fractures or dislocations may be apparent as deformity. More subtle rotational deformity will be detected by a finger crossing its neighbour when flexed and testing for this is important.

Clinical investigations

Most information will be obtained from a focused history and examination. Radiology of the hand and fingers will be necessary if bone/joint deformity or tenderness is elicited. Even obvious dislocations should be x-rayed prior to correction, as post-reduction x-rays may be overly reassuring despite significant soft tissue damage. Glass is radiopaque to a varying degree, and if a wound is caused by glass, an x-ray should be done prior to closure. Organic foreign bodies and infections may be detected by ultrasound using a small-parts soft tissue probe, and this modality is commonly available in the ED. Ultrasound is also useful to establish tendon integrity, but this is a more specialized examination.

Magnetic resonance imaging (MRI) can be useful in selected injuries as it shows the soft tissues of the hand clearly, but it is relatively unavailable acutely and should be reserved for conditions where emergent treatment is dependent on the integrity of the soft structures in the hand, which are not apparent on examination alone.

Treatment

Appropriate analgesia should be provided, as previously described. Rings should be removed from injured fingers to prevent subsequent compromise of circulation as the finger swells. Irrigating wounds with tap water does not increase the risk of infection and is economic.[3] Simple hand and finger wounds can be treated along conventional lines with judicious use of local anaesthetic and skin approximation with fine (5.0) sutures or skin closures. Hand wounds generally heal well and conservative management of small, uncomplicated hand wounds in areas of low skin tension is appropriate.[4] Digital nerve block is useful for managing finger injuries. This technique involves infiltrating local anaesthetic around the digital nerve at the base of the finger or in the palm. Approaching the digital nerve from the dorsum of the finger is less painful, but the palmar approach is more accurate, as the digital nerves lie just deep to the palmar aponeurosis. A short fine-gauge (e.g. 30 gauge) needle is used with small amounts (~1 mL) of local anaesthetic for each nerve. Choice of anaesthetic will depend on the desired length of effect, and consideration should be given to using long-acting agents for crush or bone injury when a prolonged analgesic effect is desirable. Studies have shown that the use of adrenaline with lignocaine is safe and also prolongs the anaesthetic effect.[5,6]

Hand dressings can be held in place with a conforming crepe bandage to provide a degree of compression. Stable injuries to the fingers can be managed with 'buddy' strapping, which allows for some joint movement. Elevation is essential after hand injury to reduce swelling. Minor injuries can be successfully managed in the ED, but more significant injuries usually require referral for surgical opinion.

Fingertip injuries

The fingertips have an excellent blood supply and will usually heal with good cosmetic and tactile function if basic wound care principles are followed. Fingertip injuries may involve the skin, subcutaneous tissue, nail or terminal phalanx.

The most complex type of injury to manage is one in which the terminal phalanx is exposed; these cases will require referral for surgical

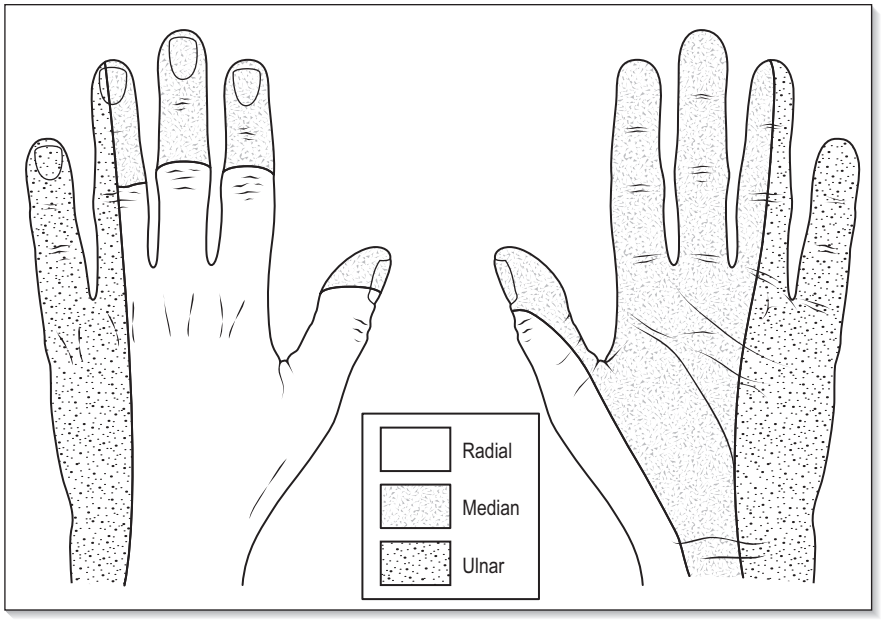

FIG. 4.5.3 The nerve supply to the hand.

treatment. If there is injury involving less than 50% of the nail and no bone is exposed, conservative treatment is often the best option. Small tuft fractures of the underlying terminal phalanx are stable and will be supported by the dressing or nail-bed repair.

Care of the fingertip will require haemostasis followed by a non-adherent dressing. Alternatives to conservative management include full-thickness skin grafts to the fingertips, advancement flaps and cross-finger flaps. These should be performed by surgeons trained in the specialist techniques and reserved for injuries involving large areas of tissue loss.

Major amputations of the fingertip or crush injuries may require terminalization of the finger. This should be fully discussed with the patient, who may be prepared to forgo finger length in exchange for early return of function. Patients requiring terminalization of a finger should be referred to a specialist hand service. Occasionally patients will bring amputated pieces of the injured fingertip with them into the ED. Recently amputated fingers can be wrapped in moist gauze and then placed in a bag and packed with ice if re-implantation is being considered by specialist hand surgeons. If there is any doubt about the viability of fingertip tissue, the patient should be referred to a specialized hand service. No attempt should ever be made to resuture avascular tissue.

Digital nerve injuries

Nerve repairs distal to the DIPJ are rarely required as the terminal branches are very fine. Any sensory loss with these distal injuries is minimal and improves with time. More proximal injuries can be repaired by a hand or plastic surgeons using microsurgery. Good results are achieved with early repair of digital nerves when the ends can be approximated without tension using a fine (>8/0) suture. The return of protective sensation depends on the extent of damage, level of repair and axon regeneration.

Nail-bed injuries

These injuries are frequently underestimated, often because of a reluctance to remove the nail. A displaced fracture or growth-plate slip of the terminal phalanx will usually be associated with nail-bed disruption. Current practice is to leave a nail when the nail remains adherent to the underlying bed. Small painful subungual haematomas can be released using a trephine burr. Often, damage to the nail bed results in spontaneous separation of the nail, followed by new nail growth, which pushes any residual nail off. Assuming that the nail root is intact, a new nail will grow back at a rate of 1 mm per week; thus full growth of a new nail takes approximately 80 days.

If required, removal of a displaced nail is achieved under digital nerve block using blunt dissection with a pair of fine forceps or scissors. The nail should be retained for use as a dressing later. Underlying fractures should be reduced with pressure and fracture haematomas irrigated away to achieve anatomical approximation of the bone ends. Fractures distal to the insertion of the profundus tendon are stable. Repair of the fragmented nail bed can be performed with fine (5/0 or 6/0) absorbable suture on an atraumatic needle. Care must be taken not to cut out with the needle, as the nail bed is extremely friable. A recent review has shown that tissue adhesive is as effective as suturing for nail-bed repair.[7] Procedural haemostasis can be achieved with the prior application of a finger tourniquet or firm pressure over the digital arteries. Ideally the nail is trimmed and reapplied as an organic splint and dressing. Follow-up with a specialized hand service should be arranged.

Distal interphalangeal joint injuries

Acute flexion injuries of the terminal phalanx may either rupture the extensor tendon at the level of the DIPJ or avulse its insertion into the terminal phalanx. This produces an acute flexion deformity of the DIPJ, known as a mallet finger. An x-ray of the finger should be taken, as an intra-articular fracture involving more than one-third of the joint surface may require internal fixation. Subluxation of the DIPJ can occur when more than half of the articular surface is involved. Small avulsion fractures and tendon ruptures are best treated by the application of a correctly fitting mallet finger splint, which should be retained for at least 8 weeks. Splint durability is important for compliance. Referral to specialized hand therapist for splinting is advised. Persisting mallet finger deformity after treatment or late presentations are best treated conservatively, as the finger is still functional despite the mallet deformity and operative repair is usually less than satisfactory.

Hyperextension of the DIPJ can cause avulsion of the profundus tendon from the terminal phalanx (Jersey finger) and requires operative repair. In this injury, there is an inability to flex the DIPJ.

Simple dislocations of the DIPJ can be reduced in the ED and rarely cause long-term instability. However, prior radiography should be performed to differentiate dislocation from the more complicated intra-articular fractures. When this injury is associated with a palmar wound, copious irrigation is required prior to closure. Antibiotics are required in these cases and follow-up should be arranged.

Middle phalangeal injuries

The middle phalanx takes the insertion of the flexor superficialis tendon slips, through which passes the profundus tendon. Fracture of the middle phalanx can disrupt the fibrous tunnel of the profundus tendon and cause adhesions. These fractures must be accurately reduced and may require internal fixation. They are usually unstable owing to the pull of the tendons. Palmar wounds at this level are likely to divide the profundus tendon or digital nerves and should be explored by a specialized hand service if these injuries are suspected on clinical grounds.

Proximal interphalangeal joint injuries

This is the joint that causes most long-term complications owing to stiffness and joint contracture. It is also the most commonly dislocated joint in the hand. The PIPJ is mechanically complex and is supported dorsally by the extensor apparatus; on the palmar aspect, it is supported by the strong fibrous volar plate. Lateral stability is provided by the collateral ligaments. Rupture of either the extensor apparatus or the volar plate will result in joint instability and potential long-term disability. Tears in the extensor apparatus may result from relatively minor blunt trauma. Dislocations of the PIPJ invariably displace both structures. Hyperextension of the PIPJ, often from basketball or netball injuries, can result in an avulsion injury of the volar plate, and a small fragment from the middle phalanx may be visible on lateral finger x-ray. Reduction of dislocations should be followed by extension splinting and early follow-up. The 'boutonnière' deformity (flexion of the PIPJ accompanied by hyperextension of the DIPJ) is a hand surgeon's nightmare and, ideally, should be prevented by careful attention to the extensor apparatus at the level of the PIPJ. These injuries should not be underestimated. Ultrasound can be used to aid in early diagnosis.

Proximal phalangeal injuries

Both flexor tendons pass along the palmar aspect of the proximal phalanx; therefore fractures of this bone tend to be unstable. Rotational deformity is particularly disabling and may not be noticeable with the finger held straight. These fractures usually require internal fixation. The lateral x-ray will often be the most useful in determining the degree of angulation or displacement. Wounds may damage digital nerves or either or both of the flexor tendons. Examination of the finger should detect these injuries and referral to a specialized hand service will be required.

Metacarpophalangeal joint injuries

Subluxation of the MCPJ may occur in the older patient after a fall on the outstretched hand. The clinical appearances are subtle and the injury is easy to miss on x-ray. The clue is the inability to extend the finger fully. In recent injuries, reduction is achieved by traction on the finger, although once the displacement is established, reduction becomes difficult even with open procedures.

MCPJ injuries caused by fist and/or tooth impact (fight bite) are common and should be assumed to be infected. The extensor tendon may be divided and x-ray may show fracture of the metacarpal head. These injuries should be treated aggressively by joint irrigation, splinting and antibiotics.

Rupture of the ulnar collateral ligament (gamekeeper's or skier's thumb) results from an abduction injury of the thumb; when complete, it results in MCPJ instability. When completely ruptured, the ligament may become folded back outside the adductor aponeurosis, which prevents healing. X-rays may be taken to identify avulsion fractures of the base of the proximal phalanx. Stress x-ray views can demonstrate joint instability, but MRI will confirm injury. Treat suspected ulnar collateral ligament injuries in a thumb spica splint and refer for specialist assessment, as early surgical repair gives the best outcome.

Metacarpal injuries

These injuries can be caused by punching, crush injury or falls onto the closed fist. The commonest injury is fracture of the neck of the fifth metacarpal, which is often treated conservatively. Correction of significant angulation (>45 degrees) should be attempted, but it is rare to achieve complete correction. Spiral fractures of the shaft of a metacarpal will result in shortening of the bone and loss of the contour of the knuckle. Angulation of index and middle finger metacarpal fractures should be corrected, but up to 20 degrees of angulation in the ring and little fingers is acceptable. Conservative management of these fractures should involve splinting the hand in intrinsic plus position (Fig. 4.5.4) with the MCPJ flexed to 70%. The fingers must be splinted almost straight, with support extending to the fingertip. Abduction injuries of the thumb may cause a Bennett fracture, which is an intra-articular fracture of the base of the thumb metacarpal. When displaced, Bennett fractures should be referred for specialist opinion.

Dorsal hand injuries

Wounds on the dorsum of the hand may divide the extensor tendons, which are relatively superficial. Complete division may be apparent by loss of full extension of a digit (extensor lag). Extensor tendons have extensive cross insertions, so over 50% of the tendon can be divided without extensor lag. Visualization of the intact tendon gliding throughout its range of movement in a wound is the only safe way to exclude damage. Repair of these tendons is relatively straightforward, as both ends of the tendon are usually visible within the wound. It should, however, only be performed by clinicians with appropriate training and experience. The extensor pollicis longus tendon can retract and therefore should be treated in a similar manner to divided flexor tendons and be referred for specialist repair.

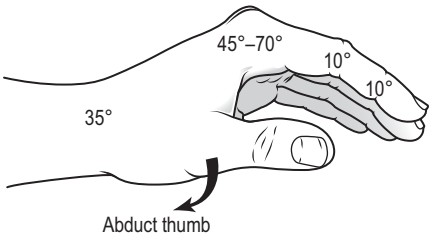

FIG. 4.5.4 Intrinsic plus—recovery position. (Reproduced with permission from American Society for the Surgery of the Hand. *The Hand.* 2nd ed. Boston: Churchill Livingstone; 1990.)

Palmar hand injuries

Penetrating wounds on the palm of the hand are likely to divide flexor tendons or main digital nerves. These injuries should be detected by examination of the function of the individual fingers as mentioned previously. Briskly bleeding wounds proximal to an area of anaesthesia are a clue to digital nerve injury because of coexisting damage to both neurovascular structures. Neurovascular and flexor tendon damage will require referral for specialist repair.

Foreign bodies in the hand can be notoriously difficult to find, and damage to other structures can result from injudicious exploration. The best results are achieved in a bloodless field with full anaesthesia. Nail-gun injuries require an x-ray prior to removal of the nail to establish its location with respect to bone and to see whether the nail has barbs that will make removal difficult. High-pressure grease- or paint-gun injuries result in extensive tissue penetration and should not be underestimated. The extent of penetration may be seen on x-ray. Wide exposure and decompression of the tract within 6 hours is associated with better outcomes; thus emergent referral to a specialized hand surgeon is necessary.

Disposition

Many minor hand injuries can be well managed in an appropriately equipped ED ambulatory care area. No attempt should be made to operate surgically on a hand without experience, good instruments, adequate lighting and fine sutures. After treatment, the hand should be elevated in a high arm sling and suitable analgesia provided. More complex injuries will require access to a specialized plastic or orthopaedic surgery hand service. When in doubt, early consultation is advisable.

Prognosis

Hand injuries recover best with early definitive treatment, as badly managed injuries can be

very difficult to salvage at a later date. Stiffness and loss of function can be avoided if good surgical principles of wound management are adhered to. Appropriate initial splinting and guarded mobilization are the cornerstones of rehabilitation. The injured hand recovers best when splinting has been in a functional position. Whenever possible, the hand should be immobilized with the fingers straight and the MCPJ flexed to 70 degrees. This can be achieved in even the most swollen hand by careful application of a volar plaster slab. Early referral for definitive surgery and subsequent rehabilitation will be essential for severe or complex injuries. An explanation to the patient of the need to prevent joint stiffness is important when the finger requires dressings for more than 3 weeks.

Prevention

Hand and finger injuries can be prevented. Strategies for prevention involve providing data for public awareness, identifying strategies (e.g. safety equipment, machinery modification) to prevent occupational injuries and lobbying officials to legislate for sensible measures to prevent injury.

CONTROVERSIES

- Solutions for wound irrigation. EDs have long used sterile solutions to cleanse wounds. In countries with clean drinking water, there is no evidence that using tap water results in more infected wounds, and it is certainly cost effective.[3]
- Foreign body removal from the hand can range from being entirely straightforward to being excessively difficult and damaging. A judgement must be made on the likely ease of removal and the facilities available. The first attempt is usually the easiest. Wood and glass can be very difficult to find in the tissues without precise localization and a bloodless field. Ultrasound is increasingly being used to locate non-radiopaque foreign bodies, which, if left, can predispose to infection.
- To suture or not? Injudicious suture of an acutely injured finger can compromise circulation and confer a secondary injury. Skin closures may be used to bring the skin edges together or, where there is gross swelling, dressings may be used to maintain the anatomy of the finger. Conservative non-suture management of small, uncomplicated hand and finger wounds is quick and safe.[4]
- Use of antibiotics. Antibiotics have no role in the initial management of clean hand injuries.[1] However, antibiotics may be needed in the case of grossly contaminated injuries and those known to have been caused by bites.
- Use of anaesthetic with adrenaline for digital nerve block has been shown to be safe.[5,6]

4.6 Pelvic injuries

Stephen Cusack

ESSENTIALS

1 **Pelvic fractures account for 3% of skeletal fractures.**

2 **Fractures are either stable or unstable. Unstable fractures result from considerable mechanical force; they are associated with concomitant injuries and with a significant overall mortality.**

3 **Understanding the mechanism of injury and recognizing the pelvic fracture pattern on x-ray provides insight into the potential for complications, such as associated haemorrhage or urogenital injuries.**

4 **Isolated stable pelvic fractures are usually treated conservatively.**

Anatomy

The pelvic ring is formed by two innominate bones and the sacrum. The innominate bones are made up of the ileum, ischium and pubis and are joined anteriorly at the symphysis pubis and posteriorly at the left and right sacroiliac joints. The lateral surface of the innominate bone forms a socket, the acetabulum, contributed to by the ileum, ischium and pubis.

Stability of the pelvic ring is dependent on the strong posterior sacroiliac, sacrotuberous and sacrospinous ligaments. Disruption of the ring can result in significant trauma to the neurovascular and soft tissue structures it protects. A break at one point in the ring merits consideration of breaks at other points on the ring.

Classification of pelvic fractures

Pelvic fractures can be open or closed, major or minor, stable or unstable depending on the degree of ring disruption; they may be associated with haemodynamic compromise and/or hollow viscus or neurological injury.

Young and Resnik classification

The Young and Resnik pelvic fracture classification (also outlined in Chapter 3.8) classifies pelvic fractures by the mechanism of injury and the direction of the causative force. It does not include isolated fractures outside the bony pelvic ring or acetabular fractures, which are discussed later.

Most pelvic fractures result from lateral compression, anteroposterior compression or vertical

shear forces. These injuries may be suggested by mechanism of injury and are confirmed radiographically.

Lateral compression injuries

Lateral compression accounts for 50% of pelvic fractures and commonly occurs when a pedestrian or motor vehicle occupant is struck from the side. Most of these injuries are stable, but as a result of the considerable forces involved, there is a high potential for associated injury. This mechanism of injury can produce several fracture patterns involving anterior and posterior pathology.

Anteriorly, there is a transverse fracture of at least one set of pubic rami. These fractures may be unilateral or bilateral and can include disruption of the pubic symphysis. The posterior element of lateral compression fractures is important but may be overlooked when one is concentrating on the anterior findings. However, it is critical in determining the functional stability of the pelvic ring and defining associated injuries.

Type 1 fractures Type 1 fractures are the most common and involve compression injury to the sacrum posteriorly and oblique pubic rami fractures anteriorly.

These injuries occur on the side of impact and are usually stable, involving impaction of the cancellous bone of the sacrum without ligamentous disruption. X-rays confirm discontinuity of the sacral foramina posteriorly.

Type 2 fractures Type 2 fractures result from greater lateral compressive forces. The iliac wing is fractured posteriorly, with the fracture line often extending to involve part of the sacroiliac joint. This leaves part of the ileum firmly attached to the sacrum.

Anteriorly, there are associated fractures of the pubic rami. Stability is determined by the degree of sacroiliac joint disruption and mobility of the anterior hemi-pelvis involved. These fractures are usually stable to external rotation and vertical movement but are more mobile to internal rotation.

Type 3 fractures Type 3 fractures usually occur when one hemi-pelvis is trapped against the ground and a lateral force rolls over the mobile hemi-pelvis. This produces a lateral compression injury to the side of primary impact and an unstable anteroposterior compressive injury to the contralateral sacroiliac joint.

Anteroposterior compression injuries

Anteroposterior compression injuries of the pelvis account for 25% of pelvic fractures. They result from anterior forces applied directly to the pelvis or indirectly via the lower extremities to produce an open-book type injury.

Type 1 injuries Type 1 injuries result from low-energy forces that stretch the ligamentous constraints of the pelvic ring. The pubic symphysis is disrupted anteriorly but with less than 2.5 cm diastasis seen radiographically. These fractures are stable and there is usually no significant posterior pelvic injury.

Type 2 injuries Type 2 injuries classically cause an open-book fracture. They involve rupture of the anterior sacroiliac, sacrospinous and sacrotuberous ligaments posteriorly and disruption of the pubic symphysis anteriorly. There is widening of the anterior sacroiliac joint with diastasis of the pubic symphysis by more than 2.5 cm on radiology; occasionally there is avulsion of the lateral border of the lower sacral segments.

Considerable force is needed to disrupt these ligaments; therefore neurovascular injuries and complications are common. The pelvis is unstable to external rotation and external compression will 'spring' the pelvis. This should be avoided.

Type 3 injuries Type 3 injuries occur when an even greater force is applied and involves disruption of all the pelvic ligaments on the affected side. Rupture of the posterior sacroiliac ligaments leads to lateral displacement and disconnection of the affected hemi-pelvis from the sacrum. These injuries are grossly unstable and associated with the highest rate of haemorrhage and neurological injury (Fig. 4.6.1).

Vertical shear injury (Malgaigne fracture)

These injuries account for only 5% of pelvic fractures. They usually occur following a fall from a height or during a motor vehicle accident, when the victim reflexly extends his or her leg against the brake pedal before impact. These mechanisms force the hemi-pelvis in a vertical direction and result in complete ligamentous or bony disruption, with cephalo-posterior hemi-pelvic displacement.

Anterior disruption occurs through the pubic symphysis or pubic rami. Posteriorly, dissociation usually occurs through the sacroiliac joint, but it may occur vertically through the sacrum. These fractures are usually unilateral but may be bilateral and are associated with significant bleeding and/or intra-abdominal injury.

FIG. 4.6.1 'Open-book' pelvic fracture, with pubic symphysis diastasis and sacroiliac disruption, following an anteroposterior compression injury.

Clinical assessment

A standard trauma management protocol is adhered to in managing the multi-trauma patient, with usual attention being paid initially to the airway, breathing and circulations (ABCs) in the primary survey and resuscitation phases of care (see Chapter 3.1).

General examination

Abdominal, perineal, rectal and a vaginal examination are performed according to suspected injury. The rectal examination in the absence of overt urethral trauma includes observation for fresh blood and an assessment of anal sphincter tone and position of the prostate. A thorough perianal and lower limb neurovascular examination is performed. The back is examined to assess for external evidence of injury to the lumbar spine, sacroiliac regions and coccyx with inspection and palpation.

Pelvic examination

The pelvis is briefly examined as part of the cardiovascular assessment in the ABC approach to trauma. The suprapubic, pelvic and urogenital regions are inspected for signs of bruising, abrasions, open wound and obvious deformity. In males, the urethral meatus is assessed for the presence of frank blood and the scrotum for bruising. Flank bruising may indicate retroperitoneal haemorrhage.

The pelvis should be gently assessed by an experienced clinician. Rough handling and repeated manipulation may disrupt critical clot. In mature systems patients may already present with a pelvic binder in situ. This should remain in place until evaluation is complete.

Radiology

The antero-posterior (AP) pelvic x-ray is an initial film that will usually rapidly alert clinicians to anterior fractures, such as pubic rami or diastasis, and may suggest complex hemi-pelvic injuries. Posterior fractures are difficult to visualize and further plain x-rays or usually computed tomography (CT) scans are needed.

Injuries associated with pelvic fractures

Haemorrhage

Haemorrhage is the most serious complication of a pelvic fracture. It may result from bleeding at fracture sites, local venous or arterial tears

and/or disruption of a major vessel. Catastrophic bleeding can result from disruption of the internal iliac arteries, their tributaries and accompanying veins as they pass over the anterior aspect of the sacroiliac joint.

Severe hypovolaemia due to persistent haemorrhage without major vessel disruption is a significant cause of mortality. Up to 4 L of blood may be lost into the retroperitoneal space before tamponade occurs. AP type 3 injuries and vertical shear injuries disrupt the sacroiliac joint and are associated with significant haemorrhage.

Treatment to minimize or stop haemorrhage associated with a pelvic fracture includes the early application of a pelvic binder across the level of the greater trochanters. Treatment beyond that is complex and best led by a senior specialist team leader using a pre-agreed algorithm. This will vary between institutions and involve any combination of resuscitative endovascular balloon occlusion of the aorta (REBOA), external fixation, interventional radiology with angiography and embolization, 'damage control' laparotomy with pelvic packing and/or open reduction with internal fixation.

Genitourinary and bladder injuries

Pelvic fractures are associated with injury to the lower urinary tract in up to 16% of cases. These are more prevalent in males, who sustain a higher rate of urethral injury. Pelvic trauma may also result in bladder rupture. The bladder is normally protected by the pelvis and rupture usually indicates significant disruption of the pelvic ring.

Almost 90% of blunt trauma patients with bladder rupture have an associated pelvic fracture. Patients are usually hypotensive with frank haematuria, although gross haematuria is a non-specific sign of genitourinary trauma and does not necessarily indicate bladder rupture. A CT scan of abdomen and pelvis should precede any specialist genitourinary radiology as contrast used for this may confound these more general examinations.

Urethral and genital injuries

Rupture of the urethra secondary to blunt trauma commonly occurs to the anterior bulbous urethra just distal to the urogenital diaphragm. It is associated with bilateral fractures of the pubic rami, pubic symphysis disruption and vertical shear injuries.

Suspect a urethral rupture in the adult male with a pelvic fracture, blood at the urethral meatus, perineal haematoma and urinary retention. A 'high-riding prostate' may be found on rectal examination; however, not all these signs may be present. A retrograde urethrogram is diagnostic and must be performed prior to urethral (Foley) catheterization when indicated clinically.

Urethral injury is rare in females, whereas injury to the female genitalia is uncommon but often overlooked. Vaginal laceration is associated with a pelvic fracture in 4% of cases. These normally present with bleeding but may be occult. A bimanual pelvic examination is necessary in women with a pelvic fracture, which may necessitate anaesthesia due to patient discomfort. Complications, such as abscess formation and sepsis, are severe, particularly if the injury is missed.

Management of the unstable pelvic fracture

The mainstay of pelvic fracture management in the emergency department (ED) is to identify and assess the degree of pelvic injury, to provide splintage, pain relief and fluid/blood resuscitation in order to minimize life-threatening haemorrhagic shock. Early identification of major pelvic trauma with mobilization of general surgical, orthopaedic, vascular, interventional radiology and intensive care specialties is essential, ideally using a pre-agreed algorithm approach.

Fluid resuscitation

Commence initial fluid resuscitation with intravenous crystalloid in the hypotensive patient with pelvic trauma using two large-bore peripheral intravenous cannulae, but rapidly change to blood and blood products if the hypotension is not immediately reversed. An average blood transfusion requirement for anteroposterior compression fractures is 15 units, for a vertical shear injury it is 9 units and for lateral compression injuries it is 3.5 units.

Therefore activate a major transfusion protocol (MTP) with blood and blood products, such as fresh frozen plasma (FFP) and platelets in a ratio that may approach 1:1:1 according to local practice. Also give tranexamic acid 1 g IV in 100 mL of normal saline over 10 minutes, followed by a 1 g infusion over 8 hours, providing these are commenced within a maximum of 3 hours of injury.

Pelvic immobilization

Pelvic binder or sling

Immobilization of the pelvis with attempted re-approximation of bony fragments creates a tamponade effect that reduces the risk of haemorrhage prior to definitive treatment. This is best achieved using a proprietary radiolucent pelvic binder device with ratchet mechanism or pelvic sling to apply compression. In mature systems this may already have been applied. Alternatively, simply brace the pelvis in a sheet, support it laterally with sandbags and internally rotate the hips with the lower legs splayed apart.

External fixation

External fixation is a rapid and simple procedure designed to immobilize and stabilize the anterior pelvis in the ED to reduce pelvic haemorrhage prior to definitive treatment. Three pins are placed through each iliac crest and are then clamped to an external frame to reduce the displaced pelvic ring injury.

The advantages of external fixation are that it is quick, effective and can proceed in the ED without delaying the continued management of the multiply injured patient. Disadvantages include a lack of support for the posterior component of the pelvic ring fracture, difficulty of placement in the obese patient and reduced pelvic surgical access in the event of laparotomy being required.

Resuscitative endovascular balloon occlusion of the aorta

REBOA has recently been adopted in some systems and has enthusiastic proponents. It involves the introduction of a balloon catheter above the bifurcation of the aorta through the femoral artery. There are considerable theoretical benefits but also potential for significant complications. It should be considered only in a mature protocolized system as a bridge to definitive treatment.

Embolization

Life-threatening arterial haemorrhage is estimated to occur in 5% to 20% of patients with blunt pelvic fracture. Emergency angiography is both diagnostic and therapeutic to control primary haemorrhage and (where available) has become the treatment of choice in patients with haemodynamic instability due to a pelvic fracture, particularly where a CT scan has shown an 'arterial blush' indicating ongoing bleeding.

Early recognition of these patients with organization of transfer to a hospital with angiography capabilities and mobilizing an interventional radiologist reduce mortality but constitute a logistical challenge. The success of the procedure is operator-dependent, time-consuming and does not address venous blood loss, which still requires appropriate replacement of blood and blood products and consideration of laparotomy with pelvic packing.

Laparotomy with pelvic packing

Continuing pelvic bleeding with haemodynamic instability when due to venous haemorrhage and/or when interventional radiology is unavailable or delayed may require laparotomy with pelvic packing, with continued blood and component therapy to prevent or treat coagulopathy, paying attention to base deficit, coagulation profile and temperature; this is followed by admission for intensive care monitoring. Surgical expertise is necessary to perform this temporizing procedure

prior to subsequent pack removal and definitive management that may include later open reduction with internal fixation.

Open pelvic fracture

Open pelvic fractures are rare and associated with increased morbidity and mortality of up to 40% to 50%. Open fractures with pelvic ring disruption lose any tamponade effect and can result in massive and fatal haemorrhage as well as a high risk of intra-abdominal injury and/or late sepsis.

Management

Control of haemorrhage is the priority in an open pelvic injury, with early surgery to avoid the increased risk of infection. Sterile gauze packed into the wound applies direct pressure tamponade. Urgent repair of associated open bowel and/or bladder injuries and the debridement of bleeding wounds is paramount, with stabilization of the pelvic fracture as the last step in treatment. The mortality remains high despite advances in imaging and aggressive treatment.

Acetabular fractures

Acetabular fractures account for 20% of pelvic fractures and are associated with posterior and lateral compression forces. Their classification is complex.

Clinical features

Acetabular fractures are caused by direct impaction of the femoral head, which may be associated with hip dislocation. These fractures are associated with sciatic and femoral nerve injury, depending on the position of the hip dislocation. A thorough neurovascular examination is mandatory.

In addition, these fractures are often associated with other pelvic injuries, knee injury, hip fractures and dislocations, which should all be looked for.

Management

Standard radiographs of the hip and pelvis may define the fracture, but a CT scan is necessary, particularly to show the anterior and posterior fragments and involvement of the ilioischial and iliopubic columns. All fractures are referred for inpatient orthopaedic management.

Stable fracture of the pelvis

Isolated pubic ramus fracture

These injuries are commonly seen in the elderly with direct trauma following a fall. The patient has difficulty in weight bearing and there is local pain and tenderness in the groin. These should be carefully looked for in any patient unable to bear weight with a suspected hip fracture, particularly when x-ray of the hip is normal.

The flexed, abducted and externally rotated (FABER) test—where the ipsilateral foot is placed on the contralateral knee, forcing the ipsilateral hip to be FABER—exacerbates pain and can assist diagnosis. Pelvic radiographs may confirm diagnosis.

Iliac wing fracture (Duverney fracture)

Direct lateral trauma may result in an isolated iliac wing fracture, known as the Duverney fracture. Patients complain of severe pain on weight bearing and walk with a waddling gait. Localized tenderness and bruising occur over the site of injury, sometimes associated with lower quadrant tenderness, and ileus.

These fractures are usually minimally displaced, rarely comminuted and are readily visualized on AP pelvic x-ray.

Isolated avulsion fractures

These are often sustained by young adults following acute stress to the muscular and ligamentous insertions onto the bony pelvis. They include anterior superior iliac spine fracture, anterior inferior iliac spine fracture and the ischial tuberosity fracture.

Anterior superior iliac spine fracture

The anterior superior iliac spine may be fractured in jumping activities due to powerful contraction of the sartorius muscle and tensor fascia lata. Such injuries cause pain on weight bearing, with local tenderness and swelling at the fracture site. Active flexion and abduction of the thigh reproduces the pain. There is usually minimal displacement of the avulsed fracture on the AP film of the pelvis. Treatment is usually conservative, although operative management is possible for significant displacement.

Antero-inferior iliac spine fracture

Forceful contraction of the rectus femoris muscle in sports that involve sprinting or kicking (forceful hip extension) may avulse the anterior inferior iliac spine. These patients complain of a sharp pain in the groin and are unable actively to flex the hip. The fracture is usually evident on plain AP pelvic views, with the fragment being displaced distally. Conservative treatment is common.

Ischial tuberosity fracture

Fracture of the ischial tuberosity is rare and occurs with forceful contraction of the hamstrings, usually in young adults whose apophyses are not fully united. They are associated with hurdling and other jumping activities. Pain may be reproduced by local palpation and by straight leg raising. Plain x-rays of the pelvis reveal minimal displacement of the apophysis from the ischium. Conservative treatment is common.

Coccygeal fracture

These fractures are more frequent in women and are caused by a fall onto the buttocks with both hips flexed. Patients have difficulty in mobilizing and have local pain, swelling, bruising and tenderness over the lower sacral region. X-ray confirmation is unnecessary if physical examination confirms an isolated injury.

Management of isolated stable fractures

Pubic ramus fractures, iliac wing fractures and avulsion fractures are treated conservatively with oral analgesia and non-weight-bearing strategies. Mobilization and physiotherapy allow resumption of normal activities in 3 to 4 weeks, followed by graduated return to high-impact sporting activities. Coccygeal fractures require rest, analgesia and stool softeners. As sitting is painful, a doughnut-ring foam cushion is helpful.

CONTROVERSIES

Optimal multidisciplinary management in the ED of the hypotensive pelvic trauma patient; what protocol, who to call and when. The use of hybrid operating theatre suites—the use of a resuscitation with angiography, percutaneous techniques and operative repair (RAPTOR) suite —allows simultaneous management strategies to occur, but evidence is lacking.

- The role of external pelvic fixation devices in the ED
- The optimal timing of angiography and arterial embolization

4.7 Hip injuries

Stephen Cusack

ESSENTIALS

1 **Fracture of the hip is a major cause of morbidity and mortality in the elderly, with a large impact on health care and resources.**

2 **Hip injuries are frequently a pathological disease of the elderly. However, hip fractures and dislocations also occur in young people who sustain high-energy trauma.**

3 **Extracapsular hip fractures are associated with significant haemorrhage.**

4 **Avascular necrosis (AVN) of the femoral head is a complication of intracapsular femoral neck fractures as well as hip dislocation.**

5 **The hip joint is least stable when flexed and adducted and thus prone to dislocation. Posterior hip dislocations are an orthopaedic emergency, as they are associated with sciatic nerve injury and AVN.**

6 **Anterior hip dislocations are associated with femoral neurovascular injury and occult hip joint fractures.**

Anatomy

The hip joint is a large ball-and-socket articulation encompassing the acetabulum and proximal femur. The hip joint provides a high degree of stability and mobility.

Blood supply

The head and intracapsular portion of the femoral neck receive the majority of their blood supply from the extracapsular trochanteric anastomosis arterial ring, with a minor supply arising from the foveal branch of the obturator artery via the ligamentum teres to the femoral head.

Retinacular arteries from the extracapsular ring pass under the reflection of the hip capsule to supply the femoral neck and head in a retrograde manner. Intracapsular fractures disrupt this 'distal-to-proximal flow' and so may result in avascular necrosis of the femoral head.

Avascular necrosis

Avascular necrosis (AVN) following hip injury refers to ischaemic bone death within the femoral head due to compromise of its blood supply. Increased bone density of the femoral head is the radiographic feature of AVN, but this may take up to 6 months to become manifest.

AVN results primarily from the disruption of the trochanteric anastomosis in femoral neck fractures and is the commonest early complication of these fractures. Traumatic haemarthrosis with or without a fracture may also result in intracapsular tamponade. AVN occurs when the intracapsular pressure exceeds the diastolic blood pressure.

AVN is also seen following posterior dislocation and is related to the degree of trauma and the length of time the femoral head is out of the joint. Early management is thus an orthopaedic emergency, as reduction within 6 hours results in an AVN rate of less than 10%.

In addition, chronic pancreatitis, alcohol abuse, sickle cell anaemia, vasculitis, irradiation, decompression illness (DCI) and the prolonged use of corticosteroids may all result in AVN.

Classification of hip fractures

Hip fractures are either intracapsular or extracapsular. Intracapsular fractures involve the femoral neck or head. Extracapsular fractures include intertrochanteric, trochanteric and subtrochanteric types and are four times more common than intracapsular fractures.

The incidence of hip fractures increases exponentially with age, with the fracture rate doubling for every decade over 50 years. Hip fractures occur most frequently in white postmenopausal women, as 50% of 65-year-old women and 100% of women over the age of 85 have a bone mineral density below fracture threshold level (osteoporosis).

Intracapsular fractures

Femoral head

Femoral head fractures are uncommon and are usually associated with dislocations of the hip. They often occur in young patients, 75% of cases being associated with motor vehicle accidents (MVAs).

Classification Fractures of the superior aspect of the femoral head are usually associated with anterior dislocation, whereas inferior femoral head fractures occur with posterior dislocation. Fractures may involve a single fragment (type 1) or comminution (type 2).

Clinical evaluation Symptoms and signs of femoral head injuries are usually those of the associated dislocation rather than the fracture itself. Femoral head fractures are not always picked up on initial x-rays. In the absence of abnormality on plain radiography and the presence of persistent pain following reduction of a hip dislocation, further imaging with a computed tomography (CT) scan should be performed.

Management Immediate orthopaedic referral is essential, as prompt reduction of the dislocation and appropriate stabilization of the fracture reduce the risk of AVN, increasing the chances of a return to full mobility. The prognosis is related to the severity of the initial trauma, time to definitive reduction and the number of failed closed relocation attempts.

Complications AVN occurs in 15% to 20% of cases, post-traumatic arthritis in 40% and myositis ossificans in 2%.

Femoral neck fractures

Intracapsular fractures are four times more common in females than males. There are four main causes of this type of injury:

- Elderly, with minimal trauma following a fall onto the greater trochanter (pathological fracture)
- Elderly, with torsion or twisting injury prior to fall (pathological fracture)
- Young person involved in high-energy trauma (excessive loading)
- Repetitive stress or cyclical loading injuries (stress fracture).

Classification The Garden classification system is commonly used to describe intracapsular neck of femur fractures.

Garden I: Incomplete, impacted or stress fractures that are stable. Trabeculae of the inferior

neck are still intact and, although they may be angulated, they are still congruous.

Garden II: Undisplaced fracture across the entire femoral neck. The weight-bearing trabeculae are interrupted, without displacement. These fractures are inherently unstable and must be fixed.

Garden III: Complete femoral neck fracture with partial displacement. There is associated rotation of the femoral head, with non-congruity of the head and acetabular trabeculae.

Garden IV: Complete subcapital fracture with total displacement of fracture fragments. There is no congruity between proximal and distal fragments, but the femoral head maintains a normal relationship with the acetabulum.

These fractures may be further simplified into non-displaced (Garden I and II) and displaced (Garden III and IV).

Clinical assessment and management

Non-displaced fractures Non-displaced fractures include stress fractures, Garden I and Garden II fractures. Stress fractures are usually the result of repetitive abnormal forces on normal bone in fit, active young people, such as military recruits or marathon runners, but they may occur with repetitive normal stresses on abnormal bones, as in rheumatoid arthritis or patients taking long-term steroids.

These fractures present with pain that is gradual in onset and worse after activity, radiating from the groin to the medial aspect of the knee. Patients walk with a limp and often present late. Physical examination reveals no obvious deformity, although there is mild discomfort on passive movement at the extremes of motion and percussion tenderness over the greater trochanter.

Additional radiological examination with a bone scan and/or magnetic resonance imaging (MRI) is indicated when initial x-rays are normal but there is persistent pain. MRI is the investigation of choice, being more sensitive than bone scans in the first 24 hours. It is of similar accuracy to bone scans in fracture assessment at 72 hours.

Stress fractures and Garden I impacted fractures are considered stable and may be treated conservatively under close orthopaedic supervision. Garden II fractures, although non-displaced, are inherently unstable and must be fixed internally.

Displaced fractures Elderly patients with displaced fractures usually present with pain in the hip area and markedly reduced hip movement. The lower limb is shortened, abducted and externally rotated distal to the fracture, albeit less than with intertrochanteric fractures.

X-ray reveals the fracture and the degree of posterior comminution of the proximal fragment. Parenteral analgesia and a femoral nerve block reduce discomfort. Skin traction will also reduce pain and help to preserve the vascularity of the femoral head.

Traumatic femoral neck fractures in the young adult are uncommon and usually involve normal bone. These fractures are outside of the Garden classification. They follow a large degree of force and have up to a 35% risk of AVN and up to a 57% risk of non-union.

Complications

Mortality Femoral neck fractures are associated with a mortality of 14% to 36% in the first year after injury, with the rate returning to the pre-fracture level after this. Mortality is increased threefold in those who were institutionalized prior to the fracture, with increased risk factors for mortality being male gender, older age, malnutrition, multiple medical problems and end-stage renal disease.

Morbidity AVN is the most common complication despite optimal treatment. Non-union, postoperative infection and osteomyelitis are also seen.

Extracapsular femoral fractures

Intertrochanteric femoral fractures

Fractures of the proximal femur that occur along a line between the greater and lesser trochanters are referred to as intertrochanteric. They are usually pathological, occur in the elderly and have a female preponderance.

Mechanism A simple fall with a direct force applied to the greater trochanter in the elderly is enough to cause an intertrochanteric femoral fracture. In young adults, these fractures are associated with high-speed MVAs or falls from a height.

Clinical assessment Patients sustaining an intertrochanteric fracture are unable to bear weight and have significant pain on hip movement. There is often a large haematoma overlying the greater trochanter owing to the highly vascular bone that is fractured without any intracapsular containment. Examination reveals a markedly shortened, abducted, significantly externally rotated lower limb.

X-rays confirm the fracture in most cases. However, internal rotation of the hip on the antero-posterior (AP) view may obscure the fracture. The lateral view depicts the size, location and degree of comminution of the fracture fragments and determines stability.

FIG. 4.7.1 Unstable comminuted intertrochanteric fracture with subtrochanteric extension.

Classification Numerous classification systems are available for intertrochanteric fractures, the simplest of which is that of Evans. This system divides intertrochanteric fractures into stable and unstable types. However, for the emergency physician, an anatomical description of the fracture detailing the degree of comminution, subtrochanteric extension and the presence of displaced posterior fragments is adequate (Fig. 4.7.1).

Management A complete evaluation is essential to formulate an early treatment plan, as intertrochanteric fractures occur most frequently in the elderly who often have associated multimorbidity. Patients may lose up to 1.5 L of blood from a comminuted fracture and are often dehydrated, malnourished and in significant pain on arrival in the emergency department (ED). Parenteral analgesia and fluid resuscitation are important in preparation for the operating theatre.

Skin traction or immobilization with sandbags prevents further soft tissue damage and bony comminution and reduces blood loss. Full preoperative evaluation requires a search for associated injuries, such as rib fractures, distal radial fractures and vertebral compression fractures at the level of T12 and L1.

An electrocardiogram (ECG), blood tests and chest x-ray help elucidate the cause of the fall and may indicate the need for associated medical treatment. Orthogeriatricians are now involved in patient care in many centres.

Treatment is with open reduction and internal fixation (ORIF), which produces better anatomical alignment, a shorter hospital stay and improved function with reduced mortality in comparison with conservative management.

Complications Survival is directly related to the patient's age and pre-existing medical conditions.

Greater trochanteric fracture

Mechanism Isolated fractures of the greater trochanter are uncommon. They usually occur in individuals between 7 and 17 years of age and involve true epiphyseal separation secondary to indirect trauma. Forceful muscular contraction by the gluteus medius causes avulsion of the apophysis. The displaced non-comminuted fragment may be separated by up to 6 cm.

Greater trochanteric fractures in adults are rare and usually result from direct trauma, causing a comminuted fracture whose fragments are rarely displaced and usually involving only part of the trochanter.

Clinical assessment Patients with a greater trochanter injury are tender to palpation over the area of avulsion or comminution, but bruising is uncommon. There is often an associated flexion deformity of the hip as a result of pain and muscle spasm, and weight bearing causes a limp.

Management The prognosis is good after these fractures. Most are treated conservatively with rest and subsequent gradual mobilization. ORIF is indicated for marked separation of the bony fragment.

Lesser trochanteric fracture

Isolated fractures of the lesser trochanter usually occur in children and young athletes, with 85% occurring before the age of 20 years.

Mechanism Lesser trochanteric fractures are usually apophyseal avulsion injuries secondary to forceful contraction of the iliopsoas.

Clinical assessment Patients complain of pain on flexion and internal rotation of the hip. Examination reveals tenderness in the femoral triangle. The patient is unable to flex the hip or raise the foot off the ground in a seated position (Ludloff sign specific for the iliopsoas muscle).

Radiology is often inconclusive, as there may not be complete separation of the bony fragment; comparison views may be required.

Management Ten days of bed rest and slow mobilization result in full recovery. Open reduction and internal fixation are not indicated, even with wide apophyseal separation.

Subtrochanteric femoral fractures

The subtrochanteric region of the femur lies between the lesser trochanter and a point 5 cm distally. Fractures in this region are termed subtrochanteric. They account for 11% of hip fractures and occur in the elderly with osteoporosis, bone metastases or end-stage renal disease. High-energy injuries in young adults with normal bone are less common.

Mechanism Ninety per cent of these fractures result from blunt trauma, either due to a simple fall in the elderly or following a high-speed MVA or fall from a height in young adults. In some countries, up to 10% are due to high-energy gunshot wounds.

Classification A variety of classification systems is available, but none is widely used. As with intertrochanteric fractures, it is best to describe the location, presence of comminution and the position of the lesser trochanter proximal or distal to the fracture line.

Clinical assessment A subtrochanteric fracture is usually isolated in the elderly. However, as substantial force is required in young adults, the presence of other injuries must be sought. The limb distal to the fracture is usually held in abduction, flexion and external rotation. Haemorrhage from a comminuted subtrochanteric fracture may be up to 2 L. The patient's circulatory status must be assessed and fluid and blood administration commenced.

Management Following parenteral analgesia and a femoral nerve block, the affected limb is immobilized in a splint. Suitable splints include proprietary splints, such as the Donway or Hare. Fluid resuscitation is started as required. The older, more laborious Thomas splint is now rarely used.

Orthopaedic referral is essential for ORIF of these fractures.

Complications In the elderly, up to a 20% mortality is associated with these fractures within the first year. They are associated with a higher rate of non-union and implant failure because subtrochanteric bone is cortical. Thus unlike the cancellous bone involved in intertrochanteric fractures, these fractures often lack the vascularity for adequate new bone growth and repair. The further down the shaft of the femur the fracture line is located, the greater the degree of non-union and implant failure.

Hip dislocation

The hip joint is inherently stable, and considerable force is required to produce a dislocation. Associated injuries must always be sought. Hip dislocations are classified anatomically into anterior and posterior, depending on the final position of the femoral head relative to the acetabular rim.

Non-prosthetic hip dislocations are orthopaedic emergencies, as the femoral head's blood supply is precarious and also because of the proximity of the sciatic nerve. Failure to reduce a hip dislocation within 6 hours dramatically increases the risk of AVN and ischaemic damage to the sciatic nerve.

Posterior hip dislocation

Mechanism

Posterior dislocations represent 85% to 90% of traumatic hip dislocations. Classically a direct distal force applied to the flexed knee, with the hip in varying degrees of flexion as when seated in the front of a car, causes a posterior dislocation of the hip. The hip and knee are usually flexed to 90 degrees and the hip is adducted, which is the least stable position for the hip to be in.

The force applied by the dashboard in a head-on collision to a seated individual may produce an isolated posterior dislocation. The abducted and partially flexed hip in the same scenario is more stable and, if the force of impact is great enough, will result in a posterior dislocation with displaced acetabular fracture.

Clinical assessment

Examination of the affected limb reveals shortening, adduction, internal rotation and some degree of flexion. A single AP pelvis radiograph is usually adequate to confirm a posterior dislocation. However, because up to half of these dislocations are associated with an acetabular, femoral head or femur fracture, further radiological imaging is essential. Judet views, AP hip with internal rotation and AP and lateral femoral views have been used extensively in the past, but are now largely superseded by CT.

Neurological examination Neurological examination is essential in a posterior dislocation, particularly with marked internal rotation, which may compress the sciatic nerve and its branches. This results in neurological deficit, particularly in the peroneal nerve distribution. Associated injuries, such as ipsilateral knee ligament disruption with a posterior cruciate rupture, must be looked for as well.

Management

The orthopaedic team is consulted early. A thorough search for associated periarticular and distal limb injuries, neurological evaluation and adequate imaging are essential in the ED.

Closed reduction

Closed reduction of a posterior hip dislocation may be performed in the ED under procedural sedation unless there is *immediate* access to an operating theatre (see Chapter 22.3).

Allis manoeuvre There are numerous methods of relocation, many requiring significant physical strength. The most common is the Allis manoeuvre, whereby the patient lies supine with assistants on either side stabilizing the pelvis by downward pressure on the anterior superior iliac spines. The operator applies longitudinal traction to the lower leg with the hip slightly flexed in the line of the femur and knee in 90 degrees of flexion. The leg is internally and externally rotated until the femoral head is rearticulated with the acetabulum. Lateral traction to the inside of the thigh may assist.

Other techniques include the lateral traction-countertraction method and the Whistler technique.

Complications

The risk of developing AVN is directly proportional to the length of time the hip remains dislocated and increases dramatically if the dislocation is not reduced within 6 hours of injury. Sciatic nerve neuropraxia may occur in 15% of cases but is usually relieved by reduction.

Permanent ischaemic changes with neurological deficit secondary to pressure necrosis have been reported in up to 3% of cases, usually in the peroneal nerve distribution. Missed knee injuries occur in up to 15% of cases, as well as patellar, tibial plateau and posterior cruciate injuries.

Anterior hip dislocation

Anterior dislocations account for 10% to 15% of traumatic hip dislocations and are associated with femoral neurovascular injury and occult hip joint fracture. They usually result from a direct blow to the abducted and externally rotated hip. When the hip is in abduction, the femoral neck or greater trochanter impinges on the rim of the acetabulum. A direct force applied distally can lever the head out of the acetabulum and tear the anterior capsule of the hip.

Classification

Anterior dislocations may be superior or inferior. Type I or superior dislocations occur when the hip is extended at the time of injury. These are also known as iliac dislocations. Type II or inferior dislocations occur when the hip is flexed at injury and are also known as obturator dislocations.

They may be further subclassified as simple dislocation, associated femoral neck fracture or associated acetabular fracture.

Clinical assessment

The superior type of injury causes an extended, externally rotated and slightly abducted distal limb. The distal limb in the inferior type of dislocation is externally rotated, abducted and in flexion. The femoral head may be palpated around the anterior superior iliac spine in superior types and in the obturator foramen in inferior types.

A neurovascular examination is essential in anterior dislocation, particularly the superior type, where trauma to the femoral artery, vein and nerve is common. Hip and pelvic radiographs must be studied carefully for associated fractures of the acetabulum and femoral head. Further imaging with CT is indicated, particularly for persistent post-reduction pain.

Management

General examination looking for associated life-threatening injuries is essential, as this type of hip dislocation is usually associated with high-energy trauma. Orthopaedic consultation is mandatory because of the high probability of vascular injury and the need for closed reduction under general anaesthesia.

Complications

Early complications in superior dislocations result from direct pressure on the femoral vessels with the potential for distal neurovascular compromise. Late complications include post-traumatic arthritis and AVN. Recurrent dislocation is common when anterior capsular healing is incomplete following inadequate immobilization after reduction.

CONTROVERSIES

- Efficacy of applying skin traction and immobilization to reduce extracapsular femoral fractures in the ED.
- Early use of CT and MRI to evaluate the reduced non-prosthetic hip to limit (missed) associated morbidity.
- Whether the hip reduction should take place in the ED or in the operating theatre; it is essential to treat hip dislocations early.

4.8 Femoral injuries

Stephen Cusack

ESSENTIALS

1 **Early reduction of femoral fractures and immobilization in traction reduces mortality.**

2 **Haemorrhagic shock is a major complication; with a closed femoral fracture the average blood loss is 1200 mL.**

3 **Fractures of the femoral shaft are associated with other significant injuries including those to the pelvis, hip and/or knee as well as multitrauma.**

Femoral shaft fracture

Mechanism

Considerable force is required to break the adult femur in the absence of osteoporosis or metastatic disease with a bony secondary. The majority of femoral shaft injuries occur in young adults following motor vehicle accidents, falls from a height or gunshot wounds.

Classification

No universally accepted classification system for femoral shaft fractures exists. A precise description of the fracture provides the orthopaedic specialist with an indication of the potential for blood loss and the urgency of definitive management.

Femoral fractures are either open or closed and may be transverse, oblique, spiral or segmental. They may occur within the proximal third, midshaft or distal third of the femur. The degree of fracture comminution, soft tissue involvement and neurovascular status should also be described.

The majority of fractures occur in young adults with healthy bones and are transverse. Greater mechanical force usually results in comminution (Fig. 4.8.1). Minimal force with pathological bone tends to produce metaphyseal fractures with propagation into the shaft.

Stress fractures

Stress fractures of the femoral shaft are described and usually occur when repetitive mechanical forces are applied to the femur, as in marathon running or among military recruits. They are associated with pain in the groin, thigh or knee. Plain x-ray is often normal and magnetic resonance imaging (MRI) or nuclear bone scans are diagnostic. These fractures are rarely displaced and are usually treated conservatively.

Clinical evaluation

The clinical diagnosis is usually straightforward. The thigh is shortened and externally rotated, with the hip held in slight abduction. Palpation reveals tenderness over the fracture site and extreme pain on attempted movement.

FIG. 4.8.1 Comminuted femoral fracture.

Neurovascular injuries are rare, but the distal pulses, capillary refill and distal sensation must be carefully examined.

Vascular damage

Vascular damage is usually limited to rupture of the profunda femoris perforating branches in closed fractures. The resulting tense, swollen haematoma is limited to the thigh and is not associated with distal circulatory compromise. Open fractures or penetrating trauma from gunshots can be associated with femoral artery injury and resultant exsanguination or vascular compromise.

Any evidence of an expanding haematoma or diminished distal pulses requires further investigation with Doppler imaging or arteriography.

Associated injuries

Commonly associated injuries include fractures of the pelvis, the femoral head and neck, dislocation of the hip and soft tissue disruption of the knee. Up to 50% of closed femoral injuries are associated with meniscal and collateral ligament injuries in the knee, although it is usually impossible to evaluate these injuries reliably in the acute setting. Up to 1.2 L of blood may extravasate into the surrounding soft tissues.

Management

The treatment of any associated significant trauma to the head, neck, thorax or pelvis should take priority. However, early reduction of a femoral fracture is an important part of haemorrhage control. Administration of analgesia, circulatory support and fracture reduction and splinting are ideally performed prior to x-ray of the lower limb unless radiology is immediately available.

Analgesia

Adequate pain relief is essential in the emergency department (ED). Intravenous opioid analgesia is necessary and titrated to effect. A femoral nerve block is an important adjunct that should be performed prior to fracture reduction and splinting (see Chapter 22.2).

Reduction and splinting

Early fracture reduction and splinting in traction decrease overall mortality and pain, limit blood loss and reduce the risk of fat embolism. Following appropriate analgesia, fractures are returned to near anatomical alignment using longitudinal traction with the knee in extension.

Proprietary splints, such as the pneumatic Donway or Hare traction splint, have replaced

the old skin traction (Thomas) splint in the ED. All splints only provide an interim solution prior to definitive management.

Fluid resuscitation

Haemorrhagic shock is a major complication, with an average blood loss from a closed femoral fracture of 1200 mL. All patients must be resuscitated with intravenous fluid and blood and kept fasted; an indwelling catheter is inserted to facilitate patient comfort and monitor fluid balance.

Orthopaedic management

Early operative fixation, typically intramedullary nailing, is indicated in adults within 8 hours. Open fractures should be swabbed for culture and sensitivity and a photo of the wound recorded; thereafter the wound is surgically dressed. These fractures will require immediate operative debridement with antibiotic cover such as Cephazolin 2 g IV or an antibiotic regimen recommended locally, followed by surgical fixation at an appropriate time.

Complications

Immediate complications of femoral fracture include fat embolus syndrome, haemorrhagic shock and adult respiratory distress syndrome, with a higher incidence in comminuted fractures. Any of these may present in the early resuscitation phase. Long-term complications include non-union, shortening and malalignment, which can all result in serious disability.

Early mobilization following surgical fixation greatly reduces complications associated with prolonged immobilization. Patients above 60 years of age with closed femoral fractures have a complication rate of 54% and a mortality rate of 17%.

CONTROVERSIES

- Arteriography, particularly in distal-third femoral fractures following proximity penetrating trauma, even in the absence of initial vascular compromise
- Diagnosis of stress fractures from repetitive exercise

4.9 Knee injuries

Michael Baker • Dean Fulford

ESSENTIALS

1 **The knee is the most commonly injured joint in the body.**

2 **Knee injuries often occur in the young, usually associated with sport.**

3 **The mechanism of injury is an essential part of the history.**

4 **Immediate joint effusion indicates internal joint disruption necessitating orthopaedic follow-up and possibly also magnetic resonance imaging (MRI).**

5 **Initial physical examination is frequently limited by pain and swelling. These patients should be referred for re-examination of the knee in 7 to 10 days' time.**

6 **Knee dislocations require urgent reduction with assessment for a popliteal artery injury.**

Anatomy

The knee is the largest, most complicated joint in the body. It is a synovial, complex hinge joint comprising the patellofemoral and tibiofemoral joints. Movement ranges from 10 degrees of extension to 140 degrees of hyperflexion, with up to 12 degrees of rotation present through the full arc.

The ligaments of the knee are classified as extra-capsular or intra-capsular. The main extra-capsular ligaments are the medial and lateral collateral ligaments (MCL and LCL). The main intra-capsular ligaments are the anterior and posterior cruciate ligaments (ACL and PCL), which are extra-synovial. The collateral ligaments provide lateral stability and stability in extension, whereas the cruciate ligaments provide knee stability in flexion.

Knee stability is further enhanced by muscular extensions, such as the vastus medialis giving patellar stability, the fibrous extension of vastus lateralis and medialis (the patellar retinaculum) strengthening the knee anteriorly and the iliotibial tract strengthening the knee in slight flexion.

Clinical assessment

An exact history of the mechanism of injury, degree of force, presence of immediate swelling and the ability to bear weight straight after the injury are essential to guide the diagnosis of soft tissue injuries. Injury may be due to direct or indirect trauma and may involve valgus, varus or rotational stresses. Immediate swelling (haemarthrosis) indicates a cruciate tear, intra-articular bony injury or dislocation. Onset of swelling over hours to days from serous effusions is often due to a chondral or meniscal injury.

Knee physical examination

Always examine both legs with the patient undressed and lying supine on a trolley (not sitting). Visual inspection may reveal swelling, bruising, erythema, deformity, scars from a previous operation and/or an associated wound.

Knee palpation

Always examine the unaffected knee first to determine the patient's normal range of motion and ligamentous laxities. Start palpation away

from the point of trauma to detect warmth, swelling, crepitus, muscle mass and neurovascular status and then to localize the areas of maximal tenderness to define the underlying pathology. Assess the insertion points of the quadriceps tendon, patellar tendon, collateral ligaments and the medial and lateral joint lines as well as the bony structures of the knee joint.

Assess active and passive movements of the knee joint, noting the degree of flexion, extension and internal and external rotation. Always test for the ability to straight leg raise while the patient is supine to assess for potential damage to the extensor mechanism of the knee.

Anterior and posterior drawer tests

Complete the examination with an assessment of the knee's functional stability. The stability of the ACL and PCL may be crudely determined with the anterior and posterior drawer tests.

The patient must be supine with the hip flexed at 45 degrees, the knee flexed at 90 degrees and the hamstrings relaxed. The examiner sits on the patient's foot to stabilize the limb and attempts to demonstrate abnormal forward movement of the tibia on the femoral condyles (positive anterior drawer test) and/or abnormal backward movement of the tibia on the femoral condyles (positive posterior drawer test). However, the accuracy of the anterior drawer test as defined by subsequent arthroscopy is only 56% for rupture of the ACL. Posterior displacement of the tibia by more than 5 mm is indicative of PCL ruptures with a specificity of 85%.

Lachman test

The Lachman test is a more sensitive manoeuvre in the acute setting for testing ACL integrity, with a sensitivity of 86% and specificity of 91%.[1] The operator supports the distal femur with one hand with the knee in 20 to 30 degrees of flexion and uses the other hand to draw the tibia forward on the femoral condyles. Increased anterior displacement of the proximal tibia compared with the unaffected limb indicates a positive test.

Collateral injury

The collateral ligaments are assessed by applying a varus or valgus stress to the knee in 30 degrees of flexion. Isolated pain on varus or valgus stress and/or opening up of the joint compared with the normal side, indicates a positive test.

McMurray test

The McMurray test is used to demonstrate a meniscal injury. The patient lies supine and the knee is passively flexed and extended. One hand is placed over the knee to feel for crepitus while the other hand rotates the tibia on the femur. Internal rotation tests the lateral meniscus and external rotation tests the medial meniscus. Pain and crepitus at the extremes of movement indicate a positive test.

Apley test

The Apley test is also used to demonstrate a meniscal injury. This is performed with the patient lying prone with the knee flexed to 90 degrees. The tibia is rotated on the femur with downward pressure on the heel. Pressure with lateral rotation is indicative of medial meniscal injury and medial rotation with lateral meniscal injury.

Radiology

Clinical decision rules to determine the requirement for knee radiography aim to reduce emergency department (ED) radiographs, waiting times and costs. The most widely used is the Ottawa knee rule.

Ottawa knee rule

The Ottawa knee rule states that an x-ray is indicated for acute knee injury in adults with any of the following:

- Age above 55 years
- Tenderness at the head of the fibula
- Isolated tenderness of the patella
- Inability to flex the knee to 90 degrees
- Inability to bear weight (take four steps) immediately and in the ED

This rule has been validated in a number of studies, with a pooled sensitivity of 98.5% and specificity of 48.6%.[2]

Standard knee x-rays

Standard knee x-ray evaluation includes anteroposterior (AP) and lateral views. The AP view assesses for the integrity of the medial and lateral joint spaces and the tibiofemoral angle. It also shows the size, position and integrity of the patella.

Lateral view may identify a lipohaemarthrosis effusion, seen as a horizontal line demarcating darker, more radiolucent fat floating on lighter, more radio-dense blood. This is indicative of an intra-articular fracture and is most helpful when the actual injury is hard to see, as with an undisplaced condylar fracture, or a patellar or tibial spine fracture.

Oblique x-rays are helpful in elucidating a tibial plateau fracture. The tunnel view enhances the intercondylar region.

A skyline x-ray is taken to further evaluate the patella and patellofemoral joint, particularly following reduction of a patellar dislocation. It can identify undisplaced vertical fractures of the patella, osteochondral defects and subtle subluxation not seen on the conventional views.

Computed tomography

Computed tomography (CT) is important to define fractures, such as those of the tibial plateau. MRI is reserved for the evaluation of complex soft tissue knee injuries unless arthroscopy is preferred.

Fractures around the knee joint

Distal femur

Distal femoral fractures account for 4% of femoral fractures. They are usually associated with high-energy injuries secondary to a fall or a direct blow to the femur in a motor vehicle accident.

Classification

Distal femoral fractures are divided anatomically into supracondylar, intercondylar and isolated condylar fractures. Supracondylar fractures are extra-articular and occur immediately above the femoral condyles. Intercondylar fractures involve separation of the femoral condyles. Although the fracture line may extend through the supracondylar region, in general, these are treated as intra-articular fractures.

Isolated condylar fractures are uncommon and occur when a varus or valgus force is applied to a weight-bearing extended knee. The tibial eminence is driven into the femoral intercondylar notch, creating an intra-articular fracture associated with significant ligamentous disruption.

Clinical assessment

Patients with an injury to the distal femur are in significant pain and unable to bear weight. Examination may reveal swelling, deformity, rotation and shortening. The joint is tender to palpation along the medial or lateral joint lines and an acute haemarthrosis secondary to associated ligamentous injury or intra-articular involvement is common.

Examine the whole lower limb to exclude ipsilateral hip dislocation, associated tibial fracture and quadriceps damage. Assess for any neurovascular deficit, including loss of sensation in the web space between the first and second toes due to deep peroneal nerve injury.

AP and lateral x-rays of the femur and knee reveal the fracture and its degree of displacement or comminution.

Management

Administer adequate analgesia and apply a non-traction splint in the ED to prevent movement at the fracture site. Early orthopaedic input is required in all cases. Fractures with joint incongruity or displacement require open reduction and internal fixation. Cast immobilization alone may be sufficient for undisplaced or impacted fractures without joint involvement, particularly in the elderly patient.

Tibial plateau fracture

The tibial plateaus are the superior articulating surfaces of the medial and lateral tibial condyles

and are covered by hyaline cartilage and a fibro-cartilaginous meniscus. Their integrity is vital for knee alignment, articulation and stability. Minimally depressed injuries are common 'missed' fractures.

Mechanism

Tibial plateau fractures account for 1% of all skeletal fractures. They are most common in the elderly, often as the result of a simple fall. They occur when a valgus or varus deforming force is applied to the weight-bearing knee. Lateral tibial plateau fractures are twice as common as medial injuries, but both tibial plateaus are involved in 10% to 30% of cases.

Anterior fractures occur when the knee is in extension and posterior fractures when the knee is flexed. High-energy complicated fractures can also occur, often in the younger age group, and are often associated with injuries to ligaments and cartilage.

Classification

Fracture classification is complex, owing to the varying degrees of comminution, displacement and compression of the plateaus. The most widely used system is that of Schatzker, which divides the factures into six different types.[3] Fracture types 1, 2 and 3 involve the lateral tibial plateau with increasing articular depression (Fig. 4.9.1). Type 4 involves the medial plateau. Fracture types 5 and 6 involve both tibial plateaus with increasing comminution and joint instability.

Segond fracture A tibial plateau avulsion fracture at the site of lateral capsular ligament insertion is called a Segond fracture. It appears as an elliptical, vertical fragment of bone parallel to the lateral condyle just distal to the plateau. Segond fractures are associated with excessive internal rotation and varus stress to the flexed knee and are usually associated with sporting injuries. They are an important marker of ACL disruption and/or medial meniscus injury and indicate severe rotatory instability.

FIG. 4.9.1 Schatzker type 3 tibial plateau fracture.

Clinical assessment

Patients present with a painful, swollen knee and are usually unable to bear weight. Pain and haemarthrosis limit active and passive movements of the knee. Focal tenderness is palpated at the fracture site and over any associated collateral ligament tears.

Distal circulatory compromise may be secondary to compression of the popliteal artery by comminuted subcondylar fragments. Peroneal nerve neuropraxia and paralysis may complicate displaced lateral condylar fractures, resulting in foot drop. Meniscal injuries occur in approximately 50% of tibial plateau fractures and ligamentous injuries are found in up to 25%. Generally lateral tibial plateau fractures are associated with disruptions of the ACL and MCL, whereas medial plateau fractures are associated with disruptions of the PCL and LCL.

Radiology

Most tibial plateau fractures are evident on standard knee x-rays, although oblique views may be required to elucidate a subtle or undisplaced fracture. CT is important to evaluate further non-displaced and comminuted fractures and for operative planning. An MRI is preferred to quantify the degree of any associated ligamentous damage.[4]

Management

Orthopaedic consultation is essential. Lateral fractures with more than 2 mm of displacement and less than 5 degrees of angulation may be treated conservatively with a cast or splint, but comminuted fractures with disruption of the articular surface require open reduction and internal fixation.[5] Other surgical indications include open injuries, fractures with vascular injury and a fracture associated with an unstable ligamentous injury.

Common complications include undiagnosed neurovascular injury, compartment syndrome and osteoarthritis.

Fractures of the tibial spine and intercondylar eminence

The tibial spine separates the medial and lateral tibial condyles and is divided into anterior and posterior areas by the intercondylar eminence. These areas provide flat surfaces for the attachment of the ACL and PCL, respectively. The intercondylar eminence is divided into a medial and a lateral tubercle visible on AP x-rays, although nothing actually attaches to them.

Mechanism

Most fractures of the tibial spine and intercondylar eminence occur in children aged 8 to 14, as the cruciate ligaments are stronger than the skeletal physeal plates.[6] Considerable force is required for these fractures to occur in an adult. The tibial spine is usually fractured during violent knee-twisting movements.

The anterior tibial spine fractures 10 times more frequently than the posterior. Intercondylar eminence fractures are associated with severe hyperextension or hyperflexion injuries.

Clinical assessment

The patient complains of severe pain, immediate swelling of the knee and inability to bear weight. The knee is usually held in slight flexion and cannot be fully extended. Examination confirms the presence of an acute haemarthrosis and limited knee movement. An associated ACL disruption may be confirmed with a positive Lachman or anterior drawer test, although pain may prevent these.

Radiology

AP and lateral x-rays plus tunnel or oblique views are used to confirm the diagnosis. MRI is preferred to quantify the degree of any associated ligamentous damage.

Management

Fractures with less than 3 mm of displacement are treated conservatively in full extension. Displaced fractures can potentially be reduced post analgesia by bringing the knee into full extension and then obtaining another x-ray. Refer a displaced fracture with marked ligamentous injury for open reduction and internal fixation.

Patellar fracture

The patella is the largest sesamoid bone in the body and lies within the quadriceps tendon. It improves the efficiency of the extensor mechanism and increases the quadriceps strength by 33% to 50% whilst also offering some protection to the femur.

Mechanism

Patellar fractures account for 1% of skeletal injuries and occur predominantly in males between the ages of 20 and 50 years. Direct trauma to the anterior aspect of the patella results in an incomplete, stellate, comminuted or vertical patellar fracture. These commonly occur in motor vehicle accidents when the knee strikes the dashboard. There is usually little or no separation of the bony fragments, as the medial and lateral quadriceps expansions remain intact.

Indirect trauma occurs when an individual stumbles or falls forwards.[7] The combination

of powerful quadriceps contraction proximally and the strong patellar insertion distally overcomes the intrinsic strength of the patella and leads to a transverse fracture. These fractures account for up to 80% of patellar fractures and occur mainly in the central and lower thirds of the patella.

Clinical assessment

Examination reveals pain, swelling and bruising over the patella. The ability to walk and extend the knee actively are dependent on the type of fracture and are important when surgical repair is being considered. Test for the ability to perform a straight leg raise while the patient is in a supine position in order to confirm the integrity of the knee extensor mechanism.

A patient with a non-displaced fracture may be ambulatory and able to demonstrate active knee extension against gravity. Patients with displaced transverse patellar fractures are generally unable to extend the knee actively.

Radiology

Patellar fracture is diagnosed by x-ray with additional skyline views. A fracture must be differentiated from a bipartite patella, which represents failure of the patella ossification centres to fuse, as seen in 1% to 6% of the population. The bipartite patella has smooth borders that are well corticated, with minimal separation between fragments; x-ray the contralateral patella if you are unsure.

Management

Patients with minimally displaced fractures who can straight leg raise are treated conservatively in full extension initially, with progressive flexion after 2 to 3 weeks.

Surgical treatment is required for displaced fractures of 3-mm separation or 2-mm step off and/or those patients who are unable to straight leg raise.

Dislocations around the knee joint

Dislocation of the knee

Knee dislocations are rare and usually occur in males in their third decade. A knee dislocation is an orthopaedic emergency associated with vascular damage and requires urgent reduction.

Mechanism

Tibial femoral knee dislocation usually involves rupture of both cruciate ligaments and one collateral ligament. Such injuries are associated with high-velocity trauma, as from a motorcycle incident. They are described with respect to the displacement of the tibia in relation to the femur. Anterior dislocations are the most common.

Clinical assessment

Spontaneous reduction prior to the ED is common, so a high index of suspicion and careful assessment are required. Examination usually reveals gross distortion of the knee, with the clinical deformity being easily palpable. Knee dislocations are associated with a high rate of peroneal artery (20% to 80%) and popliteal nerve injury; therefore a careful neurovascular assessment is essential.

Compression and distortion of the posteriorly placed popliteal artery and vein may cause distal vascular compromise, although 10% of vascular injuries are associated with normal pedal pulses. Peroneal nerve dysfunction is present in up to 50% of patients suffering knee dislocation, causing foot drop and sensory impairment of the dorsum of the foot and lateral border of the foot and leg.

Radiology

Immediate plain x-rays confirm the dislocation, but should not delay analgesia and reduction.

Management

Prompt consultation with the orthopaedic and vascular teams is essential, with early reduction under procedural sedation and analgesia (PSA) in the ED. Neurovascular status should then be reassessed and documented. The risk of developing a compartment syndrome and/or needing amputation is increased when reduction is not performed within 6 hours. Failed reduction requires open reduction under general anaesthesia.

Traditionally angiography was performed in all cases of knee joint dislocation. There is now a move towards a more selective approach, reserving imaging for cases with an abnormal distal pulse or ankle-brachial index (the ratio of the systolic blood pressure measured at the ankle to that measured at the brachial artery) of less than 0.9 detected on serial examinations.[8]

Patellar dislocation

Traumatic patellar dislocation is common and may become recurrent, with further patellar subluxation or dislocation. The majority of dislocations occur in the setting of patellofemoral dysplasia or malalignment syndromes secondary to hypoplastic vastus medialis, a shallow trochlear groove or genu valgum. Lateral dislocations are overwhelmingly the most common, usually caused by a noncontact twisting injury with the knee extended and the foot externally rotated. Less commonly a direct blow to the patella may be the cause. The medial patellofemoral ligament is the primary patellar constraint in the first 20 degrees of knee flexion and is disrupted by being stretched in subluxations and torn in a dislocation.

Clinical assessment

Patients complain of the knee suddenly 'giving way', accompanied by immediate pain and swelling. They are unable to bear weight or extend the knee. Palpation reveals an anterior defect, a laterally deviated patella and swelling. In a spontaneously reduced injury, the 'apprehension test', performed by applying gentle lateral pressure on the medial border of the patella, may confirm the diagnosis.

Standard AP and lateral plus skyline x-rays are important to exclude an associated osteochondral fracture. However, particularly in recurrent dislocations or when the diagnosis is clear, x-ray can follow immediate reduction.

Management

Closed reduction is performed following suitable analgesia and, commonly, nitrous oxide sedation. Apply anteromedial pressure to the lateral aspect of the patella while gently extending the knee. Immobilize the knee in an extension splint for 3 to 6 weeks after post-reduction x-rays to allow the medial retinaculum time to heal.

Complications

Up to 50% of patients suffer symptoms of instability or anterior knee pain following traumatic dislocation. Recurrent dislocation occurs in over 15% of cases and may require surgical repair.

Proximal tibiofibular joint dislocation

Mechanism

The proximal tibiofibular joint is supported by a capsule anteriorly, the popliteus muscle posteriorly and the LCL superiorly. Tibiofibular joint dislocation is rare and possible only when the LCL support is relaxed with the knee in flexion. Such dislocations occur mainly as violent athletic twisting injuries, as during the shot put.

Clinical assessment

The patient is able to bear weight with difficulty, with point tenderness over the fibular head. Neuropraxia of the common peroneal nerve is unusual.

Radiology

AP and lateral comparison views reveal the dislocation, which is usually antero-lateral.

Management

Reduce under PSA by flexing the knee to 80 to 110 degrees and applying firm pressure over the head of fibula opposite to the direction of dislocation. Success is associated with a satisfying 'click'. Immobilization post-reduction is controversial. Surgical intervention is rarely needed.

Soft tissue knee injuries

Collateral ligaments

Damage to the medial and lateral ligaments is often associated with sporting events. These injuries are graded 1 to 3, indicating the degree of disruption to the ligamentous fibres, as follows:

- Grade 1: stretching of the fibres only
- Grade 2: partial tear, mild instability but firm end point on stress testing
- Grade 3: complete disruption of fibres, clear instability with no end point on stress testing.

Medial collateral ligament

The MCL complex comprises a long superficial ligament with a distal point of insertion and a short deep ligament attached to the medial meniscus and stabilizing it. The MCL provides medial stabilization to the knee joint in conjunction with the capsule and semi-membranosus, resisting valgus laxity and medial rotational instability.

MCL injuries are the most common isolated ligamentous injury of the knee. They occur when an excessive valgus force is applied to the knee, usually by a direct blow to the lateral aspect. The greater the valgus deforming force, the greater the risk of an associated ACL disruption. Evaluate for saphenous nerve dysfunction, especially in grade 3 injuries.

Lateral collateral ligament

The LCL is a cord-like ligament running from the lateral epicondyle of the femur to the head of the fibula. It is separated from the lateral meniscus by the popliteal tendon. The LCL is the major lateral stabilizer of the knee, providing the main resistance to varus deforming forces, especially when the knee is extended.

LCL injuries are less common but more debilitating than MCL injuries. The lower incidence of LCL injuries is a result of the lateral ligament's mobility and the protective effect of the opposite leg. These injuries result from a direct blow to the medial aspect of the knee. Associated injuries to the insertion of biceps femoris and to the common peroneal nerve at the fibular head must be excluded.

Clinical assessment

Examine for point tenderness at the site of injury, demonstrable laxity and a haemarthrosis. Gently stress the affected ligament complex to check for reproducible pain. Complete rupture of the ligament complex is associated with instability, and stress testing causes the joint line to open up on the affected side.

Test the collaterals in 30 degrees of flexion to negate the reinforcing effect of the ACL when the knee is in full extension. For the MCL, apply pressure to the lateral joint line with one hand while the other hand creates a valgus stress by gently pushing the medial malleolus laterally. The opposite stress is applied when the LCL is tested. If you test the collaterals at 0-degree flexion and there is opening up of the joint, an associated cruciate ligament injury is indicated.

Radiology

Standard x-rays reveal collateral ligament injury only when there has been a bony avulsion. Calcification at the origin of the MCL occurs in chronic injuries (e.g. Pellegrini-Stieda). In complex cases, an MRI delineates the degree of ligamentous disruption and highlights associated injuries.

Management

The majority of isolated collateral ligament injuries are treated conservatively provided that damage to the ACL and PCL complexes has been excluded.[9] Discomfort is reduced by immobilizing the knee in a proprietary splint, such as a three-panel Velcro knee immobilizer, or by an elastic knee support, with ice massage and anti-inflammatory drugs.

Quadriceps strengthening exercises are essential to aid recovery and early return to movement using a hinged splint. Early orthopaedic opinion is sought for a grade 3 injury to consider surgical repair, as this is best done within 48 hours of injury.

Cruciate ligaments

The cruciate ligaments are the primary stabilizers of the knee in flexion and extension.

Anterior cruciate ligament

The ACL extends from the medial aspect of the lateral femoral condyle to the anterior intercondylar area of the tibia. It prevents anterior displacement of the tibia relative to the femur and limits extension of the lateral condyle of the femur. It helps to control the rotation of the knee in twisting and turning activities and is much more commonly injured than the PCL.

Mechanism The ACL is commonly injured during sports with a non-contact pivoting mechanism, whereby the flexed knee suffers a sudden twisting movement with the foot firmly planted on the ground. Less commonly, injury results from direct trauma as the tibia is forcefully displaced anteriorly on the femur or the femur is displaced posteriorly on the tibia.

Clinical assessment ACL injuries are classically associated with sudden severe pain and an audible 'pop', with an acute haemarthrosis and inability to bear weight. Immediate swelling of the knee indicates serious intra-articular pathology.

The anterior drawer test or Lachman test is used to assess ACL integrity. ACL disruption is associated with meniscal and collateral ligament injuries in 50% of cases, with the most common combination involving the triad of ACL and MCL disruption with a lateral meniscal tear.

Radiology X-rays are usually normal but may show an avulsion fracture of the proximal lateral tibia (Segond fracture), which is pathognomonic for an ACL injury. An MRI scan, having over 90% sensitivity and specificity, is necessary to determine ACL rupture with certainty.

Management Arthroscopy is the gold standard in assessing the integrity of the ACL and has the advantage of allowing simultaneous debridement and repair. The decision to undertake reconstruction is dependent on a number of factors including the patient's age, type and level of activity, the degree of instability, presence of other knee structures injured and the time post-injury.

Both autograft and allograft materials have been used in the repair. However, meta- analysis shows insufficient evidence to determine the superiority of surgical repair over conservative management for non-athletes as regards long-term function and joint stability.

Posterior cruciate ligament

The PCL extends from the lateral aspect of the medial femoral condyle to the posterior intercondylar area of the tibia. It is the primary restraint for posterior tibial translation relative to the femur. It is essential in providing mechanical support when one is walking downhill or down stairs.

Mechanism PCL rupture is normally caused by a posteriorly directed force on the proximal tibia, such as dashboard injuries, knee dislocation or a hyperflexion athletic injury with a planted foot.

Clinical assessment Immediate pain and swelling are common with PCL rupture, which, unlike rupture of the ACL, rarely causes any popping or tearing sensation. Stability is usually adequate to allow partial weight bearing. Isolated PCL ruptures result in posterior 'sag' of the tibia compared with the unaffected limb, with the posterior drawer test performed to assess PCL integrity. Associated multi-ligamentous injuries are common (40%) and must be actively sought.

Radiology X-rays may reveal avulsion of the posterior tibial spine but, as with ACL injuries, MRI demonstrates over 90% sensitivity and specificity for PCL rupture and may be more reliable than arthroscopic examination.

Management The treatment of isolated PCL rupture is largely non-operative and focuses initially on pain management and non-weight-bearing immobilization. When a PCL injury is combined with other ligamentous injuries, operative intervention is usually necessary.

Patellar tendon rupture

The patellar tendon is the final connection of the extensor mechanism from the inferior pole of the patella to the tibial tuberosity. Rupture usually occurs in the third and fourth decades and is often associated with preceding patellar tendonitis or steroid injections. Injury is associated with a sudden forceful quadriceps contraction as in jumping sports or missing a step on stairs. Patients describe a popping sensation with significant pain.

Examination

Examination may reveal a palpable defect. Test the extensor mechanism by asking the patient to straight leg raise against gravity. Inability to do this is highly suggestive of a complete rupture; however if the retinaculum is still intact, a straight leg raise may still be possible albeit with an extensor lag of a few degrees. In complete ruptures, x-rays will display a high-riding patella. Ultrasound is effective at confirming the diagnosis; however, MRI is most sensitive at differentiating a partial from a complete rupture.

Partial tears are treated non-operatively with cast immobilization in extension for 6 weeks. Complete tears of the patellar tendon are referred to the orthopaedic specialist for surgical intervention.

Quadriceps tendon injury

The quadriceps tendon is a trilaminar junction of the quadriceps muscle. Rupture is commonest in the patients over 40 years old and is associated with medical conditions such as diabetes, renal failure and also intra-articular steroid injections. In younger patients the mechanism is usually a direct blow to the knee. this injury is associated with intense pain and the patient is unable to walk without assistance. It is three times more common than patellar tendon rupture.

Examination

Examination reveals a tender, palpable defect more apparent on attempted knee extension. Swelling secondary to a haemarthrosis and bruising are usually present. The straight leg raise is impossible in complete rupture, whereas extension of the knee from a flexed position cannot be performed in a partial tear.

Comparison lateral knee x-rays may demonstrate a low-lying patella in the affected knee. In doubtful cases, MRI is indicated to distinguish between a partial and a complete rupture.

Management

A partial tear is treated non-operatively, but a complete rupture requires early surgical intervention for the best results.

Patellar (jumper's knee) and quadriceps tendonitis

Both these extensor tendons are susceptible to tendonitis secondary to repetitive overloading, as in athletes who participate in running and jumping activities. Patellar tendonitis is more common than quadriceps tendonitis. Patients present with anterior knee pain, with point tenderness over the inferior or superior pole of the patella.

Inflammation and pain in patellar tendinitis at the insertion point of the patella tendon into the patella is six times more common than at the insertion to the tibial tuberosity. Patellar tendonitis may be associated with fragmentation of the inferior pole of the patella on x-ray.

Initial treatment includes rest, ice and anti-inflammatory medication. Longer-term recovery and prevention requires conditioning and training of the extensor musculature.

Meniscal injury

The menisci are semilunar fibrocartilaginous structures found on the medial and lateral sides of the superior aspect of the tibia. They enhance the fluidity of articulation between the femoral and tibial condyles and increase the stability of the tibiofemoral articulation.

The medial meniscus is immobile, being firmly attached to the deep portion of the medial collateral ligament and joint capsule, and is most frequently injured. The lateral meniscus has a uniform thickness and a larger tibial area than the medial with no attachment to the LCL.

Mechanism

Meniscal injuries are usually associated with collateral or cruciate ligament injury, which should be sought when the acutely injured knee is being examined. Chronic degenerative processes account for only a small percentage of injuries. The menisci are uncommonly injured in isolation, but suspect an isolated meniscal injury in the young athlete sustaining a violent twisting or rotational injury to the weight-bearing knee.

Clinical assessment

The patient is able partially to bear weight following meniscal injury and usually complains of pain at the medial or lateral joint line. Delayed swelling, intermittent locking and a sensation of the knee 'giving way', with a sudden loss of stability, are clues to meniscal damage.

Examination usually confirms the presence of an effusion and joint line tenderness, which is the most sensitive examination finding. The McMurray test may be positive but is not pathognomonic and, acutely, pain can prevent adequate hyperflexion for the test to be accurate.

The 'locked' knee is held in 30 degrees of flexion, with a springy block to extension on examination and associated pain.

Radiology

Routine x-rays do not show any direct evidence of meniscal damage but are useful to exclude commonly associated bony injuries. MRI is most sensitive in determining both meniscal and ligamentous injuries.

Management

In the young athlete and in patients with mechanical symptoms (locking or giving way), arthroscopy is used to evaluate and treat these injuries with either repair or partial meniscectomy. An acutely locked knee should be referred for urgent arthroscopy.

4.10 Tibial and fibular injuries

Michael Baker • Dean Fulford

ESSENTIALS

1 **Tibial shaft fractures are the commonest long bone fracture, with the subcutaneous nature of the tibia leaving it vulnerable to open injury.**

2 **Neurovascular injury and compartment syndrome are risks in tibial shaft fractures.**

3 **Proximal fibular fractures are associated with common peroneal (lateral popliteal) nerve injury.**

4 **Tibial tubercle injuries range from apophysitis to fracture.**

Anatomy

The tibia is the weight-bearing strut of the lower leg. Proximally the tibia articulates with the femoral condyles and distally the bony extension provides medial stability to the ankle joint. Its shaft is triangular in cross section and is subcutaneous anteromedially.

The fibular head is proximal and connects to the fibular shaft by the neck. Distally, the fibula is palpated subcutaneously as the lateral malleolus.

The tibia and fibula are connected by superior and inferior tibiofibular joints and a dense interosseous membrane. Distally, this union is strengthened by a syndesmosis, which enhances the stability of the ankle mortise.

Fascial compartments of the lower leg

The lower leg is divided by bone and fascia into four compartments. Each compartment contains a sensory nerve and muscles with specific functions. Increased pressure within a compartment is evaluated clinically by impaired function according to the functional anatomy.

Anterior compartment

The anterior compartment contains the tibialis anterior, extensor hallucis longus, extensor digitorum longus and peroneus tertius, which dorsiflex the ankle and foot. The deep peroneal nerve supplies these muscles and the first web space of the foot. The anterior tibial artery is contained within the compartment down to the ankle, where it becomes the dorsalis pedis artery.

Lateral compartment

The lateral compartment contains the peroneus longus and peroneus brevis, which evert the foot, and the superficial peroneal nerve, which supplies sensation to the dorsum of the foot.

Superficial posterior compartment

The superficial posterior compartment contains the gastrocnemius, plantaris and soleus muscles, which plantarflex the ankle. The sural nerve lies in this compartment before piercing the fascia to supply the lateral side of the foot and distal calf.

Deep posterior compartment

The deep posterior compartment contains the tibialis posterior, flexor hallucis longus and flexor digitorum longus, which work to plantarflex the foot and toes. The popliteus is also in this compartment and is used for unlocking the knee when walking. The tibial nerve supplies sensory function to the sole of the foot. The compartment is transversed by the posterior tibial and peroneal arteries.

Fractures of the tibia

Tibial shaft fracture

Tibial shaft fractures are the most common long bone fracture. They are also the commonest open fracture owing to the subcutaneous nature of the tibial shaft.

A considerable amount of direct or indirect energy is needed for the tibial shaft to fracture. Direct injuries may occur secondary to bending forces or a direct blow. Direct violence causes deformation at the site of contact, resulting in transverse or comminuted, usually open, fractures. High-energy injuries have an increased degree of displacement, comminution, soft tissue injury and fibular involvement. They are largely unstable, with marked vascular and interosseous injury. There is a high risk of compartment syndrome, with up to 15% complicated by malunion or non-union.

Indirect torsional forces applied to the tibia produce a spiral fracture as the body rotates about a fixed foot. Such injuries are common in skiing incidents and have increasing degrees of comminution depending on the amount of energy applied.

Classification

The description of the fracture must be clear and concise in relation to the following (Table 4.10.1 for the AO classification of tibial shaft fractures)[1]:

- Skin integrity: open or closed
- Anatomic site: proximal, middle or distal third
- Fracture type: transverse, oblique, spiral or comminuted
- Angulation of the distal fragment in relation to the proximal fragment, expressed in degrees and direction (anterior, posterior, varus or valgus)
- Degree of displacement and rotation
- Involvement of the fibula
- Any joint involvement

Clinical assessment

Pain at the site of fracture is usually severe. The patient is unable to bear weight and inspection reveals swelling and possibly deformity of the leg. The skin is checked for integrity and to identify areas of pressure caused by any displaced fragments. The neurovascular status of the lower leg and foot is assessed as a matter of urgency, including skin colour, capillary refill and the distal dorsalis pedis and posterior tibial pulses. Associated injuries of the ipsilateral femur, hip, knee, foot and pelvis must be excluded.

Table 4.10.1 AO classification of tibial shaft fractures

Type A (simple)	1	Spiral
	2	Oblique (angle >30 degrees)
	3	Transverse (angle <30 degrees)
Type B (multi-frag wedge)	1	Spiral wedge
	2	Bending wedge
	3	Fragmented wedge
Type C (multi-frag complex)	1	Spiral wedge
	2	Segmental
	3	Irregular

Nerve injury Contusion of the peroneal nerve may occur in high-energy injuries with proximal fibular fractures, although direct peroneal nerve injury can occur rarely in a closed tibial shaft fracture. The motor function of the deep peroneal nerve is tested by active ankle and toe dorsiflexion and the sensory function is tested in the first dorsal web space. The motor function of the superficial peroneal nerve is tested by active foot eversion and the sensory function is tested over the dorsal lateral aspect of the foot.

Radiology

Anteroposterior (AP) and lateral views of the lower leg must include the entire tibia and fibula in order to define the tibial fracture (fracture pattern, displacement and comminution) as well as to detect any associated fibular fracture (Fig. 4.10.1). X-ray of the knee and ankle joint will help to detect associated joint involvement.

Management

Parenteral analgesia is the first priority (usually an intravenous opiate), followed by reduction of any displaced and/or open fractures plus immobilization in a long leg cast.

FIG. 4.10.1 Open, oblique, distal-third tibial fracture with displaced varus deformity and fibular involvement.

Compartment syndrome

Emergency department (ED) assessment and documentation of the neurovascular status is essential to exclude acute neurovascular injury as well as to detect actual or potential compartment syndrome. Development of a compartment syndrome may occur in up to 20% of closed injuries and can take up to 24 hours to appear. The deep posterior compartment is most commonly affected, followed by the anterior compartment.

Increasing pain despite reduction and casting is an early indicator of compartment syndrome. The diagnosis should be suspected if there is still severe pain and pain on passive movement despite significant intravenous opiates. Diminished sensation over the territory of the distal sensory nerve may be seen. Loss of distal pulses and paralysis are both late findings and indicate irreversible compartment ischaemia.

Compartment pressures If assessment is unreliable (e.g. an obtunded patient) or the diagnosis is unclear, compartment pressures may be measured. The exact figure is controversial, but a compartment syndrome is suggested by a compartment pressure greater than 30 mmHg or within 30 mmHg of the diastolic blood pressure (the delta pressure). Routine continuous pressure monitoring in tibial shaft fractures does not result in an improved outcome and is not recommended.[2]

Open wounds

Open wounds are assessed for depth and associated soft tissue damage and then dressed to avoid further contamination. Reduce a displaced, rotated or angulated fracture in the ED under appropriate procedural sedation and analgesia (see Chapter 22.3). Reduction aims to stop local swelling, release the tension of any skin 'tented' over a displaced fracture and relieve associated soft tissue damage. Exposed bone is returned under the skin after appropriate decontamination. Check the tetanus status and give parenteral antibiotics, such as cephazolin 2 g IV every 8 hours.

Immobilize the leg following reduction in 10 to 20 degrees of knee flexion and request post-reduction x-rays to confirm the position. Re-check and document the neurovascular status of the lower leg and foot.

Definitive orthopaedic management

There are various options for definitive management, including conservative management, closed reduction, open reduction and internal fixation (ORIF) and intramedullary rods. No approach is superior, with a meta-analysis finding insufficient evidence to support any particular management option.[3]

Non-operative management Non-operative management in an above-knee plaster of Paris (POP) cast is appropriate for a low-energy fracture without significant comminution, shortening or displacement. Conservative management may also be appropriate for fractures with more than 50% cortical contact, less than 5 degrees of varus/valgus angulation, less than 10 degrees of anterior or posterior angulation, less than 10 degrees of rotation and no more than 10 mm of shortening.[4]

Operative management Operative management is considered for patients with a high-energy displaced fracture, open fracture or those who have failed closed treatment. Intramedullary nailing results in a shorter hospital stay, fewer outpatient visits and earlier return to work.[5] ORIF is also considered for displaced intra-articular fractures of the tibia involving the knee or ankle.

Fracture of the tibial tubercle

The tibial tubercle lies proximally on the anterior border of the shaft of the tibia. It is readily palpable beneath the infrapatellar bursa and receives the insertion of the patellar tendon. Fractures of the tubercle are uncommon and occur in adolescents aged 12 to 15 years, typically as a result of indirect injury sustained during sports involving jumping and producing an avulsion fracture. Risk factors for this condition include Osgood-Schlatter disease and osteogenesis imperfecta.[6] As in the case of other tibial fractures, up to 20% are complicated by compartment syndrome.

Three grades of injury are described by Watson-Jones. In type I injuries, a small fragment of tuberosity distal to the growth plate is avulsed. Type II injuries involve displacement of the whole tuberosity, including a portion of the epiphysis. Type III injuries are type II with intra-articular involvement.

Examination reveals pain and tenderness over the anterior aspect of the knee and proximal tibia. There may be a haemarthrosis and loss of active extension, depending on the severity of the injury.

Plain x-rays confirm the diagnosis. The lateral tibial view reveals the avulsed fragment, its degree of displacement and comminution.

Management is dependent on the degree of displacement and the presence of joint involvement. Watson-Jones type I and II injuries with displacement of less than 2 mm are treated with long leg casts until healed. Type III or significantly displaced injuries require ORIF with tension band wiring and fixation screws.[7]

Osgood-Schlatter disease (traction apophysitis of the tibial tubercle)

This condition is the primary differential diagnosis to tibial tuberosity fractures. It represents a

traction apophysitis of the tibial tubercle caused by repeated micro-trauma to the growing tubercle during adolescence. It is chronic and, unlike fractures of the tubercle, is not accompanied by a haemarthrosis. Active knee extension is possible albeit painful. There is point tenderness over the tibial tubercle, often accompanied by a palpable lump.

Treatment is conservative, with rest, ice, compression and non-steroidal anti-inflammatory drugs (NSAIDs), followed by a graded return to sporting activities. This is a self-limiting condition with full recovery expected in 1 to 2 years when the apophysis closes.

Tibial stress fractures

Tibial stress fractures are common, affecting the proximal third of the tibia in adolescents and the junction of middle and distal thirds of the tibia in runners. Clinically there is point tenderness. X-rays may show an anterior uni-cortical fracture but are frequently negative if taken early in the clinical course. X-rays taken 3 to 5 weeks after the onset of pain often show a periosteal reaction. Magnetic resonance imaging (MRI)—the imaging modality of choice due to its high sensitivity and ability to detect injury early—has largely replaced bone scans.

The differential diagnosis includes 'shin splints', fascial hernias and exertional compartment syndrome. Management is conservative, reducing activity and impact on the tibia. Symptoms may persist for over 12 months.

Shin splints

Shin splints, also known as 'medial tibial stress syndrome', are characterized by exercise-induced pain in the mid-section of the leg, with tenderness along the posteromedial border of the middle and distal thirds of the tibia. The tenderness is usually more diffuse than the localized tenderness of a stress fracture. There may be traction periostitis near the origin of the soleus. Rarer is lateral tibial stress syndrome, involving periostitis of the tibialis anterior. For suspected skin splints, x-ray to rule out stress fractures and treat conservatively with rest, ice, compression and elevation (RICE); cessation of the precipitating exercise; and anti-inflammatories.

Fractures of the fibula

Proximal fibular fractures may occur in isolation (uncommon) or in association with tibial and ankle injuries.

Associated fracture of the tibial shaft

Most fibular fractures are associated with a fracture of the tibial shaft and management is as for tibial fractures. The pattern of the associated fibular fracture indicates the degree of energy imparted.

The fibula usually heals well with whatever treatment is selected for the tibia, with a high rate of union. Complications of fibular fractures associated with tibial shaft fractures are rare.

Isolated fractures of the proximal fibula

Isolated proximal fractures of the fibular shaft are less common. They are usually associated with a direct blow to the lateral aspect of the leg, causing local tenderness, swelling, bruising and difficulty walking. A neurovascular assessment is important, as the common peroneal nerve passes around the neck of fibula and may be contused or disrupted in these isolated injuries. Rarely, thrombosis of the anterior tibial artery may occur.

Full-length AP and lateral x-rays of the tibia and fibula, including the ankle and knee joints, will confirm the fracture pattern.

Management

Non-displaced fractures associated with little pain are treated with ice, compression bandage, analgesia and crutches, with weight bearing as tolerated. Fractures with significant pain may require a long leg cast for comfort. A severely displaced fracture or one associated with peroneal nerve deficit, such as foot drop, requires swift orthopaedic consultation.

Maisonneuve fracture

A rupture of the medial malleolus or deltoid ligament associated with a proximal fibular fracture is termed a Maisonneuve fracture. These fractures are unstable and occur when an external rotatory force is applied to the ankle, resulting in partial or complete disruption of the syndesmosis between the tibia and fibula. Palpation of the proximal fibula following a complex ankle injury is therefore essential to exclude this fracture. All these fractures must be referred to the orthopaedic team for operative fixation.

4.11 Ankle joint injuries

Michael Baker • Dean Fulford

ESSENTIALS

1 **Ankle injuries are common and occur as isolated injuries or in relation to high-energy multitrauma.**

2 **Lateral malleolar fractures are the most common ankle fracture.**

3 **The Ottawa ankle rules (OAR) are used to determine the need for imaging of the ankle (or midfoot) in adults with an isolated acute ankle injury.**

4 **The Weber and Henderson (Potts) classifications are the most commonly used for describing ankle fractures.**

5 **Ankle sprains should be mobilized early.**

6 **The calf-squeeze test (Thompson or Simmond test) is used to confirm the diagnosis of Achilles tendon rupture.**

Anatomy

The ankle joint is a complex hinge joint that permits articulation between the tibia, fibula and talus, providing a stable but mobile support for the body. It helps absorb the forces of ambulation, maintain an upright posture and allows for uneven terrain.

The stability of the ankle joint relates to the bony architecture, joint capsule and ligaments. The bones and ligaments are best visualized as a ring structure centring on the talus, which provides stability. This ring is made up of the tibial plafond, medial malleolus, medial (deltoid) ligament, calcaneus, lateral collateral ligaments, lateral malleolus and syndesmotic ligaments. The joint becomes unstable when more than one element of this ring structure is disrupted.

Bony mortise

The lateral malleolus of the distal fibula, the medial malleolus of the distal tibia and the distal tibial plafond form the bony mortise of the joint. This provides intrinsic stability, constraining the wedge-shaped talus distally. The medial ligament of the ankle (deltoid ligament) fans out from the tip of the medial malleolus to attach to the tuberosity of the navicular, the medial aspect of the talus and the sustentaculum tali of the calcaneus. The lateral ligament comprises three discrete parts, the anterior and posterior talofibular ligaments and the calcaneofibular ligament.

Most ankle joint injuries are a result of abnormal movement of the talus within the mortise. Movement causes stress to the encompassing ring of structures of the ankle joint, with instability arising when disruption of the malleoli or their associated ligaments results in distraction of the talus within the mortise.

Clinical assessment

Injuries around the ankle include fractures to the ankle and adjacent tarsal bones, ligamentous sprains, dislocations and tendon ruptures. All these are considered when the patient with an ankle injury is being assessed.

History

Inability to bear weight and the presence of swelling immediately following an injury imply significant pathology. Additional essential information includes the circumstances of the injury, position of the foot at the time and the magnitude and direction of loading forces applied, particularly rotational. A history of inversion injury should prompt the examiner to assess also the base of the fifth metatarsal for an avulsion fracture by the insertion of peroneus brevis.

Examination

Examination of the ankle includes the entire lower leg and begins with a comparison between the injured and non-injured sides. Note the skin integrity and presence of bruising, swelling or deformity.

Palpate for point tenderness to localize ligament, bone or tendon injury, which should commence at a site away from the area of obvious injury. The entire length of the tibia and fibula—as well as the base of the fifth metatarsal, calcaneus and Achilles tendon—are examined. Palpation of the posterior aspects of the malleoli should commence 6 cm proximally and include both ends of the collateral ligament attachments. The anterior plafond and the medial and lateral aspects of the talar dome are then palpated in plantarflexion.

Then assess the range of active and passive motion at the ankle joint, including inversion, eversion, dorsiflexion and plantarflexion. A soft tissue injury is likely when there is a significant difference between the active and passive ranges of motion.

Finally, always check the foot for motor or sensory impairment, capillary return, the presence of dorsalis pedis and posterior tibial pulses and injury to the base of the fifth metatarsal.

Stress testing for ligamentous instability

Stress testing for ligamentous instability of the acutely injured ankle and/or an evaluation of weight-bearing ability should proceed only when clinical suspicion of a fracture is low. All patients require appropriate analgesia for evaluation.

The talar tilt test assesses the calcaneofibular ligament by applying a gentle inversion stress to the calcaneum and talus simultaneously.

The anterior and posterior drawer tests assess the anterior and posterior talofibular ligaments by gentle forward traction on the heel in neutral/20 degrees of flexion.

Radiology

Standard radiography of the acutely injured ankle includes antero-posterior, lateral and mortise views. All patients with an obviously deformed fracture or dislocation should have immediate x-ray following analgesia.

The need for imaging of the ankle or midfoot in a patient with less obvious injury may be determined using the Ottawa ankle rules (OAR). When used on a competent patient, the OAR are more than 98% sensitive for detecting clinically relevant ankle fractures in adults and children.[1–4]

Ottawa ankle rules

These rules specify that an ankle x-ray series is required only if there is any pain in the malleolar region and any one of the following:

- Bone tenderness over the posterior aspect or inferior tip of the distal 6 cm of the lateral malleolus

- Bone tenderness over the posterior aspect or inferior tip of the distal 6 cm of the medial malleolus
- Inability to bear weight for at least four steps, both immediately after the injury and at the time of emergency department (ED) evaluation.

The OAR also includes indications for taking an additional foot x-ray series (see 'Foot injuries', Chapter 4.12).

Other imaging

Computed tomography (CT) is used to evaluate further complex fractures and magnetic resonance imaging (MRI) for recalcitrant ligamentous injuries.

Ankle fracture classification

Several classification systems are used to describe ankle fractures, the Weber classification system being the most widely used.

Weber classification

The Weber classification system (1972) divides ankle fractures into three types, based on the level at which the fibula fractures. The more proximal the fibular fracture, the greater the associated syndesmosis disruption and ankle instability.

Type A fractures involve the distal fibula below the level of the tibial plafond; type B involve an oblique or spiral fracture at the level of the syndesmosis; and type C occur when the fibula is fractured above the level of the syndesmosis (ankle joint).

The original Weber classification system does not take into account medial or posterior malleolar fractures. The AO system applies three subdivisions to each Weber fracture type to account for these injuries and to define further ankle stability.[5]

Henderson or Pott classification

The Henderson or Pott classification is a simple system based on radiographic findings:

- Uni-malleolar fractures affecting the lateral or medial malleolus. The stability of these fractures is dependent on the integrity of contralateral ligaments and the inferior tibiofibular joint.
- Bi-malleolar fractures affecting the medial and lateral malleoli, which are usually unstable.
- Tri-malleolar fractures involving the medial, lateral and posterior tibial plafonds, which are always unstable.

Fracture management

A grossly displaced fracture is reduced in ED under procedural sedation and analgesia prior to imaging if distal ischaemia is identified and/or the skin integrity compromised (Fig. 4.11.1). These will require elevation and orthopaedic admission for operative management.

FIG. 4.11.1 Unstable bimalleolar ankle fracture.

Non-displaced fractures

Non-displaced (<3 mm) unimalleolar Weber A fractures with an intact mortise joint (no talar shift) on x-ray are treated non-operatively in a below-knee plaster of Paris (POP) cast in a neutral position—that is, with the ankle at 90 degrees with no inversion or eversion. Refer these injuries for orthopaedic follow-up with advice that fracture movement may occur and that operative intervention may still be required.

The management of an isolated non-displaced Weber B injury with the fracture line at the level of the syndesmosis is controversial. If the deltoid ligament is intact and there is no talar shift, a conservative approach results in good outcomes with low rates of subsequent surgical intervention.[6]

Displaced fractures

Displaced and potentially unstable fractures require early orthopaedic consultation, including all bi-malleolar and tri-malleolar fractures, those uni-malleolar fractures with contralateral ligamentous injuries and Weber C injuries. The majority of these injuries will require operative intervention (open reduction and internal fixation [ORIF]).

Fractures of the tibial plafond (pilon)

Tibial plafond (pilon = hammer) fractures involve the distal tibial metaphysis and result from high-energy injuries directed through the talus into the distal tibia with tibial plafond disruption. The frequency has increased owing to greater numbers of motor vehicle incidents and falls from heights. They are usually associated with other multiple injuries and often open, comminuted or associated with extensive soft tissue deformity.

Reduce and splint the fracture under appropriate analgesia and procedural sedation to decrease the potential for massive soft tissue swelling, which may convert a closed fracture to an open one as a result of overlying skin necrosis. Treatment usually requires operative fixation.

Maisonneuve fracture

The Maisonneuve fracture is a fracture of the proximal third of the fibula associated with a medial malleolar fracture or disruption of the medial (deltoid) ligament, resulting from external rotation. The proximal fibular fracture is associated with disruption of the interosseous membrane from the tibiofibular syndesmosis up to the proximal fibular head. It may be complicated by a common peroneal nerve injury. These fractures are unstable and require operative fixation.

Ankle dislocations

Ankle dislocations are frequently associated with a fracture, which may be open or closed. They result from considerable energy, such as when force is directed against the plantarflexed foot, squeezing the talus out of the mortise. Posterior dislocations are the most common. All require orthopaedic advice for consideration of internal fixation and ligamentous repair.

Closed dislocations

Closed dislocations are associated with marked soft tissue disruption and skin tethering, although neurovascular compromise is uncommon. These dislocations are reduced promptly in the ED to minimize associated soft tissue injury, using gentle manipulation to correct the deformity under appropriate procedural sedation and analgesia.

Despite the potential for ligamentous disruption, closed dislocations usually have an excellent outcome following immobilization for 8 weeks.

Open dislocations

Open dislocations may be associated with disruption of the dorsalis pedis and posterior tibial vessels. They require surgical assessment in theatre but again should initially be reduced and splinted with POP in the ED. Open injuries are

associated with more long-term complications than closed, in particular traumatic arthritis and reduced mobility.

Soft-tissue injuries

Ligamentous injuries

Ankle sprains

Ankle sprains are among the most common injuries presenting to the ED: 75% of injuries to the ankle are sprains, 90% of which affect the lateral ligament complex, predominantly the anterior talofibular ligament (ATFL). Typically injuries to the lateral ligament proceed from anterior to posterior as increasing force is applied.

Medial ligament disruption is more frequently associated with lateral malleolar fractures or Maisonneuve-type injuries involving the proximal fibula and disruption of the syndesmosis.

Lateral ligament injuries

Lateral ligament injuries are graded according to the degree of fibre disruption and reflect the progression of injury from anterior to posterior as well as subsequent stability of the ankle joint. Accurate assessment of joint stability is frequently not possible in the ED setting due to pain, which limits examination, necessitating referral for reassessment.

These injuries are graded as follows:

- Grade I: stretching, usually of the ATFL. Patients are usually able to bear weight with minimal swelling and normal stress testing.
- Grade II: partial tear of a ligament. There is pain at rest, difficulty in bearing weight, significant swelling and mild to moderate joint instability.
- Grade III: complete tear of the ligament. Patients are unable to bear weight due to severe pain, with immediate swelling and marked joint instability.

Grade I and most grade II injuries are treated conservatively with rest, ice, compression, elevation and non-steroidal anti-inflammatory medication. Early functional treatment is likely better than immobilization in the treatment of lateral ligament injuries.[7]

Operative intervention for grade III lateral ligament injuries is controversial, since conservative and surgical therapy are associated with similar clinical outcomes. Surgery may improve perceived stability and reduce pain; it is more commonly undertaken in the athlete.[8]

Conservative treatment includes cast immobilization for 6 to 8 weeks with orthopaedic follow-up. Delayed surgical repair or reconstruction has similar results to early intervention.

Achilles tendon rupture

Achilles tendon rupture is traditionally associated with sedentary middle-aged men during a burst of unaccustomed strenuous physical activity, although young, fit athletes also sustain this injury.

Predisposing medical conditions when present include rheumatoid arthritis, systemic lupus erythematosus (SLE), chronic renal failure, gout, hyperparathyroidism and long-term steroid or fluoroquinolone use. The segment of the Achilles tendon particularly prone to rupture lies 4 to 6 cm proximal to the tendon's insertion into the calcaneus, as blood vessels that supply this area are prone to atrophy. The resultant reduction in collagen cross-linking leads to a reduced tensile strength in the tendon, with the majority of tears complete.

History

Rupture usually occurs while pushing off with a weight-bearing foot but may occur with sudden dorsiflexion. The sensation of a direct blow to the back of the ankle and even an audible 'pop' are followed by difficulty in walking. Patients often state that they thought they had been hit or kicked from behind.

Examination

Examination reveals a visible and/or palpable deficit in the tendon, although swelling around the tendon sheath rapidly masks these signs. Some degree of plantarflexion of the ankle joint is preserved by the other long flexors of the ankle, foot and toes. This should therefore *not* be used to determine if the Achilles tendon is intact, although the patient cannot stand on tiptoe.

Calf-squeeze test (Thompson or Simmond test)

The calf-squeeze test (Thompson or Simmond test) confirms the diagnosis of a rupture with a sensitivity of 96%. Perform this with the patient kneeling on a chair with the feet hanging free over the edge. Alternatively, it is often more comfortable for the patient to lie prone with the feet and ankles extended hanging freely beyond the end of the examination couch.

Demonstrate normal plantarflexion initially on the unaffected calf by gently squeezing just distal to its maximal girth. Absence of plantarflexion in the affected limb is a positive test and confirms Achilles rupture. Ultrasound is useful if the diagnosis is in doubt and can demonstrate partial or full-thickness tears of the tendon as well as measure the size of the defect.

Management

The choice of operative or non-operative treatment is controversial.[9] Surgery is more likely to be offered to younger patients, those who are diagnosed early and those with a larger defect. Operative risks include fistula formation, skin necrosis and infection. However, the procedure has a lower rate of muscle atrophy, a lower re-rupture rate and allows earlier resumption of physical activity. Minimally invasive techniques have resulted in reduced infection rates and time to return to work but a higher rate of sural nerve injury.

Non-operative management includes applying a POP cast to the ankle in equinus (full plantarflexion) to bring the two ends of the ruptured tendon into apposition. One regimen involves a cast for 3 weeks in equinus, 3 weeks in partial plantarflexion and then 2 to 3 weeks in the neutral position. Complications of non-operative management include a higher re-rupture rate (requiring surgical intervention).[10]

CONTROVERSIES

- Whether internal fixation results in an improved outcome compared with conservative management in Weber type B fractures
- The role of a controlled ankle motion (CAM) walking boot in the management of ankle sprains and minor lateral malleolus fractures
- Operative versus conservative management of Achilles tendon rupture

4.12 Foot injuries

Michael Baker • Dean Fulford

ESSENTIALS

1 **Most calcaneal fractures are intra-articular; they are associated with a Bohler angle of less than 20 degrees and are at risk of developing compartment syndrome.**

2 **Major talar fractures have a significant risk of subsequent avascular necrosis.**

3 **Fractures of the base of the second metatarsal are pathognomic of Lisfranc injury (Fleck sign).**

4 **Computed tomography (CT) imaging is indicated in Lisfranc injuries as well as complicated talar, calcaneal and navicular fractures.**

5 **Jones fractures are clinically distinct from tuberosity avulsion fractures and have a significant rate of nonunion.**

Anatomy

The foot is composed of 28 bones with 57 articular surfaces. It may be divided into three anatomical regions: the hindfoot, containing the talus and calcaneum; the midfoot, containing the navicular, cuboid and cuneiforms; and the forefoot, containing the metatarsals and phalanges.

The subtalar joint collectively describes the three articulations of the inferior aspect of the talus with the calcaneus. It allows inversion and eversion of the hindfoot. The midtarsal joints incorporate the talonavicular and calcaneocuboid joints that connect the hindfoot and midfoot and allow abduction and adduction of the forefoot. The five tarsometatarsal joints (Lisfranc joint complex) connect the midfoot and forefoot and form an arch, which gives stability to the foot.

Clinical assessment

History

Injury to the foot occurs as a result of direct or indirect trauma. Direct trauma is often associated with considerable soft-tissue swelling and fracture. Indirect trauma from a twisting injury usually results in minor avulsion-type injuries. Record any pain, swelling, loss of function, reduced sensation and deformity or associated ankle injury.

Examination

Inspect the area with the patient lying on a bed with both lower limbs exposed and compare the affected with the unaffected limb to identify bruising, swelling, deformity, skin wounds, pallor or cyanosis.

Point tenderness or crepitus may be elicited at the site of fracture. Specific areas to palpate include the Achilles tendon, calcaneus, base of the fifth metatarsal, the navicular and the area under the head of the second metatarsal.

Ask the patient to demonstrate active foot movements before performing gentle passive movements and compare with the other foot. Evaluate subtalar motion with the foot in a neutral position with one hand on the lower leg and the other holding the heel. The heel is inverted and everted and should attain 25 degrees of movement.

Midtarsal motion is assessed with one hand stabilizing the heel while the other hand grasps the forefoot at the bases of the metatarsals. The forefoot is pronated, supinated, adducted and abducted. Finally, forefoot motion is evaluated by individually flexing and extending the metatarsophalangeal (MTP) and interphalangeal (IP) joints.

If no obvious focus of the pain is found during the initial examination, ask the patient to stand and walk. Assess the circulation by observing capillary refill, skin colour and the presence of the dorsalis pedis and posterior tibial pulses. Neurological assessment includes motor and sensory function.

Radiology

Standard imaging includes anteroposterior (AP), lateral and 45-degree internal oblique projections. The lateral view visualizes the hindfoot and soft tissues, whereas the oblique and AP projections image the midfoot and forefoot. An axial calcaneal view should also be requested as clinically indicated to best visualize the hindfoot; it may reveal a subtle calcaneal fracture.

Ottawa ankle and foot rules

The Ottawa ankle and foot rules provide indications for x-ray of suspected midfoot fractures.[1] All patients with obvious deformities should have x-rays. However, if clinical findings are more subtle, a foot x-ray is required *only* if there is pain in the midfoot region and any one of the following:

- Bone tenderness over the navicular
- Bone tenderness at the base of the fifth metatarsal
- Inability to bear weight for at least four steps, both immediately after the injury and at the time of emergency department (ED) evaluation

This clinical decision rule has a sensitivity approaching 100% and its routine use has been predicted to reduce unnecessary x-rays by 30% to 40%.[1] These rules do not apply to suspected hindfoot or forefoot fractures.

Other imaging

Magnetic resonance imaging (MRI) is indicated when a stress fracture is suspected and may be positive 2 to 3 weeks before conventional radiographs demonstrate a fracture. Computed tomography (CT) is used for imaging the calcaneum, subtalar joint and Lisfranc joint in more complex injuries or when a fracture is strongly suspected but plain x-rays are inconclusive.

Hindfoot injuries

Calcaneal fractures

The calcaneus is the largest bone in the foot and is the most commonly fractured tarsal bone. It forms the heel of the foot, provides vertical support for the body's weight and functions as a springboard for locomotion. The majority of fractures of the calcaneus occur as a result of direct axial compression during a fall from a height. Seven per cent are bilateral. Injuries to the lower extremity are present in 25% of cases and vertebral compression fractures are found in 10%; therefore these regions must be examined as well.

Mechanism and classification

Patients usually present following a fall with direct trauma to the heel. Approximately 75% of calcaneal fractures are intra-articular (body and posterior facet compression fractures), with the remainder extra-articular (anterior process, calcaneal tuberosity or sustentaculum tali).

FIG. 4.12.1 Intra-articular comminuted calcaneal fracture.

Intra-articular fractures may be non-displaced or displaced but are frequently comminuted owing to cancellous bone in the calcaneus and the magnitude of associated force (Fig. 4.12.1).

An isolated fracture of the anterior process of the calcaneus is commonly misdiagnosed as an ankle sprain.[2] It results from inversion causing an avulsion fracture or forced dorsiflexion producing compression against the cuboid.

Clinical assessment

The patient may be able to walk, but weight bearing on the heel is impossible. Examination reveals pain, swelling and tenderness over the heel, with bruising that may extend over the sole of the foot. Associated fractures are common, so examination of the vertebral column, pelvis, affected lower extremity and opposing calcaneus is essential.

Radiology

Standard x-rays usually reveal most comminuted calcaneal fractures, whereas more subtle fractures are visualized with the aid of specific axial (Harris) calcaneal views or on CT. The AP view demonstrates the anterosuperior calcaneus and calcaneocuboid joint. The lateral view may reveal compression fractures of the body and posterior facet.

The Bohler angle The Bohler angle is formed by the intersection of a line drawn from the most cephalad point on the tuberosity to the highest point of the posterior facet, with the line from the latter to the most cephalad part of the posterior process of the calcaneus. It normally ranges from 20 to 40 degrees measured on the lateral x-ray. A compression fracture is likely if the Bohler angle is less than 20 degrees.[3] A CT scan is necessary to define complex or equivocal fractures and is useful in preoperative planning.

Management

Calcaneal fractures notoriously have poor outcomes, with up to 50% of such patients suffering chronic pain and functional disability. Intra-articular, displaced and comminuted fractures are prone to gross swelling of the foot with a risk of compartment syndrome. Admit patients with these fractures for elevation, CT scan and consideration of surgical intervention. Operative intervention may be indicated in younger patients and those with greater degrees of Bohler angle disruption.[4]

Extra-articular fractures and fractures of the anterior process of the calcaneus are usually non-displaced and are treated conservatively in a posterior non-weight-bearing cast for 10 to 12 weeks.

Talar fractures

The talus provides support for the body when standing and bears more weight per surface area than any other foot bone. It has no muscular attachments; instead, it and is held in place by the malleoli and ligaments and comprises a head, neck and body.

The head has articulations with the navicular and calcaneus and the body articulates with the tibia, fibula and calcaneus. The neck joins the head and body and is extra-articular. The blood supply to the talus arises from an anastomotic ring from the peroneal, posterior and anterior tibial arteries and is tenuous and easily disrupted, leading to avascular necrosis (AVN).

Mechanism and classification

Talar fractures are the second most common tarsal fracture. Minor fractures do not involve the weight-bearing surfaces of the bone and are commonly caused by inversion injuries to the plantar- or dorsiflexed foot. They frequently result from minimal trauma and may present as an apparent ankle sprain. They include avulsion fractures, lateral process fractures (commonly seen in snowboarders) and posterior talar process fractures. A high index of suspicion is needed to identify these injuries and avoid long-term complications from a delay in diagnosis and treatment.[2]

Talar fractures of the neck, body or head follow significant force, such as a motor vehicle accident (MVA), or involve axial loading in a fall from a height (when they are associated with calcaneal fracture). They are commonly accompanied by a subtalar dislocation.

Talar dome fracture

Talar dome fractures are difficult to diagnose on plain films, although a large ankle joint effusion may be apparent. Request specific plain x-ray talar views, although a CT scan is frequently required to confirm the diagnosis. These fractures are important to diagnose as they involve the weight-bearing articular surface of the talus within the ankle joint and missed injury may result in chronic pain and post-traumatic osteoarthritis.

Talar neck fractures

Talar neck fractures account for 50% of talar injuries and are related to extreme dorsiflexion injuries. The Hawkins classification is used to describe these fractures. Type I fractures are non-displaced with the fracture line entering the subtalar joint between the middle and posterior facets. The risk of AVN with this injury is less than 10%. Type II fractures are identified by any degree of displacement with subtalar subluxation and have a 30% incidence of AVN. Type III injuries involve displaced talar neck fracture with dislocation of both the subtalar and tibiotalar joints. The incidence of AVN is up to 90%. Type IV injuries are the same as type III with added talonavicular dislocation and AVN rates of close to 100%. Commonly associated injuries include vertebral compression, calcaneal and medial malleolar fractures.

Talar head fractures

Talar head fractures are uncommon and result from a compressive force applied to the plantarflexed foot and are associated with disruption of the talonavicular joint and navicular fractures.

Clinical evaluation

Minimally displaced talar fractures are usually subtle. The patient presents following an inversion injury with mild swelling around the ankle joint and is able partially to bear weight. Active plantar- and dorsiflexion is possible, but inversion and eversion at the subtalar joint is painful. Major talar fractures are associated with large compressive forces and cause considerable swelling and tenderness dorsally.

Radiology

Standard x-rays of the foot reveal all but the most subtle avulsion fractures. A CT scan is required when there is clinical suspicion of talar fracture, but plain films are inconclusive and/or used only for preoperative planning.

Management

Talar fractures (especially neck fractures) have a significant risk of subsequent AVN. A displaced fracture, especially if associated with neurovascular or cutaneous compromise, should be reduced in the ED under procedural sedation and analgesia by grasping the hindfoot and midfoot and applying longitudinal traction in plantarflexion. Apply a plaster of Paris (POP) posterior splint with

the ankle dorsiflexed at 90 degrees. Refer these fractures to an orthopaedic specialist for open reduction and internal fixation.

Undisplaced talar fractures are treated with a below-knee non-weight-bearing posterior cast with orthopaedic follow-up.

Subtalar dislocation

Subtalar dislocations are rare and follow considerable deforming forces. Such injuries involve the simultaneous dislocation of the talonavicular and talocalcaneal joints, with preservation of the tibiotalar joint.

Mechanism and classification

Subtalar dislocations are classically associated with MVAs, but a number occur during sport, particularly basketball. They are described in terms of the final position of the foot in relation to the talus. Medial dislocations account for 80% of these injuries and are caused by forceful foot inversion in plantarflexion. Ten per cent of subtalar dislocations are open (usually lateral dislocations) and 50% are associated with proximally located injuries.[5]

Clinical assessment

Subtalar dislocations are associated with obvious deformity, swelling and tension of the skin over the opposing joint margin. Neurovascular status is rarely compromised. Standard x-rays are difficult to interpret because of the distortion of the foot. The most helpful is the lateral view, which shows talar head superior to navicular (medial dislocation) or talar head inferior to navicular (lateral dislocation).

Management

Under appropriate procedural sedation and analgesia, reduce a closed subtalar dislocation in the ED so as to minimize the chance of tented skin over the head of the talus becoming necrotic.

Closed reduction of a subtalar dislocation requires firm longitudinal traction applied to the foot, with countertraction on the leg with the knee flexed to relax the tension from the Achilles tendon on the calcaneum, thereby increasing the mobility of the hindfoot. The foot is plantar flexed and initially everted (for medial dislocations) or inverted (for lateral dislocations), with digital pressure over the head of the talus to reverse the deformity. Eighty per cent of dislocations can be reduced non-operatively. Following reduction the ankle is placed in a posterior POP splint in 90 degrees of dorsiflexion. Orthopaedic consultation is required.

Midfoot fractures

The midfoot comprises the navicular, cuboid and cuneiform bones. It is inherently stable and is rarely significantly injured. However, midfoot fractures are associated with a delay in diagnosis owing to the difficulty in x-ray interpretation and poorly localized pain. The Ottawa ankle rules are accurate in determining which patients with midfoot pain require imaging.[1]

Navicular fractures

The navicular is a curved bone with extensive articulations. It has a tenuous blood supply and, like the talus, is susceptible to AVN.

Mechanism and classification

The navicular is the most commonly injured midfoot bone, although the overall incidence is rare. Fractures may involve the dorsal surface, the tuberosity or the body. The dorsal avulsion fracture, due to an eversion injury, is the most common and is associated with deltoid ligament or talonavicular capsular injury. Tuberosity fractures also result from eversion injuries with avulsion of the posterior tibial tendon insertion. Body fractures from axial loading are rare and are frequently comminuted.

Clinical evaluation

Point tenderness is elicited over the dorsum and medial aspect of the midfoot. Passive eversion and active inversion reproduce the pain. Standard x-rays usually reveal the fracture, with an oblique 45-degree view optimal for suspected tuberosity fractures; however, a CT scan may be required.

Management

Refer all intra-articular, displaced or comminuted fractures to the orthopaedic specialist, as they are frequently complicated by AVN. Treat dorsal avulsion and tuberosity fractures conservatively in a cast for 6 weeks. Navicular body fractures may require internal fixation.

Cuboid fractures

Cuboid fractures are rare in isolation and are most commonly associated with Lisfranc-type injuries, with forced foot abduction and eversion injuries (the 'nutcracker' compression fracture of the cuboid between the calcaneus and lateral metatarsal heads) and fractures of the posterior malleolus. They are best visualized with an oblique foot x-ray.

Management

All cuboid fractures require orthopaedic consultation. Treatment ranges from weight-bearing POP casts for undisplaced fractures to operative fixation for displaced and comminuted fractures.

Cuneiform fractures

These fractures are extremely rare and usually occur from direct trauma. An associated Lisfranc injury should be excluded. Displaced fractures require orthopaedic intervention, but non-displaced fractures are treated conservatively in a cast.

Lisfranc fractures and dislocations

The Lisfranc joint complex includes the articulation of the first three metatarsal bases with their respective cuneiforms and articulation of the fourth and fifth metatarsal bases with the cuboid. The second metatarsal, the 'keystone' of the complex, is largely responsible for the stability of the Lisfranc joint.

Mechanism and classification

Injury results from rotational forces applied to the fixed forefoot, axial loads and crush injury. Although commonly associated with MVAs, Lisfranc injuries may also occur in sports that involve fixation of the forefoot, such as horse riding and rowing.

There are three types, classified by the direction of dislocation in the horizontal plane. Divergent dislocations usually involve medial and lateral splaying of the first and second metatarsals. In ipsilateral (homolateral) dislocations, all five metatarsals are displaced in the same direction, either medially or laterally. In isolated dislocations, one or more of the metatarsals is displaced away from the others.

A Lisfranc dislocation is usually associated with fracture of the metatarsals, particularly the second metatarsal base, and, in 40% of cases, with fracture of the midfoot.[6]

Clinical assessment

Lisfranc injuries should be suspected when a midfoot fracture is present. They are associated with severe midfoot pain and inability to bear weight on the toes. Examination reveals deformity, swelling and bruising over the dorsum of the foot. Point tenderness over the joint, with pain on passive abduction and pronation, may also be present. Although vascular compromise is uncommon, significant haemorrhage can occur with disruption of the dorsalis pedis branch to the plantar arch as it passes between the first and second metatarsal bases.

Radiology

Standard x-rays are sufficient to visualize most Lisfranc injuries. The AP view identifies Lisfranc fractures and oblique views determine their alignment. Fracture of the base of the second metatarsal is pathognomic of a Lisfranc injury (the 'fleck sign' indicating avulsion of the Lisfranc ligament), sometimes with diastasis between the first and second metatarsals. Mal-alignment may be seen between the medial base of the second metatarsal and the medial border of the second cuneiform. Lateral views identify the presence of dorsal displacement of the first or

second metatarsal base. Once such an injury has been detected, a CT scan is necessary to define the degree of disruption to the Lisfranc joint complex.

Management

Refer all Lisfranc injuries for orthopaedic consultation. Most are treated with closed reduction and screw and/or K-wire fixation, followed by non-weight bearing for 12 weeks.[7] Despite aggressive management, complex regional pain syndrome and degenerative arthritis are common.

Forefoot fractures and dislocations

Metatarsal shaft fractures

Metatarsal shaft fractures occur as a result of direct trauma or a rotational injury to the fixed forefoot. Metatarsal fractures are associated with difficulty in weight bearing with ill-defined tenderness and bruising over the plantar aspect of the foot. There may be an accompanying Lisfranc injury or phalangeal fracture. As the second and third metatarsals are relatively fixed, they are prone to stress fractures, typically occurring with repetitive trauma such as long-distance running.

Standard x-rays will detect most fractures and determine their alignment, angulation and displacement. Occult stress fractures may be evident only on CT or MRI.

Management

Undisplaced closed shaft fractures of the second to fourth metatarsals are treated with a stiff-soled shoe or walking boot with weight bearing as tolerated for 3 to 4 weeks. Orthopaedic consultation and/or closed reduction and a non-weight-bearing cast for 6 weeks are necessary when there are multiple fractures, greater than 4 mm of displacement or 10 degrees of angulation in the sagittal plane.[8]

Hallux (great toe) metatarsal fractures

Injury to the great toe metatarsal requires more aggressive treatment because of its load-bearing function. Non-displaced fractures require 4 to 6 weeks in a walking boot, whereas displaced fractures require operative intervention.

Metatarsal head and neck fractures

These fractures usually result from direct trauma and are often multiple. Treat a non-displaced fracture with a walking cast for 4 to 6 weeks. Displaced fractures require orthopaedic input and closed reduction to maintain the integrity of the transverse plantar arch.

Fractures of the base of the fifth metatarsal

These are the most common of the metatarsal fractures, with two distinct types. The commonest fracture is to the fifth metatarsal tuberosity, occurring when the plantarflexed foot suddenly inverts. It is an avulsion injury by the lateral band of the plantar aponeurosis and is transverse in orientation. Rarely, the fracture line extends into the cuboid-metatarsal articulation but not into the joint between the fourth and fifth metatarsals.

Jones fracture

The second type is the Jones fracture, defined as a transverse fracture at the metaphyseal-diaphyseal junction involving the fourth to fifth metatarsal articulations and is prone to non-union.[7] Activities such as jumping and dancing are typically associated with such injury. The Jones fracture is distinct from the diaphyseal stress fracture, which occurs distal to the intermetatarsal joint in athletes enduring repetitive microtrauma.

The patient has difficulty weight bearing with both types of fracture. There is point tenderness over the base of the fifth metatarsal and passive inversion is painful.

In children, the normal growth plate at the base of the fifth metatarsal should not be confused with an acute fracture. Fracture lines usually pass transversely through the base of the fifth metatarsal, whereas growth plates run in a longitudinal or oblique direction.

Management

Tuberosity fractures heal well and are treated in a stiff-soled shoe or controlled ankle motion (CAM) boot with weight bearing as tolerated.[9] A non-displaced Jones fracture that does not extend beyond the distal limit of the fourth/fifth intermetatarsal articulation is treated in a non-weight-bearing cast for 6 to 8 weeks. Jones fractures that are significantly displaced should be considered for surgical fixation. There is a lower threshold to advise surgery in an athlete, as surgery results in faster time to union and return to sport.[10]

Metatarsophalangeal dislocations

The fifth MTP joint is most commonly involved and is typically dislocated laterally when the little toe is snagged on an object. The rare first MTP joint dislocation is usually dorsal and follows violent hyperextension injury. These dislocations are usually obvious, with the metatarsal head palpable on the plantar surface. Dislocations to other toes are more subtle.

Management

Most MTP joint dislocations are readily reduced with longitudinal traction under local anaesthesia. After reduction they are managed with a buddy strap.

First MTP joint dislocations are more difficult to reduce and may require open reduction if there is buttonholing of the joint capsule. Once reduced, they are treated in a POP walking cast with a toe-plate extension for 3 weeks.

Phalangeal fractures and dislocations

Phalangeal fractures are common and usually occur with direct trauma, most often involving the proximal phalanx. They are associated with pain, deformity and difficulty walking.

Management

Non-displaced fractures heal well and are 'buddy strapped' to reduce pain and prevent displacement. Place gauze between the splinted toes to prevent skin maceration. Pain may be expected for up to 3 weeks until the fracture is stabilized by callus.

Reduce a displaced fracture with traction under digital nerve anaesthesia. Operative fixation may be indicated if the fracture is unstable, is rotated or involves the hallux.

IP dislocations are uncommon and usually involve the hallux. They are reduced with longitudinal traction under digital nerve anaesthesia. Those involving the great toe require a toe-plated walking cast for 3 weeks following reduction. All other IP dislocations are treated with a buddy strap once reduced.

4.13 Osteomyelitis

Arthur Hennessy

ESSENTIALS

1 ***Staphylococcus aureus*** **is the most frequent pathogen in all age groups.**

2 **Surgery, trauma and diabetes predispose to chronic infection in adults.**

3 **Diagnosis may be difficult, relying on a combination of clinical features, imaging studies and microbiological cultures. Laboratory testing is often unhelpful.**

4 **Successful treatment requires appropriate parenteral antibiotics with surgical clearance of any necrotic bone.**

Introduction

Osteomyelitis is an inflammatory process of the bone secondary to infection, usually with a pyogenic organism. It is an infrequent but important presentation to the emergency department.

Aetiology, pathogenesis and pathology

Osteomyelitis predominantly occurs in children and the aged. It is acquired via haematogenous spread in the former and associated with comorbidity—such as trauma, surgery, vascular insufficiency and diabetes—in the latter. Osteomyelitis may also be due to the spread of infection from contiguous structures.

Haematogenous spread in children typically affects the long bones; in adults, osteomyelitis is most common in the spine, sternoclavicular joints and sacroiliac joints.[1] Common bacterial pathogens are listed according to age group in Table 4.13.1.[1,2]

Pathology

Inoculation of bone by bacteria causes alterations in pH and capillary permeability, which contribute to regional oedema, cytokine release, tissue breakdown, leucocyte recruitment and decreased oxygen tension. These processes increase local pressure, leading to small vessel thrombosis and bone deterioration.[3]

As the infection spreads into the medullary cavity, increased pressure causes extension into the cortex, with subsequent spread into the subperiosteal space and, finally, to the periosteum and adjacent soft tissues, forming an abscess. Necrosis of cortical bone follows with the formation of bone fragments or sequestra harbouring bacteria. At this stage the infection is considered to be chronic osteomyelitis.

Rarely infection also stimulates a layer of new bone deposition from stripping of the periosteum, known as an *involucrum*. Tracts may perforate the involucrum with an opening known as a *cloaca*. A tract reaching the skin surface is termed a *sinus*.[4]

Epidemiology

Acute osteomyelitis affects 0.1% to 0.8% of the otherwise healthy adult population in the United States. Methicillin-resistant *Staphylococcus aureus* (MRSA) strains have become more common, especially after surgery in hospital. A rising trend in infection rates related to increased surgical procedures has been noted.

In countries with limited medical resources, tuberculosis may be an important infection, as well as brucellosis. Agricultural injuries, industrial accidents and traumatic wounds—where prompt and adequate debridement and repair are uncommon—as well as a lack of laboratory facilities and effective antimicrobial agents account for the increased incidence of osteomyelitis.[5]

Table 4.13.1 Bacterial causes of osteomyelitis

Age group	*Typical bacteria*
Newborn to 4 months	*Staphylococcus aureus* including MRSA, group A and group B *Streptococcus*
Older children	*S. aureus* including MRSA, group A *Streptococcus*, *Streptococcus pneumoniae*, *Kingella kingae*
Adults	*S. aureus* including MRSA, *Streptococcus* spp., gram-negative species
Unusual organisms	Anaerobic bacteria, *Brucella* spp., *Mycobacterium tuberculosis*, fungi

MRSA, Methicillin-resistant *Staphylococcus aureus*.
(From Miller MD, Hart J, MacKnight JM. *Essential Orthopaedics*. Philadelphia: Saunders Elsevier; 2010; and Hatzenbuehler J, Pulling TJ. Diagnosis and management of osteomyelitis. *Am Fam Phys*. 2011;84:1027–1033.)

Clinical features

A new onset of localized bone pain and fever is suspicious. Enquire about a history of injury including soft tissue, which may serve as a nidus of secondary bone infection. Enquire also about a history of diabetes, surgery or a compound injury. Intravenous drug abuse is associated with osteomyelitis. In the paediatric population, the onset may be insidious.

Risk factors

The risk factors for osteomyelitis are recent surgery, including joint replacement; trauma, including a puncture wound; wound infections; peripheral vascular disease; diabetes, especially in the presence of a diabetic foot ulcer; immunosuppression, such as chemotherapy; steroids, alcohol and intravenous drug abuse; sickle cell disease and iatrogenic causes such as a peripheral intravenous cannula or central line.[2,6]

Examination

Patients may not appear toxic or unwell and often have few constitutional symptoms. Look for mild fever with warmth, tenderness and swelling at the site of pain. The elderly may present with a fever, non-traumatic back or neck pain and localized tenderness due to the involvement of vertebral bodies. Joint movement may be restricted if osteomyelitis is periarticular or involves a joint space.

Diabetic patients may present with a painless foot ulcer due to associated neuropathy. The presence of a scar, ulcer or sinuses may signify chronic infection. Children can present with malaise, fatigue and irritability.

Investigations

Laboratory tests

Laboratory tests, although useful, are nonspecific. The white cell count is unreliable in

confirming or excluding osteomyelitis. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) may be elevated in acute infection. Conversely, a normal ESR and CRP may occur, particularly in chronic infection. However, when the clinical suspicion is low, they are reassuring in that no further urgent investigation is required.[7]

Microbiology

Microbial cultures are essential to the diagnosis and treatment of osteomyelitis.[2] Positive cultures from bone biopsy and histopathology are the key to the definitive diagnosis of osteomyelitis.

Blood cultures are positive in over 50% of acute infections, especially if spread is by the haematogenous route. A superficial wound culture does not contribute significantly to a diagnosis of osteomyelitis.

Chronic infections are more likely to have polymicrobial involvement, including anaerobic, mycobacterial and fungal organisms. Specific cultures or microbiological testing are needed for suspected pathogens. See Box 4.13.1 for criteria for the diagnosis, in order of decreasing diagnostic value.[8]

Box 4.13.1 Criteria for the diagnosis of osteomyelitis (in decreasing order of diagnostic utility)

- Bone biopsy with positive bacterial culture
- Imaging studies demonstrating contiguous soft tissue infection or bone destruction
- Clinical signs of exposed bone, persistent sinus tract[a]
- Chronic wound over a surgical site or fracture[a]
- Laboratory evaluation—positive blood cultures, elevated ESR, CRP

[a]Chronic osteomyelitis

CRP, C-reactive protein; *ESR*, erythrocyte sedimentation rate. (Reproduced with permission from American Society of Plastic Surgeons. Evidence-based clinical practice guideline: chronic wounds of the lower extremity. http://www.plasticsurgery.org/Documents/medical-professionals/health-policy/evidence-practice/Evidence-based-Clinical-Practice-Guideline-Chronic-Wounds-of-the-Lower-Extremity.pdf. Accessed February 2013.)

Imaging studies

X-rays

Plain radiographs may help to suggest the correct diagnosis and exclude other differential diagnoses.[9] In pyogenic infection, the first changes in bone are periosteal elevation; next are focal lucency, bony resorption or radiodense, avascular areas known as *sequestra*.

X-ray changes are not seen until the infectious process has been present for 10 days to 2 to 3 weeks or more; thus they are of limited value in diagnosing early osteomyelitis.

Ultrasonography and bone scan

Ultrasonography helps to localize the site and extent of infection and provides guidance for diagnostic aspiration or bone biopsy. As it is readily accessible, it may be performed without delay.

Nuclear medicine scans, though sensitive, lack specificity but are useful when magnetic resonance imaging (MRI) is contraindicated and/or metalwork affects the computed tomography (CT) images.

Computed tomography and magnetic resonance imaging

CT provides excellent images and identifies subtle changes, particularly in long bones; it is also used for spinal infection if MRI is not available.

MRI allows the earliest detection of osteomyelitis, usually within 3 to 5 days after onset, and demonstrates the extent of involvement and activity of the disease. Of the various imaging modalities, it has the best sensitivity and specificity.[2] MRI is the investigation of choice in vertebral osteomyelitis and helps to exclude extension to discitis or an epidural abscess.

Differential diagnosis

Arthritis, tumours such as an Ewing sarcoma or osteoid osteoma, traumatic injury and gout all should be considered. Septic arthritis may coexist with osteomyelitis in joints, such as the hip and shoulder.

Management

Hospitalization may be needed with multispecialty evaluation, imaging and treatment. Early admission under the orthopaedic team can shorten the length of hospital stay. Antibiotic therapy should be aimed at stopping disease progression as well as avoiding the development of resistance. Early surgical intervention helps to confirm the infection, identify the aetiological agent and remove dead or devitalized tissue.

Treatment must be guided by the results of Gram stain and culture. All initial antibiotic regimens should include an anti-staphylococcal agent, as this organism accounts for over 80% of cases. This should be with vancomycin if MRSA is suspected. Empiric antibiotic therapy for osteomyelitis is suggested in Table 4.13.2. However, it is *essential* to seek expert microbiology advice on local organisms and their sensitivities.[2,6]

Prognosis

The outcome for osteomyelitis depends on predisposing factors, underlying disease processes, the bone involved and treatment duration, although this may not be clear at the start of therapy. The duration of follow-up is uncertain and the final outcome and morbidity may be influenced by the treatment and complicating factors.

Chronic osteomyelitis and sinus tracts will not be controlled by antibiotic therapy alone;

Table 4.13.2 Empiric antibiotic therapy for osteomyelitis

Risk factor	*Likely infecting organism*	*Antibiotic regimen*
Nil or MRSA unlikely	*Staphylococcus aureus*	Di 2 g IV q 6 h
Postoperative, with or without orthopaedic implant	*S. aureus* and coagulase-negative staphylococci	Vancomycin 1.5 g IV q 12 h
Elderly, haematogenous spread	*S. aureus* including MRSA, Gram-negative bacteria	Vancomycin 1.5 g IV q 12 h with piperacillin–tazobactam 4.5 g IV q 6 h
Diabetes mellitus or vascular insufficiency	Polymicrobial: *S. aureus* and *Streptococcus pyogenes* plus coliforms and anaerobes	Vancomycin 1.5 g IV q 12 h with piperacillin–tazobactam 4.5 g IV q 6 h
IV drug use	*S. aureus* including MRSA and *Pseudomonas aeruginosa*	Vancomycin 1.5 g IV q 12 h
Sickle cell anaemia	*Salmonella*, Gram-negative bacteria (*S. aureus* becoming more common)	Ciprofloxacin 750 mg orally q 12 h or 400 mg IV q 12 h

Note: It is essential to seek microbiology advice about local organisms and sensitivities.

(From Tintinalli JE, Stapczynski JS, Ma OJ, et al. *Tintinalli's Emergency Medicine: A Comprehensive Study Guide*. 8th ed. New York: McGraw Hill Medical; 2016; and Hatzenbuehler J, Pulling TJ. Diagnosis and management of osteomyelitis. *Am Fam Phys*. 2011;84:1027–1033.)

surgery is essential for their eradication. A squamous cell carcinoma in a tract is a rare long-term complication.

Prevention

The risk of osteomyelitis is reduced by eliminating sources of infection and by infection control measures prior to surgery. Prompt treatment of infections and effective surgical debridement of an injury may help to avoid subsequent infection. Diabetic foot osteomyelitis increases the risk of amputation. With adequate management of the early stage of diabetic foot infections, the rate of amputation can be lowered.[5]

CONTROVERSIES

- The optimum duration for parenteral antibiotics
- Balance between parenteral and oral routes
- Inpatient versus outpatient therapy
- Role of surgery in complicated cases

SECTION 5

CARDIOVASCULAR EMERGENCIES

Edited by *Conor Deasy*

5.1 Chest pain

Rohan Laging

ESSENTIALS

1 **The life-threatening differential diagnoses of acute coronary syndrome (ACS, Chapter 5.2), pulmonary embolism (PE; Chapter 5.5) and thoracic aortic dissection (Chapter 5.10) should be considered in all presentations of chest pain.**

2 **ACS is common, life threatening and treatable, so identifying and treating ACS is fundamental to the management of chest pain.**

3 **A normal ECG does not rule out ACS.**

4 **The history, examination, traditionally accepted risk factors and clinician gestalt have limited value in definitively ruling ACS in or out.**

5 **Gastro-oesophageal pain should generally be diagnosed in the emergency department only after ACS has been excluded.**

6 **Anxiety may contribute to chest pain of both a serious and benign aetiology and is an inadequate sole diagnosis.**

Introduction

Chest pain is a common presenting complaint in emergency medicine and could be considered the archetypal emergency medicine topic in that frequently the cause is benign but the differential diagnoses are deadly and the emergency provider must use a combination of careful assessment, risk stratification tools, institution-specific pathways and clinician gestalt to safely and effectively manage the patient.

Epidemiology

In the Australian Institute for Health and Welfare 2017 report, *pain in the throat and chest* was the second most common principal diagnosis (after *abdominal and pelvic pain*). According to International Statistical Classification of Diseases and Related Health Problems, Tenth Revision, Australian Modification. (ICD-10-AM) it represented 3.6% of all emergency department (ED) presentations.[1] Moreover, ischaemic heart disease is the single greatest cause of death in the Western world.

The incidence of acute chest pain presenting to the ED appears to be increasing. Awareness of the importance of early treatment for myocardial infarction (MI) has led to public information campaigns that increase ED attendances with chest pain. Meanwhile, general practitioners are increasingly being bypassed in favour of an emergency ambulance response. These changes in health service use have coincided in many developed countries with a decrease in the incidence of coronary heart disease. It therefore seems likely that patients presenting to the ED with acute chest pain have a decreasing prevalence of ACS and increasing prevalence of more benign conditions.

Differential diagnosis and approach

The main differential diagnoses are presented in Table 5.1.1, along with a hierarchical schema in Fig. 5.1.1. ACS comprises unstable angina (UA), ST-elevation myocardial infarction (STEMI) and non–ST-elevation myocardial infarction (NSTEMI). It is both common and life threatening and therefore inevitably the primary focus of assessment.

As stated, the serious differentials of ACS, PE and aortic dissection should be considered in *all* patients presenting with pain or discomfort in the region of the chest, which should include the jaw, shoulders and upper abdomen.

Historical teaching separates typical from atypical pain (see section on 'Clinical features'),

Table 5.1.1 Causes of acute chest pain

Cardiac	Myocardial infarction Unstable angina Stable angina
Pleuritic	Pulmonary embolus Pneumothorax Pneumonia Pleurisy
Pericardial	Pericarditis Pneumo-mediastinum
Gastro-oesophageal	Gastro-oesophageal reflux Oesophageal spasm
Musculoskeletal	Muscular strain Epidemic myalgia Tietze syndrome
Abdominal	Peptic ulcer Biliary colic/ cholecystitis Pancreatitis
Neurological	Cervical/thoracic nerve root compression Herpes zoster
Mixed	Aortic dissection

but this distinction should not be made; rather, all comers should be assessed on their individual merit, keeping in mind the potential morbidity and mortality of the differentials in this patient group. Traditional cardiac risk factors identified by the Framingham Heart Study,[2] though relevant on a population level, are of limited diagnostic utility when one is faced with an individual presenting with chest pain.

ACS is discussed in detail in Chapter 5.2, pulmonary embolus in Chapter 5.5 and aortic dissection in Chapter 5.10. A brief summary of the other differentials follows.

Musculoskeletal chest pain may be related to a precipitating episode, such as chest wall injury or related to episodes of pectoral or intercostal engagement outside of the patient's normal activity. Alternatively, it may be caused by inflammation in chest wall structures. Tietze syndrome (costochondritis) is most commonly seen in women and is characterized by tenderness of the costochondral cartilages. Epidemic myalgia (Bornholm disease) is due to inflammation of chest wall muscles and pleura after viral infection, typically due to Coxsackie B. Herpes zoster produces severe pain along the distribution of a thoracic nerve and may be misdiagnosed as musculoskeletal pain if the patient presents before any rash or vesicles have developed. Hyper- or paraesthesia in the affected dermatome may precede the rash of *Varicella zoster* and can be assessed by running a finger across several dermatomes in the affected area.

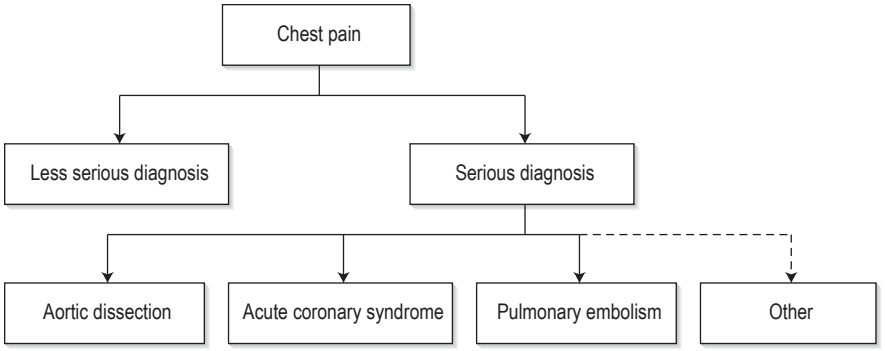

FIG. 5.1.1 Diagnostic schema for acute chest pain.

Gastro-oesophageal pain occurs when gastric contents reflux into the oesophagus or when the oesophageal muscles spasm. Gastritis can be mistaken for the pain of acute MI but may be accompanied by epigastric tenderness, radiation to the back and an association with food ingestion and patient position.

Pneumo-mediastinum can occur spontaneously after vigorous exercise, vomiting or an asthma attack or may be associated with barotrauma from diving or inhalation during drug abuse. Pericarditis is most commonly caused by viral infection but may be associated with systemic illness, such as uraemia or autoimmune disease, or it may follow MI or cardiac surgery (Dressler syndrome).

Pleurisy produces pain that is worse on inspiration and may have a benign or serious aetiology. It may occur secondary to viral respiratory tract infections, pneumonia or pulmonary infarcts such as those caused by pulmonary embolus. For this reason it should be thought of more as a symptom or process rather than a disease of itself.

Spontaneous pneumothorax usually causes pleuritic pain and is more often seen in tall, thin people and smokers. It is usually diagnosed by chest x-ray, but ultrasound has been shown to have greater sensitivity.[3]

There are a number of serious abdominal complaints that may present as chest pain. These include biliary colic, cholecystitis, peptic ulcer disease and pancreatitis. Failure to take a careful history and examine the abdomen may lead to delayed diagnosis.

Anxiety may contribute to chest pain but is not a sole cause of it.

Finally, a substantial proportion of patients will be labelled entirely appropriately as 'non-specific chest pain' after ED evaluation. These patients have pain that simply cannot be categorized into a clear diagnostic group. It is more honest to accept this than apply an inaccurate diagnostic label.

Clinical features

Clinical assessment is primarily aimed at identifying patients with a significant risk of serious pathology who require further investigation and possibly inpatient care. The assessment is often focused on the risk stratification for ACS, given that this is the most common serious pathology in those presenting with chest pain.

ACS is classically associated with chest pain that is crushing, gripping or squeezing in nature and radiates to the left arm, but the reality is that making the distinction between 'typical' and 'atypical' presentations is not particularly useful in diagnosing ACS, particularly in those over 70 years of age.[4] Table 5.1.2 shows the clinical predictors associated with ACS that may assist in its diagnosis. The only useful positive predictors, expressed here as likelihood ratios (LR) on history are pain radiating to the right or both shoulders (LR+ 2.3–2.6), diaphoresis (LR+ 1.4–6.4), vomiting (LR+ 0.9–3.1), change in stable pattern of angina (LR+ 2) and exacerbation with exertion (LR+ 1.8). Risk factors for coronary heart disease should be noted, although they may have surprisingly little diagnostic value.

Clinical examination is of limited diagnostic value and is mainly aimed at identifying non-cardiac causes of chest pain or complications of ACS, such as arrhythmia, heart failure or cardiogenic shock. Reproducible chest wall tenderness is less likely to be cardiac (negative predictive value [NPV] for ACS 98%),[5] but this finding does not exclude the possibility of ACS.

Clinical assessment should not focus only on ACS but should aim to identify other causes positively.

PE is diagnostically challenging. Suspicion should be raised by chest pain that is pleuritic in nature, haemoptysis, associated breathlessness, features of deep vein thrombosis or risk factors for venous thromboembolism (immobilization, malignancy, recent trauma or surgery, pregnancy, intravenous drug abuse or previous

Table 5.1.2 Characteristics of each predictive clinical feature as a diagnostic test for acute coronary syndrome in the emergency department

thromboembolism). Clinical examination may reveal tachycardia, tachypnoea or features of deep vein thrombosis. Once the diagnosis of PE is entertained, evidence-based decision support algorithms should be applied using the Wells criteria and PERC rule (see Chapter 5.5).

Aortic dissection is characterized by severe pain radiating to the back with associated diaphoresis. Neurological symptoms or signs, sometimes transient, are often present, as is syncope. Clinical examination may reveal discrepancy between blood pressure in the right and left arms or pulse delay between the radial arteries or the radial and femoral arteries. Assessment features and their likelihood ratios for aortic dissection are shown in Table 5.1.3.[6] It should be understood that it is the *number* of findings of aortic dissection present on history and examination that has a cumulative effect on the positive likelihood ratio (Fig. 5.1.2 and Chapter 5.10).

Clinical assessment of chest pain should always include examination of the abdomen to identify tenderness, guarding, rebound tenderness or a positive Murphy sign.

Clinical investigations

The ECG is the most useful clinical investigation and should be performed on all patients presenting with acute non-traumatic chest pain within 10 minutes of arrival. Table 5.1.2 demonstrates the performance of ECG features for ACS. It is important to recognize that a normal ECG does not rule out MI. ST-segment elevation or depression, new Q waves and new conduction defects are specific for acute MI and predict adverse outcome. ECG changes in PE are less specific but include sinus tachycardia, evidence of acute pulmonary hypertension (prominent right precordial R waves or T-wave inversions, new right bundle branch block) and perhaps the eponymous McGinn-White sign ($S_1Q_3T_3$ pattern on the ECG). The ECG is neither sensitive nor specific in cases of aortic dissection, but when the ostia of the right coronary artery are involved, changes of inferior ischaemia may be evident.

The importance of repeating the ECG cannot be over-emphasized, especially in cases where there is clinical suspicion. This applies to both patients with resolved chest pain and those initially presenting with chest pain who subsequently become pain free. In the case of the latter, Wellen syndrome comprising either biphasic or deep T-wave inversions in leads V2 and V3 secondary to critical proximal stenosis of the left anterior descending (LAD) artery should be sought.

With regard to the cardiac monitoring of chest pain patients, if the ECG is normal or nonspecific and the patient no longer has chest pain, it is safe to remove cardiac monitoring if not required for another reason.[7] This is most relevant for the patient travelling to the radiology department to have his or her x-ray or the patient being moved to the observation area in the ED.

As in the case of clinical examination, the chest radiograph is mainly intended to identify non-cardiac causes of chest pain, such as a pneumothorax or fractured rib and complications of MI, such as left ventricular failure. Although it is often routinely ordered, it is not usually helpful.

Serum troponin measurement is the pillar that supports both rational, evidence-based risk stratification in ACS and thoughtless, arbitrary practice that may lead to unnecessary admissions and harm. Given the sensitivity of modern troponin assays for myocardial necrosis, it is therefore important that testing be done wisely.

Many EDs will now be using high-sensitivity troponin assays (hsTs)—certainly this is the recommendation of both the National Heart Foundation and the European Society of Cardiology. The hsT assay is defined in the third universal definition of MI by its ability to measure circulating troponin in most healthy individuals, allowing accurate description of a reference range and demonstrating an acceptable level of imprecision at the 99th percentile (≤10% coefficient of variation).[8] The advantage of hsT over older, less sensitive assays is earlier detection of MI, shorter time frames for repeated testing and increased sensitivity to smaller cardiac events. The disadvantage is the potential for false-positive results requiring hospital admission and investigation as well as unnecessary anxiety for the patient due to the reduced specificity. This is not to say the detected troponin has not been generated by damaged myocardium but that some values may not be clinically significant; an example would be the hsT elevation in healthy, long-distance runners.

Troponin elevation is not specific for MI, and low levels may not indicate significant pathology. Even substantial troponin elevations may not be due to ACS. Troponin can be elevated in pulmonary embolus, sepsis, renal failure, burns, systemic inflammatory conditions, congestive heart failure, cardiac infiltrative diseases, cardiac contusion, critical acute neurological diseases such as subarachnoid haemorrhage and a number of other illnesses.

Repeat troponin testing is recommended when ACS is suspected, and the measured level is either below the reference range when the first test is within a pre-determined time frame or when the level is equivocal in the clinical setting. The National Heart Foundation and the Cardiac Society of Australia and New Zealand recommend repeat hsT testing at 2 hours if the thrombolysis in myocardial infarction (TIMI; see further on) score is ≤1 and at 6 hours if it is not and at 12 hours if conventional or point-of-care troponin assays are being used.

It is important to review your institution's guidelines on troponin testing, as local practices vary and may be in response to assay performance and population variation. Many departments have *chest pain units* to manage the observation, serial testing and disposition of this patient group. Some of these combine serial troponin testing with inpatient functional cardiac tests such as exercise ECG, thallium scans and exercise transthoracic echocardiography or anatomical cardiac tests, namely computed tomography (CT) coronary angiography (CTCA) and CT calcium scoring (CTCS), the latter's role primarily being in risk assessment of the asymptomatic individual.

Further cardiac testing in intermediate-risk patient groups with suspected coronary artery disease, that is, non–low-risk patients with negative serial ECGs and troponin levels who are symptom free, is broadly recommended. Exactly which patient groups stand to benefit from further investigation is still to be elucidated, but it is likely to indeed be a small group: serial hsT testing with a normal ECG probably performs with a 99% sensitivity with a NPV of 99.5% for acute myocardial infarction in those presenting with suspected ACS.[9] It should also be acknowledged that the available tests generally diagnose *fixed* obstruction and therefore may assist in prognostication over the long term but will not, importantly, make the acute diagnosis of ACS or risk-stratify.[10] Furthermore, in a large retrospective study of over 400,000 chest pain presentations, the rate of hospitalization for MI was 0.33% and there was no difference in this rate between those that underwent further cardiac testing (exercise ECG, myocardial perfusion studies, CTCA) and those who did not; however, the former group were significantly more likely to undergo cardiac catheterization and revascularization procedures.[11]

Australian, European, British and American guidelines nonetheless recommend further cardiac testing for non–low-risk individuals with suspected ACS. The Society of Cardiovascular Computed Tomography Guidelines Committee state that CTCA is appropriate for low (TIMI 0) and intermediate (TIMI 2) patient groups in whom ACS is suspected. The aforementioned Australian and New Zealand guidelines advise against further testing in those aged less than 40 years without ECG changes or serial troponin elevation, no ongoing symptoms and no symptoms to suggest angina. The timing of further cardiac testing is somewhat equivocal in the current literature, but most guidelines recommend that it occur during hospitalization or soon after discharge. As stated, in practice it is best to consult with local guidelines and policies or, in their absence, co-develop these with relevant stakeholders.

A number of clinical risk scores have been developed to assist in the risk stratification for ACS in patients presenting to EDs. The TIMI score has been developed and validated as a predictor of adverse outcome in patients with diagnosed ACS (see Chapter 5.2). More recently, the TIMI score has been validated on unselected patients with chest pain and been found to assist in their risk stratification. The HEART (History, ECG, Age, Risk factors, Troponin) score was developed prospectively with the same intention. Other tools exist such as the GRACE (Global Registry of Acute Coronary Events) and EDACS (Emergency Department Assessment of Chest pain Score). As in the case of all clinical decision tools, it is important to understand their limitations and their role to complement the patient workup rather than supplant it. The HEART and TIMI scores are presented in Table 5.1.4. These scores have been combined with serial troponin and ECG results to form accelerated diagnostic pathways, as in the ADAPT (2-hour accelerated diagnostic protocol) trial, which utilized the TIMI score and 2-hour hsT to identify a low-risk population of chest pain patients with high accuracy. More recently, the HEART score outperformed the TIMI and GRACE scores in discriminating between those with and without major adverse cardiac events at 6 weeks following presentation.

The National Heart Foundation and the Cardiac Society of Australia and New Zealand make a strong recommendation that patients' receive care guided by an evidence-based Suspected ACS Assessment Protocol that includes formal risk stratification', citing level 1A evidence. An example of this can be found at: https://www.heartfoundation.org.au/images/uploads/publications/Clinical_Guidelines_for_the_Management_of_Acute_Coronary_Syndromes_2016.pdf.

A higher clinical index of suspicion for coronary disease should apply to Aboriginal and Torres Strait Islander populations, although these demographic factors are not featured in typical stratification tools, and in those infected with human immunodeficiency virus (HIV). The workup for PE warrants a detailed discussion, which can be found in Chapter 5.5. D-dimer should be ordered only in patients who have a low-risk Wells score (0 to 4) and are PERC (Pulmonary Embolism Rule out Criteria)-positive; advanced imaging is required for those with positive D-dimers or a Wells score greater than 4. In cases of confirmed PE, serum BNP (Brain Natriuretic Peptide) and troponin together with echocardiography determine the presence of sub-massive PE, which in some patients could be treated with thrombolysis.

The diagnosis of thoracic aortic dissection is usually made by CTA, although a chest x-ray performed prior may demonstrate a widened mediastinum, pleural cap, rightward displacement of the trachea, evidence of pericardial effusion, pleural effusion, a double aortic contour or an indistinct aortic knuckle. The use of D-dimer to exclude aortic dissection is controversial, but there may be a role for it in patients considered at lower risk.

Table 5.1.4 Thrombolysis in myocardial infarction and HEART scores

TIMI risk score[a]	*Value*	*Total score*	*Major adverse cardiac event at 30 days (95% CI)*
Age ≥65	1	0	1.7% (0.42–2.95)
≥3 CAD risk factors	1	1	8.2% (5.27–11.4)
Aspirin use in last 7 days	1	2	8.6% (5.02–12.08)
Known CAD (≥50% stenosis)	1	3	16.8% (10.91–22.62)
Severe angina last 24 h	1	4	24.6% (16.38–32.77)
Elevated cardiac markers	1	5	37.5% (21.25–53.75)
ST deviation ≥0.5 mm	1	6	33.3% (0–100)

HEART[b]		
History	Slightly suspicious Moderately suspicious Highly suspicious	0 1 2
ECG	Normal Non-specific repolarization disturbance Significant ST-segment depression	0 1 2

Treatment

Treatment of acute chest pain is directed at the specific cause. The treatment of ACS is outlined in Chapter 5.2, pulmonary embolus in Chapter 5.5 and aortic dissection in Chapter 5.10.

Patients with suspected ACS undergoing workup in the ED should be treated with aspirin 300 mg (immediate-release) and oxygen if SpO_2 is less than 94%. The target should be 88% to 92% if the patient has chronic obstructive airways disease. It is reasonable to administer GTN Glyceryl trinitrate sublingually or via spray, progressing to titrated doses of intravenous morphine or a GTN infusion while the diagnosis of ACS is being entertained but not yet confirmed.

Musculoskeletal chest pain, regardless of the underlying aetiology, should be treated with simple analgesia, non-steroidal anti-inflammatory drugs being the most effective agents. It is also worth considering whether anxiety may be exacerbating the patient's symptoms.

Gastro-oesophageal pain can be treated acutely by antacids and proton pump inhibitors. Note that relief of symptoms after administration is an unreliable diagnostic test, just as response to GTN treatment has no diagnostic utility in suspected ACS.

If anxiety is thought to contribute to the presentation, this should be openly acknowledged to the patient. A sensitive approach is needed, and it is best to convey to the patient that his or her anxiety may be contributory rather than solely responsible. After adequate investigation and follow-up has been arranged for non–anxiety-related aetiologies, the patient should be encouraged to follow up with his or her general practitioner (GP) for counselling and in some cases anxiolytics and cognitive behavioural therapy.

Non-specific chest pain obviously presents a challenge. With no clear diagnosis, it is difficult to advise an appropriate treatment. However, patients can be advised that, although no clear diagnosis can be made, about half such patients presenting to the ED have no further episodes of pain over the following month.

Finally, an acute episode of chest pain provides an opportunity to identify and manage cardiac risk factors at a time when the patient is likely to be receptive to lifestyle advice. Smokers should be advised to use the episode as a stimulus to quit, and they should be referred to smoking cessation resources. General dietary and exercise advice may also be helpful. Blood pressure, blood glucose and lipid profile may be requested as part of clinical assessment, although any abnormalities identified should preferably be referred to the patient's general practitioner, who will be best placed to provide overall cardiovascular risk assessment, intervention and long-term follow-up.

Disposition

Disposition should reflect the severity of the suspected or final diagnosis as well as patient factors including access to follow-up. It is worth restating the importance of admitting high risk patients for ACS even in the absence of positive troponin testing or ECG abnormalities. A chest pain flow-chart such as those published by the National Heart foundation of Australia and Cardiac Society of Australia and New Zealand can be used to guide disposition and further testing (see Chapter 5.2).

Prognosis

Prognosis will also depend upon the underlying pathology; the prognoses of various causes of chest pain are discussed in the relevant chapters of this book. Patients with no obvious diagnosis after clinical assessment, ECG and troponin testing have an excellent prognosis. There is some evidence that patients who attend the ED with chest pain have a higher risk of adverse cardiac events than the general population even if cardiac disease is 'ruled out' at initial presentation, but this risk is not high enough to warrant active intervention beyond ensuring that any cardiac risk factors identified have been addressed.

CONTROVERSIES

- The cut points for 'positive' hsT in your institution—weighing up the sensitivity to capture ACS early against the reduced specificity prompting unnecessary admission.
- The role of accelerated chest pain pathways that use increasingly brief observation and serial troponin measurement to minimize ED length of stays and hospital resources. Can a balance between resource utilization and safety be found?
- Patient selection for further cardiac testing.
- The role of CTCA and CTCS in suspected ACS. Can this form part of the risk stratification for non–high-risk presentations?
- The use of D-dimer to exclude aortic dissection.

5.2 Acute coronary syndromes

Rohan Laging

ESSENTIALS

1 **Every patient with possible acute coronary syndrome (ACS) must have a 12-lead ECG performed and interpreted as soon as possible, ideally within 10 minutes after arrival, to identify whether he or she may benefit from reperfusion therapy.**

2 **Every patient with suspected ACS should be given aspirin unless he or she has a strong contraindication.**

3 **The ECG cannot exclude ACS.**

4 **Patients presenting with possible ACS should undergo risk stratification and receive further care guided by a suspected ACS assessment protocol (suspected ACS-AP).**

5 **Percutaneous coronary intervention (PCI) is preferred over thrombolysis for reperfusion in ST-elevation myocardial infarction (STEMI) provided that it can be performed within 90 minutes.**

6 **In cases of STEMI, the emergency clinician should act decisively and rapidly to institute reperfusion therapy.**

7 **Primary prevention of ACS involves overall cardiovascular risk assessment and is most appropriately undertaken in primary care.**

Introduction

Acute coronary syndrome (ACS) is the most common life-threatening condition in emergency medicine. Failure to identify and treat it promptly risks avoidable morbidity and mortality.

The spectrum of disorders comprised by ACS is represented in Fig. 5.2.1. They range from the acute myocardial infarction (AMI) patterns of ST elevation acute myocardial infarction (STEMI) to non–ST-elevation elevation acute myocardial infarction (NSTEMI) and non–ST-elevation elevation ACS (NSTEACS), which broadly includes both NSTEMI and unstable angina (UA). A new left bundle branch block (LBBB) with the diagnosis of AMI may be categorized as STEMI, as this condition requires the same treatment pathway. AMI is defined in pathological terms as myocardial cell death due to prolonged ischaemia.

Box 5.2.1 contains the Third Universal Definition of Myocardial Infarction. It is worth noting the breadth of the current diagnostic spectrum in the age of high-sensitivity biomarkers.

See Chapter 5.1 for a more detailed description of the process of diagnosis and risk stratification for possible ACS.

Patients presenting with possible ACS should undergo formal risk stratification and receive further care guided by a suspected ACS-AP. An example of this can be found at: https://www.heartfoundation.org.au/images/uploads/publications/Assessment_protocol_for_suspected_ACS_using_a_highly_sensitive_lab-based_assay-2016.pdf. Suspected ACS-APs use a combination

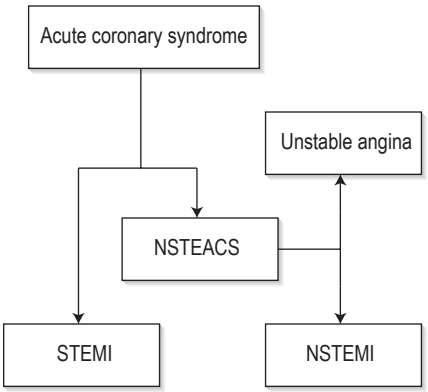

FIG. 5.2.1 Acute coronary syndrome. *NSTEACS,* non–ST-elevation acute coronary syndrome; *NSTEMI,* non–ST-elevation myocardial infarction; *STEMI,* ST-elevation myocardial infarction.

of validated risk-stratification tools (such as TIMI (Thrombolysis in Myocardial Infarction) or HEART (History, ECG, Age, Risk factors, Troponin) score), with electrocardiograph (ECG) and biomarker features to determine an appropriate clinical pathway for the patient. This includes repeat cardiac biomarker testing, safe disposition and outpatient investigation. Pathways such as the ADAPT (2-hour accelerated diagnostic protocol) have demonstrated a negative predictive value (NPV) of greater than 99% for major adverse cardiac events (MACE), and enable the identification of patients who are suitable for early discharge.[1] Emergency departments should develop their suspected ACS-APs in collaboration with their cardiology and laboratory colleagues.

With regard to risk factors for ischaemic heart disease (IHD), both clinicians and patients are generally aware of those derived from the Framingham study[2]; these also feature in the aforementioned risk-stratification tools and therefore in many suspected ACS-APs. There is increasing

Box 5.2.1 Third consensus definition of acute myocardial infarction

The detection of a rise and/or fall of cardiac biomarker values, with at least one of the values being elevated (i.e. >99th percentile upper reference limit), preferably cardiac troponin. In addition, at least one of the five following diagnostic criteria should be met:

1. Symptoms of ischemia
2. New (or presumably new) significant ST/T-wave changes or left bundle-branch block (LBBB)
3. Development of pathological Q waves on ECG
4. Imaging evidence of new loss of viable myocardium or regional wall motion abnormality
5. Identification of intracoronary thrombus by angiography or autopsy

(From Thygesen K, Alpert JS, Jaffe AS, et al. Third universal definition of myocardial infarction. *Circulation*. 2012;126(16):2020–2035).

Box 5.2.2 Types of myocardial infarction from the third universal definition of myocardial infarction

Type 1—Spontaneous MI. Related to atherosclerotic plaque rupture, ulceration, fissuring, erosion, or dissection with resulting intraluminal thrombus in one or more of the coronary arteries.

Type 2—MI secondary to an ischaemic imbalance. A condition other than coronary artery disease contributes to an imbalance between oxygen supply and demand (e.g. coronary artery spasm, embolism or endothelial dysfunction, tachy/brady-arrhythmias, anaemia, respiratory failure, hypotension and hypertension with or without left ventricular hypertrophy [LVH]).

Type 3—MI resulting in death when biomarker values are unavailable

Type 4a—MI related to PCI

Type 4b—MI related to stent thrombosis

Type 5—MI related to coronary artery bypass grafting (CABG)

MI, Myocardial infarction; *PCI*, percutaneous coronary intervention

evidence demonstrating the association between human immunodeficiency virus (HIV) and IHD,[3] so this information should also be sought from the patient presenting with possible ACS.

Table 5.2.1 summarises evidence-based recommendations on the assessment and treatment in suspected and confirmed ACS.

Pathology

ACS is nearly always caused by a coronary artery atheroma or disruption of its endothelial layer resulting in thrombotic occlusion, which impairs blood flow and myocardial oxygen delivery. This occlusion leads to myocardial ischaemia or infarction depending on a number of factors including duration and extent of occlusion, myocardial oxygen demand and antecedent physiological conditions such as anaemia and circulating catecholamine levels.

The nature of the presentation reflects the pathophysiology of the coronary occlusion. Many people have coronary atheromas but are asymptomatic because it is not extensive enough to occlude coronary blood flow. Others have a degree of coronary occlusion that does not cause symptoms unless myocardial oxygen demand is increased by exertion or acute illness. Fissuring or rupture of a coronary atheroma leading to rapid vessel obstruction and STEMI may present with the classic presentation of AMI, with a sudden onset of severe crushing chest pain. Cardiac chest pain that occurs in a fixed and predictable pattern of exertion and is rapidly relieved by rest is known as stable angina and is not classified as an ACS.

Not all coronary artery occlusion is due to an atheroma. Prinzmetal or variant angina is a syndrome in which myocardial ischaemia is associated with coronary artery spasm; it is characterized by transient ST-elevation on the ECG and may be seen in cocaine use. Coronary angiography may show a minor atheroma or normal coronary arteries.

Other rare causes of coronary artery occlusion include Kawasaki disease, in which occlusion is due to inflammation in the coronary artery, aortic dissection that involves the ostia of the coronary arteries—in particular the right coronary artery (RCA)—and spontaneous coronary artery dissection.

The anatomical location of coronary artery occlusion in ACS determines the clinical presentation, ECG findings and likelihood of complications. The most common site for myocardial infarction (MI) is the anterior or antero-septal region. It usually results from occlusion of the left anterior descending (LAD) artery and has a worse prognosis than other types of MI; complications are also more common, including sudden cardiac death. Lateral infarction is usually caused by occlusion of the circumflex artery or the diagonal branch of the LAD artery. Inferior MI is usually caused by occlusion of the RCA or the circumflex artery. It has a better prognosis than anterior infarction, and ventricular dysfunction is less likely, although heart block due to involvement of the atrioventricular node is more common. Posterior infarction is usually due to occlusion of the RCA or, less commonly, the circumflex artery in patients with dominance of the left coronary circulation. Posterior or inferior MI may result in right ventricular (RV) infarction, leading to RV failure. Further details are provided in the sections titled Investigations and Complications.

The Third Universal Definition of Myocardial Infarction describes five categories of MI (Box 5.2.2). Types 1 and 2 are most relevant to the ED setting.

Epidemiology

Although coronary heart disease (CHD) mortality rates have declined over the past four decades in western countries, this condition remains responsible for about one-third of all deaths in individuals over age 35. Nearly half of all middle-aged men and one-third of middle-aged women in the United States will develop some manifestation of CHD.

In Australia,[4]

- The age-standardized rate for acute coronary events is twice as high in men as in women; the rate of acute coronary events increases rapidly with age, with the rate among the 85-and-over age group (3005 per 100,000 population) more than three times that for the 65-to-74 age group (854 per 100,000 population) and six times the rate for the 55-to-64 age group (502 per 100,000 population).
- The rate of acute coronary events fell by 24% from an age-standardized rate between 2007 and 2012.

Clinical features

Clinical assessment of suspected ACS is described in detail in Chapter 5.1, and Table 5.1.2 details the features on clinical assessment that have the most discriminatory value in diagnosing ACS. In short, patients presenting with chest pain radiating to the right or both shoulders, diaphoresis, dyspnoea, vomiting or pain, as in a previous MI, are more likely to have ACS, and those with pleuritic pain or pain that is reproducible to palpation are less likely. Note that no single assessment feature is particularly useful in ACS diagnosis.

Clinical assessment of cardiac pain is required to distinguish between stable angina and ACS. Stable angina is characterized by pain that is predictable, precipitated by exertion, relieved promptly by rest or glyceryl trinitrate (GTN) and is not becoming more frequent or severe. The symptoms of UA, a form of ACS, are unpredictable or occur with increasing severity or decreased effort. It is useful to grade the level of exertion a patient needs to experience angina symptoms so as to assist in the diagnosis of UA; the New York Heart Association (NYHA) grading is commonly applied (Table 5.2.2), although its original use was in the description of dyspnea relating to heart failure.

Clinical examination is generally unhelpful in making the diagnosis of ACS, which should be based on clinical history and investigations. However, clinical examination is essential to identify complications of ACS and to rule out differential diagnoses. Heart failure may be identified by poor peripheral circulation, tachycardia, pulmonary crepitations, elevated jugular venous

Table 5.2.1 NHFA and CSANZ: Australian Clinical Guidelines for the Management of Acute Coronary Syndromes 2016—*Strong* recommendations for the initial assessment of chest pain, acute reperfusion and management in ACS, timing of invasive management in NSTEACS and pharmacology for ACS

Recommendation	*Level of evidence*
It is recommended that a patient with acute chest pain or other symptoms suggestive of an ACS receive a 12-lead ECG and that this ECG be assessed for signs of myocardial ischaemia by an ECG-experienced clinician within 10 min of first acute clinical contact.	IIIC
A patient presenting with acute chest pain or other symptoms suggestive of an ACS should receive care guided by an evidence-based suspected ACS assessment protocol (suspected ACS-AP) that includes formal risk stratification.	IA
Using serial sampling, cardiac-specific troponin levels should be measured at hospital presentation and at clearly defined periods after presentation using a validated suspected ACS-AP in patients with symptoms of possible ACS.	IA
For patients with STEMI presenting within 12 h of symptom onset and in the absence of advanced age, frailty and comorbidities that influence the individual's overall survival, emergency reperfusion therapy with either PCI or fibrinolytic therapy is recommended.	IA
Primary PCI is preferred for reperfusion therapy in patients with STEMI if it can be performed within 90 min of first medical contact; otherwise fibrinolytic therapy is preferred for those without contraindications.	IA
Among patients treated with fibrinolytic therapy, for those with ≤50% ST recovery at 60–90 min and/or with haemodynamic instability, immediate transfer for angiography with a view to rescue angioplasty is recommended.	IB
Among high- and very high-risk patients with non–ST-elevation acute coronary syndromes (NSTEACS) (except type 2 MI), a strategy of angiography with coronary revascularization (PCI or coronary artery bypass grafts) where appropriate is recommended.	IA
Patients with NSTEACS who have no recurrent symptoms and no risk criteria are considered at low risk for ischaemic events and can be managed with a selective invasive strategy guided by provocative testing for inducible ischaemia.	IA
Very high-risk patients: Among patients with NSTEACS with very high-risk criteria (ongoing ischaemia, haemodynamic compromise, arrhythmias, mechanical complication of MI, acute heart failure, recurrent dynamic or widespread ST-elevation and /or T-wave changes on ECG), an immediate invasive strategy is recommended (i.e. within 2 h of admission).	IIC
Aspirin 300 mg orally initially (dissolved or chewed) followed by 100–150 mg/day is recommended for all patients with ACS in the absence of hypersensitivity.	IA
Among patients with confirmed ACS at intermediate to very high-risk of recurrent ischaemic events, use of a P2Y12 inhibitor (ticagrelor 180 mg orally, then 90 mg twice daily or prasugrel 60 mg orally, then 10 mg daily or clopidogrel 300–600 mg orally then 75 mg/day) is recommended in addition to aspirin.	IA
Intravenous glycoprotein IIb/IIIa inhibition in combination with heparin is recommended at the time of PCI among patients with high-risk clinical and angiographic characteristics or for treating thrombotic complications among patients with ACS.	IB
Either unfractionated heparin or enoxaparin is recommended in patients with ACS at intermediate to high risk of ischaemic events.	IA

ACS, Acute coronary syndrome; *ECG*, electrocardiogram; *MI*, myocardial infarction; *PCI*, percutaneous coronary intervention; *STEMI*, ST-elevation myocardial infarction

Table 5.2.2 New York Heart Association functional classification

Class	*Patient symptoms*

III	Marked limitation of physical activity. Comfortable at rest.
IV	Unable to carry on any physical activity without symptoms.

pressure and a third heart sound on cardiac auscultation. The additional finding of hypotension may suggest cardiogenic shock. A systolic murmur raises the possibility of papillary muscle rupture or ventricular septal defect secondary to MI, although pre-existing aortic or mitral valve disease are much more common.

Differential diagnosis

Alternative diagnoses and their differentiation from ACS are described in Chapter 5.1. The most potentially serious alternative diagnoses are pulmonary embolus and aortic dissection. These should be considered in *all* patients presenting with atraumatic pain between the jaw and upper abdomen.

Clinical investigations

The ECG is the critical test to perform on patients with suspected ACS and should be undertaken and interpreted by a clinician within 10 minutes of the patient arriving. If there is uncertainty over interpretation, senior assistance should be sought immediately. Repeating the ECG as the patient's clinical picture evolves is important, and again, once the patient is pain-free to examine for Wellen syndrome.

The diagnostic criteria of a STEMI are a clinical history of typical chest discomfort or pain of greater than 20 minutes duration (which may have resolved by the time of presentation) and ECG criteria with persistent (>20 minutes) ST elevation in ≥2 contiguous leads of:

- ≥2.5 mm ST elevation in leads V2–V3 in men under 40 years, or
- ≥2.0 mm ST elevation in leads V2–V3 in men over 40 years, or
- ≥1.5 mm ST elevation in V2–V3 in women, or
- ≥1.0 mm in other leads, or
- Development of new onset LBBB.

With regard to new LBBB, diagnosis can often be challenging due the need to access prior ECGs and patient records. The Sgarbossa criteria[5] can assist the diagnosis of STEMI in the setting of prior LBBB or when it is not known if the observed LBBB is new. They are:

- ST elevation ≥1 mm concordant with QRS (5 points);
- ST depression ≥1 mm in leads V1–V3 (3 points); and
- ST elevation ≥5 mm discordant with the QRS (2 points).

Three or more points is 90% specific for MI, but only 36% sensitive. The modified Sgarbossa criteria[6] perform better, and replace ST elevation ≥5mm discordant with the QRS with ST elevation to S-wave depth (ST/S ratio) of ≤0.25. In diagnostically difficult cases, an echocardiogram can be performed to assess for regional wall motion abnormalities and specialist opinion can be sought on the need for urgent revascularization. These criteria can also be applied to those who have ventricular pacing.

The location of ischaemic changes on ECG reflects the anatomy of the affected coronary vessel. LAD artery typically produces anteroseptal changes, left circumflex (LCx) artery anterolateral changes, RCA inferior changes and the posterior descending artery (PDA)—which may arise from either the LCx or the RCA—resulting in posterior changes.

The presence of anterior ST depression with prominent R waves in the right precordial leads should prompt consideration of a posterior MI, and a posterior ECG should be performed accordingly. Inferior MI with ST elevation greater in III than II may indicate RV infarct. These complicate up to 40% of inferior STEMIs and render the patient highly preload sensitive and at risk of hypotension, particularly in response to GTN. Other findings in RV infarct include ST elevation in V1 (especially with ST depression in V2) and ST elevation in V1 > V2. Performing right-sided leads will demonstrate V4R abnormality, with ST elevation of greater than 1 mm being 100% sensitive and 87% specific for RV infarction.[7]

De Winter sign and Wellens syndrome are two eponymous characteristic ECG findings in proximal LAD occlusion. De Winter sign or de Winter T waves describe an upsloping ST depression in leads V1–V6 with associated symmetrical and prominent T waves, often with ST elevation in aVR.[8] Wellen' syndrome is perhaps even more fascinating, as the characteristic biphasic (type A) or deeply inverted (type B) T wave inversion is typically only seen when the patient is pain free, and often cardiac biomarkers are normal. Both entities should be considered as STEMI equivalents with regards to management.

There are many other ECG findings that may be seen in ACS, not forgetting that ECG may also be completely normal or benign in appearance. Less specific ECG features which suggest ACS include peaked or *hyperacute* T waves, T wave inversions or biphasic T waves, loss of R wave progression and pathological Q waves.

The ECG should also be inspected for the consequences of MI, such as conduction blocks and dysrhythmias and antecedent factors such as left ventricular (LV) hypertrophy associated with hypertension.

Other ECG changes may be useful in diagnosing AMI and are described in Chapter 5.1 and Table 5.1.2.

Biochemical markers are discussed in detail in Chapter 5.1. Their role is to identify patients with probable ACS and to rule out ACS if negative. However, it should be remembered that a negative cardiac biomarker, even high sensitivity troponin (hsT) performed within an optimal time frame, does not exclude underlying coronary vascular disease.

Outpatient functional and anatomical testing is discussed in Chapter 5.1. Institution specific variability in the choice of further cardiac testing reflects the mixed evidence in this area, and should prompt the reader to familiarize themselves with their local practice.

Treatment

All patients with possible ACS should be assessed and observed in an environment which permits physiological monitoring, repeat ECGs and access to advanced resuscitation equipment. The workup and treatment for ACS should occur in parallel to minimize potential delays.

Treatments for all acute coronary syndromes

Analgesia

GTN and intravenous (IV) morphine are the agents of choice in suspected ACS. Sublingual GTN may be appropriate if pain is mild to moderate, but severe pain usually requires titrated IV morphine. If IV morphine fails to control pain and the clinical condition is suitable, IV GTN by infusion at a rate titrated to effect (20–200 μg/min) is indicated.

Aspirin

Immediate release aspirin 300 mg should be administered unless already given (e.g. by emergency services or general practitioner) or contraindicated. The principal contraindication to aspirin is known allergy. A previous history of gastritis or indigestion is not a contraindication to the use of aspirin in ACS.

Oxygen

Supplemental oxygen is recommended for those with oxygen saturation less than 94%. Routine oxygen therapy in those with ACS may increase infarct size, but has not been shown to affect 1-year all-cause mortality.[9] Those with chronic obstructive airways disease should have oxygen therapy titrated to 88% to 92%.

Box 5.2.3 Contraindications to fibrinolytic therapy (NHFA and CSANZ 2016)

Consider expert consultation with any of the following:
- BP >180/110 mm Hg
- Recent trauma or surgery
- Gastrointestinal or genitourinary bleeding within the previous 2–4 weeks
- Stroke/transient ischaemic attack within 12 months
- Prior intracranial haemorrhage at any time
- Current anticoagulation or bleeding diathesis (relative contraindication with warfarin)

Reperfusion therapy

In patients with confirmed STEMI, emergency reperfusion is indicated to improve short and long-term survival and minimize the impact on cardiac function. Primary percutaneous coronary intervention (PCI) is the preferred reperfusion therapy if it can be performed within 90 minutes of first medical contact, otherwise fibrinolysis should be performed in those without contraindications (Box 5.2.3). Meta-analyses have demonstrated a survival benefit of primary PCI over thrombolysis, with reductions in both 30-day mortality, MI recurrence and stroke risk.[10] PCI may take the form of balloon angioplasty, thrombectomy and stent placement with bare metal stent (BMS) or drug-eluting stent (DES). Failed PCI may necessitate coronary artery bypass grafting (CABG).

The choice of thrombolytic agent will depend on availability and local practices, but streptokinase (1.5 million units IV infusion over 30 to 60 minutes) should be avoided due to higher rates of hypotension and intracerebral haemorrhage when compared to other agents, and in Aboriginal and Torres Strait Islander patients because they have a high prevalence of streptococcal antibodies. Currently available agents in Australia are tenecteplase (30 to 50 mg IV bolus), reteplase (10 units IV followed by a further 10 units 30 minutes later), and alteplase (weight-based bolus and infusion regimen).

Coronary angiography with a view to either PCI or CABG is recommended in patients with NSTEACS who are deemed either very high or high risk (Table 5.2.3). Compared with a non-invasive approach, a routine early invasive approach reduces the combined end-point

Table 5.2.3 Markers of increased risk of mortality and recurrent events among patients with confirmed ACS (NHFA and CSANZ 2016)

Risk classification	*Clinical characteristic*
Very high	Haemodynamic instability, heart failure, cardiogenic shock or mechanical complications of MI Life-threatening arrhythmias or cardiac arrest Recurrent or ongoing ischaemia or recurrent dynamic ST- or T-wave changes, particularly with intermittent ST elevation, De Winter T- wave changes or Wellens syndrome or widespread ST elevation in two coronary territories
High	Rise and or fall in troponin level consistent with MI Dynamic ST- and/or T-wave changes with or without symptoms, GRACE score >140
Intermediate	Diabetes mellitus. Renal insufficiency (glomerular filtration rate <60 mL/m per 1.73 m^2) LV ejection fraction <40% Prior revascularization with PCI or CABG GRACE score >109 and <140

ACS, Acute coronary syndrome; *CABG*, coronary artery bypass graft; *GRACE*, global registry of acute coronary events; *LV*, left ventricular; *MI*, myocardial infarction; *PCI*, percutaneous coronary intervention.

of death, recurrent MI and cardiovascular rehospitalization at 12 months but the benefit on mortality alone is probably absent.[11] Regardless, all NSTEACS patients require urgent expert cardiology opinion in the emergency department.

Timely institution of therapy requires adherence to a clinical pathway, the design of which should be co-developed in a hospital system with pre-hospital services, emergency physicians, cardiologists and clinical pharmacists. In primary PCI capable centres, such a pathway should minimize the door to balloon time (DTB) to less than 60 minutes. In non-primary PCI centres, the pathway should effect a transfer to a primary PCI centre where the anticipated door out to door in time is less than 30 minutes (i.e. total time from first medical contact to balloon time is less than 90 minutes), or immediately after unsuccessful thrombolysis or urgently (within 3 to 24 hours) after successful thrombolysis. All cases of STEMI with cardiogenic shock should be transferred immediately to a primary PCI centre regardless of their response to thrombolysis.

In cases where there is greater than 12 hours to first medical contact, thrombolysis should be avoided and urgent, but not emergent, transfer to a primary PCI centre should be arranged.

Other therapies

With regards to therapies that increase the risk of bleeding, the potential benefits and harms need to be assessed at an individual patient level. Expert cardiology opinion is recommended for the institution of the following agents.

$P2Y_{12}$ receptor inhibitors

These agents inhibit platelet function and are recommended in addition to aspirin in those patients with confirmed ACS and at intermediate or higher risk (see Table 5.2.3) of recurrent ischaemic events (including those with STEMI). The choice of agent is likely to be institution specific, but both ticagrelor (180 mg orally, then 90 mg twice daily) and prasugrel (60 mg orally then 10 mg daily) have been found to reduce death and recurrent MI but increase risk of major bleeding when compared to clopidogrel (300 to 600 mg orally, then 75 mg daily). Therefore the latter is preferred in patients greater than 75 years of age, with body weight less than 60 kg or a history of transient ischaemic attacks (TIAs) or strokes.

Glycoprotein IIb/IIIa inhibitors

These antagonists of platelet aggregation, used in combination with heparin, should be initiated in ACS patients imminently undergoing or during PCI who have high-risk angiographic characteristics or thrombotic complications. For this reason, they should not be routinely initiated in the ED. This class includes abciximab, tirofiban and eptifibatide.

Antithrombin therapy

Enoxoparin or unfractionated heparin (UFH) is recommended in patients with ACS and at intermediate to very high risk of ischaemic events (see Table 5.2.3). Enoxaparin inhibits factor Xa at the nexus of the intrinsic and extrinsic coagulation cascades, and UFH potentiates antithrombin III thereby inactivating thrombin and factor Xa. Therapy with either benefits those patients with ACS managed invasively or conservatively. Enoxaparin may be preferred due to simpler dosing and not requiring activated partial thromboplastin time (aPTT) monitoring and is dosed at 1 mg/kg subcutaneously twice daily. Those undergoing fibrinolysis should receive a 30 mg IV bolus if under 75 years, with dosing modified in those older than 75 years or with chronic renal impairment—it is best to consult your local guideline. Patients on a novel oral anticoagulant agent (NOAC) or warfarin need further specialist advice.

Direct thrombin inhibitors

Bivalirudin instead of the combination of glycoprotein IIb/IIIa inhibitors and heparin may reduce bleeding events in ACS patients. This is not the sole decision of the emergency clinician.

β-Blockers

Non-urgent initiation of a β-blocker is recommended unless contraindicated.

Disposition

Patients with ACS should be admitted to a coronary care unit, unless old age, frailty or significant comorbidities determine otherwise. The cardiac catheterization laboratory may precede the coronary care unit depending on the nature of the ACS. The intensive care unit is required for those patients post emergent CABG, with cardiogenic shock or relevant life-threatening co-existing acute medical pathology.

Complications

Arrhythmias and conduction disturbances (see Chapter 5.4)

Chapters 5.4 and 5.6 detail the not uncommon complications of ACS, arrhythmias and pericarditis, respectively.

Pericarditis (see Chapter 5.6)

Acute left ventricular failure and cardiogenic shock

Most MIs are accompanied by some degree of LV failure, which may range in severity from asymptomatic to pulmonary oedema and cardiogenic shock, the mortality proportionally increasing

Table 5.2.4 Killip class and mortality in ST-elevation myocardial infarction

Killip Class	*Long-term follow-up mortality (%)*
I	17.7
II	27.3
III	30.4
IV	48.8

(Table 5.2.4). With regard to Killip class (I being no clinical signs of heart failure, IV being cardiogenic shock), there is negligible difference in 30-day and long-term mortality between NSTEMI and STEMI patients.[12]

Management includes maintaining adequate oxygenation, correcting electrolyte imbalances and optimizing ventricular filling pressures. Patients with pulmonary oedema may require non-invasive ventilatory support (see Chapter 5.3). If there is hypotension or other evidence of inadequate perfusion in the presence of adequate intravascular volume, inotropes should be initiated early and aggressively. PCI has been shown to improve outcome for patients with STEMI accompanied by cardiogenic shock. LV assist devices may bridge to recovery, cardiac surgery or transplantation in selected patients.

Thromboembolism

Thrombus can form on areas of hypokinetic myocardium due to relative stasis and the prothrombotic effects of local inflammatory changes. It is more common with large anterior infarctions with LV aneurysm formation, where the incidence has been reported to be up to 10%. Echocardiography is used to confirm the presence of thrombus. Systemic anticoagulation is indicated to reduce the risk of embolic complications.

Mechanical defects

These may include

- ventricular aneurysm formation with the attendant risk of thrombus formation and embolization
- acute mitral insufficiency secondary to papillary muscle dysfunction/rupture
- ventricular septal defect
- free wall rupture, which may present as sudden death or acute pericardial tamponade.

Complications of therapy

Major bleeding, in particular intracerebral haemorrhage, is a risk with any antiplatelet or anticoagulation therapy and the perceived risks of such therapies need to be balanced against the potential benefits—sometimes shared decision-making with the patient or appointed medical

Table 5.2.5 NHFA and CSANZ: Australian Clinical Guidelines for the Management of Acute Coronary Syndromes, 2016

Recommendation	*Level of evidence*
Aspirin (100–150 mg/day) should be continued indefinitely unless it is not tolerated or an indication for anticoagulation becomes apparent.	IA
Clopidogrel should be prescribed if aspirin is contraindicated or not tolerated.	IA
Dual-anti-platelet therapy with aspirin and a P2Y12 inhibitor (clopidogrel or ticagrelor) should be prescribed for up to 12 months in patients with ACS regardless of whether coronary revascularization was performed. The use of prasugrel for up to 12 months should be confined to patients receiving PCI.	IA
Initiate and continue indefinitely the highest tolerated dose of HMG-CoA reductase inhibitors (statins) for a patient following hospitalization with ACS unless contraindicated or there is a history of intolerance.	IA
Initiate treatment with vasodilatory beta blockers in patients with a reduced LV systolic function (LV ejection fraction ≤40%) unless contraindicated.	IIA
Initiate and continue angiotensin converting enzyme (ACE) inhibitors (or angiotensin receptor blockers) in patients with evidence of heart failure, LV systolic dysfunction, diabetes, anterior myocardial infarction or co-existent hypertension.	IA
Attendance at cardiac rehabilitation or undertaking a structured secondary prevention service is recommended for all patients hospitalized with ACS.	IA

ACS, Acute coronary syndrome; *LV*, left ventricular; *MI*, myocardial infarction; *PCI*, percutaneous coronary intervention.

decision-maker is wise. PCI may inadvertently cause coronary artery perforation or dissection, radial or femoral entry site complications such as false aneurysm, and stent related complications such as early and delayed stent thrombosis.

Prognosis

The prognosis is dependent on myriad factors which include but are not limited to: age and comorbidities, social factors and ability to access medical care and follow up, socioeconomic status, extent of coronary vessel disease, the presence and extent of LV dysfunction, mechanical complications, arrhythmias or cardiac arrest and response to initial treatment.

Primary and secondary prevention

Through wide dissemination of the classic Framingham risk factors via various and multitude public health campaigns, patients are commonly aware of the life-style choices that increase their risk of IHD, irrespective of whether they ascribe to them. While overall cardiovascular risk assessment and counselling is most appropriately undertaken in primary care, a presentation with chest pain that ultimately leads to a benign diagnosis presents an opportunity to engage the patient to reflect on ways they might reduce their IHD risk profile.

Patients being discharged from the hospital with a diagnosis of ACS, should be prescribed, in the absence of contraindications: indefinite aspirin, a $P2Y_{12}$ inhibitor, an HMG-CoA reductase inhibitor (statin) in the highest tolerated dose, a vasodilatory beta-blocker if EF ≤40% and an ACE inhibitor or angiotensin receptor blocker if there is heart failure, LV systolic dysfunction, diabetes mellitus, anterior MI or hypertension. They should also be referred for cardiac rehabilitation (Table 5.2.5).

CONTROVERSIES

- The safety and efficiency considerations in the use of an ultra-short (1 hour or less) suspected ACS-AP
- The use of coronary artery CT and calcium scores in the chest pain workup and in primary prevention
- Defining a more prescriptive algorithm of not only which chest pain patient groups to investigate further as outpatients but also with which provocative tests
- Determining which patients will benefit from cardiac monitoring, both within the ED and in admitted patients as the demand for resources increases in our hospitals

5.3 Assessment and management of acute pulmonary oedema

David Lightfoot

ESSENTIALS

1 Severe acute pulmonary oedema (APO) is associated with high morbidity and mortality.

2 APO is a pathophysiological state characterized by a maldistribution of fluid; most patients do not have fluid overload.

3 Diagnosis relies on a thorough history, focused physical exam and investigations including ECG, lung ultrasound and chest x-ray.

4 Therapy is aimed at maintaining oxygenation and cardiac output and reversing the underlying pathophysiology. Reversible causes should be sought and corrected.

5 Hypotensive patients require ventilatory and inotropic support.

6 For most patients, the mainstays of therapy are oxygen; vasodilatation, usually with nitrates; and non-invasive ventilation (NIV).

7 NIV is safe and effective in APO. It has been shown to reduce rates of intubation, admission to an intensive care unit (ICU) and death.

Introduction

Acute pulmonary oedema (APO) occurs mainly in elderly patients; if severe, it is associated with a very poor long-term prognosis.[1] It is a pathophysiological state characterized by fluid-filled alveolar spaces, with resulting impaired alveolar gas exchange and reduced lung compliance. Acute dyspnoea, hypoxia and increased work of breathing are the resultant symptoms and signs. APO occurs when increased pulmonary capillary pressure, reduced plasma oncotic pressure or changes in pulmonary capillary permeability cause plasma to leave the capillaries and build up in the pulmonary interstitium. When this occurs at such a rate that lymphatic drainage from the lung cannot keep up, flooding of the alveoli results.

Aetiology and pathophysiology

The causes of APO can be divided into two categories: cardiogenic (the commonest cause in emergency department [ED] patients) and non-cardiogenic. In cardiogenic APO, an acute reduction in cardiac output (left atrial outflow obstruction or left ventricular [LV] dysfunction) associated with an increase in systemic vascular resistance (SVR) leads to back pressure on the pulmonary vasculature, with a resultant increased pulmonary capillary pressure. Once established, APO can lead to a downward spiral where decreasing oxygenation and increasing pulmonary vascular resistance (with its resultant increased right ventricular end-diastolic pressure) worsens LV dysfunction as well as pulmonary oedema.[2] In most cases the patient has a maldistribution of fluid rather than fluid overload. He or she may, in fact, have a whole-body fluid deficit. This understanding has led to a change in the management of this condition from the use of large doses of diuretics to a focus on vasodilators and NIV, which reduce SVR and improve cardiac output. Some of the causes of cardiogenic pulmonary oedema are listed in Box 5.3.1.

In non-cardiogenic APO, the mechanism is thought to be increased pulmonary vascular permeability brought about by an insult and leading to alveolar flooding. Injury to alveolar cells will also reduce their ability to clear this oedema fluid from the alveolar space (which may also play some role in cardiogenic APO). Some of the causes of non-cardiogenic pulmonary oedema are listed in Box 5.3.2.

Clinical assessment

History

As with all emergencies, clinical assessment and management should take place in parallel. There is usually a history of sudden-onset severe dyspnoea that may be associated with a feeling of drowning. A focused history concentrating on the recent occurrence of chest pain, palpitations, a past history of ischaemic heart disease, worsening congestive heart failure or another causative factor (see Boxes 5.3.1 and 5.3.2) is sought. Details of current medications and compliance are also important.

Box 5.3.1 Causes of cardiogenic pulmonary oedema

- Acute valvular dysfunction (e.g. rupture, endocarditis)
- Anaemia
- Arrhythmias (e.g. atrial fibrillation, ventricular tachycardia)
- Dietary (including salt), physical or emotional excess
- Fluid overload; may be iatrogenic
- Medication adverse effect
- Medication non-compliance
- Myocardial ischaemia/infarction
- Myocarditis
- Post-cardioversion
- Pulmonary embolus
- Severe hypertension
- Worsening congestive heart failure

Box 5.3.2 Causes of non-cardiogenic pulmonary oedema

- Airway obstruction
- Aspiration
- Asthma
- Disseminated intravascular coagulopathy (DIC)
- Eclampsia
- Head injury, intracerebral haemorrhage, hyperbaric oxygen treatment, inhalation injury
- Lung re-expansion (e.g. after treatment of a pneumothorax)
- Lung reperfusion
- Near drowning/cold water immersion
- Opiates and opiate antagonists (naloxone and naltrexone)
- Pancreatitis
- Pulmonary embolism (thrombus, fat, amniotic fluid, other)
- Rapid ascent to high altitude
- Renal/hepatic failure
- Self-contained underwater breathing apparatus (SCUBA) diving
- Sepsis
- Shock
- Toxins
- Trauma

Examination

Patients are usually pale or cyanosed, diaphoretic (sometimes profusely) and frightened. If hypoxic or hypercapnic, they may be confused. They strive to maintain an upright position at all costs and may be unable to sit still. They may cough up pink or white frothy sputum, adding to their feeling of drowning. They are almost always tachycardic. Their respiratory rate is high, with use of the accessory muscles of respiration, and their breathing is often noisy. They are hypoxic, with reduced oxygen saturations. Most patients are hypertensive or normotensive. Hypotension indicates cardiogenic shock and a very poor prognosis. Similarly, skin mottling or other signs of poor peripheral perfusion indicate worsening cardiac function and a poorer prognosis. There may be a raised jugular venous pressure (JVP), a third heart sound or gallop rhythm on cardiac auscultation and signs of right heart strain. (These features will not be present in cases of non-cardiogenic pulmonary oedema.) Signs of chronic heart failure should also be sought, as well as murmurs that may hint at the precipitant. The chest may be dull to percussion, and fine crepitations, which are often extensive, will be heard on auscultation. Initially these crepitations may be limited to the lung bases, but they can also be heard higher in the chest (right to the apices) as the oedema worsens. Importantly, there may be other adventitial lung sounds, including wheeze or 'cardiac asthma'.

Clinical investigations

Electrocardiogram

An ECG is required, looking for acute ischaemia. Where there is evidence of ST-elevation myocardial infarction (STEMI), it should immediately be treated with appropriate reperfusion strategies. Similarly, precipitating arrhythmias should be sought and treated.

Imaging

A chest x-ray will show cardiac size (usually enlarged) and help to differentiate APO from airways disease. The chest x-ray findings of pulmonary oedema reflect the changes in fluid distribution. Initially, blood is diverted to the upper-lobe veins, which become more prominent than normal. As the oedema worsens, interstitial oedema results in basilar and hilar infiltrates, which are hazy and more confluent than patchy, and interlobular oedema is seen as Kerley B lines (thin 1- to 2-cm-long lines in the lung peripheries perpendicular to the pleural surfaces). There is loss of vascular delineation. In severe APO, widespread changes representing alveolar oedema appear. There may also be pleural effusions if the interstitial pressure exceeds the pleural pressure. Changes associated with the underlying cause can also be seen; for example, cardiomegaly and pleural effusions in cardiogenic APO. It is important to note that the x-ray changes may not be bilateral and may mimic consolidation from other causes, such as pneumonia.

Ultrasound (US) in the ED can be a useful adjunct to physical examination.[3–5] It has high sensitivity and specificity in diagnosing APO.[5] During US of the chest, homogeneous vertical comet tails or B lines, which originate from the pleural line and continue to the bottom of the screen, characterize pulmonary oedema. These are US resonance artefacts generated by oedematous interlobular septa and are initially seen in the lung bases; however, as oedema worsens, they extend upwards to the apices. US can be used to help differentiate the cause of a patient's dyspnoea. In acute lung injury or acute respiratory distress syndrome (ARDS), the B lines are non-homogeneous with areas of sparing. In patients with airways disease, horizontal A lines may be seen, with an absence of B lines. The B lines resolve as pulmonary oedema improves and may be used to follow response to therapy. Findings of jugular venous distension on US exam are also consistent with APO. US of the heart (echocardiography) may also be useful in determining the cause of the APO (e.g. wall motion abnormalities in acute myocardial ischaemia/infarction, right ventricular dilatation/strain in pulmonary embolus and acute valvular dysfunction).

Blood tests

Blood tests include the following:

Haemoglobin—anaemia as a cause or differential.

Electrolytes—may be deranged due to diuretics, angiotensin-converting enzyme inhibitors (ACEIs) and other medications or in renal failure; deranged electrolytes may be the underlying cause of arrhythmias.

Cardiac biomarkers and/or other cause specific bloods as indicated—for example, lipase when pancreatitis is suspected as a cause.

Blood gases—looking for acid-base and ventilation abnormalities, which may help guide management.

Natriuretic peptides—brain or B-type natriuretic peptide (BNP) or N-terminal pro-brain natriuretic peptide (NT-proBNP) levels, which may be useful in distinguishing APO from other causes of acute dyspnoea.[6]

BNP is the active part of a hormone (pro-BNP) secreted by ventricular myocytes in response to stretch. Its physiological function is to oppose the effects of the activated renin-angiotensin-aldosterone system. NT-proBNP is the inactive part cleaved from pro-BNP and has a longer plasma half-life than BNP. Its levels are also age dependent, meaning that 'rule in' cut points must be age-qualified. Plasma levels rise during acute heart failure and APO. In the setting of acute dyspnoea, levels of BNP below 100 pg/mL (or NT-proBNP <300 pg/mL) make a diagnosis of acute heart failure and APO less likely. Conversely, when the BNP levels are greater than 500 pg/mL (or NT-proBNP >450 pg/mL [age<50], >900 pg/mL [age 50–75] and >1800 pg/mL [age >75]), acute heart failure is more likely. Unfortunately intermediate levels are difficult to interpret and other diagnoses should be sought prior to making a diagnosis of APO. That said, it has been estimated that on combining the intermediate levels of natriuretic peptide (NP) markers with historical and exam findings consistent with APO, the diagnostic probability of heart failure will be around 75%. Diagnostic accuracy may also be improved by combining US with NP levels[4] or using predictive modelling.[7] False-positive levels may result from such conditions as pulmonary embolism, sepsis and renal failure as well as advancing age. Positive levels may also occur in patients with chronic heart failure but with a different cause of their acute dyspnoea. In addition, because of delayed secretion, false-negative results may occur in the early phases of APO. False-negative results may also be found in obese patients and those with valvular or pericardial heart disease. These aspects, as well as the relatively high cost of the test, have limited its use in EDs in some countries. Currently the main utility of these tests in the Australasian context involves serial levels as a guide to therapeutic response, often in patients with chronic heart failure. There is potential for using changes in NP levels within an ED presentation to guide disposition decisions (including discharge of patients with non-APO heart failure), but this has not yet been studied prospectively.

Oximetry

Oximetry (in some cases supplemented with blood gases) will reflect severity and help monitor the patient's response to therapy. Rarely, in more severe cases, invasive monitoring may be useful.

Treatment

In all patients with APO, management strategies should provide supportive care to maximize cardiac output and oxygenation, followed by treatment of the underlying cause.

Treatment of the patient with non-cardiogenic pulmonary oedema consists of removing the patient from the causative environment, supportive therapies aimed at maintaining oxygenation—including non-invasive and invasive ventilation in severe cases—and treating the underlying cause. These patients have lung injury; therefore low-volume, low-pressure,

lung-protective ventilation regimens should be followed.

Most patients with APO in the ED have a cardiogenic aetiology. Therapy varies according to haemodynamic parameters.

Normotensive or hypertensive patients

The foundations of treatment are reduction of preload and afterload with nitrates and optimization of oxygenation, often with non-invasive ventilatory support. The patient should be managed sitting up. This posture reduces ventilation-perfusion mismatch and helps with the work of breathing.

Pharmacotherapy

Nitrates

Nitrates are the mainstay of the pharmacological therapy of APO. They act to increase cyclic guanosine monophosphate (cGMP) in vascular smooth muscle cells, leading to relaxation. In lower doses, these agents predominantly cause venodilatation and preload reduction. They may also modulate the effects of endogenous catecholamines released during the APO episode. At higher doses, the arterioles are also affected, leading to the reduction of afterload and blood pressure. In addition, coronary artery dilation leads to increased coronary blood flow. The end result is that myocardial work and oxygen demands are reduced whilst oxygen delivery is improved. By reversing the pathophysiological processes that underlie it, nitrates are therefore the ideal agents for treating APO. Their use is limited by their hypotensive effect and by the tachyphylaxis that occurs with prolonged use. Therefore they should be titrated against the patient's haemodynamics, and they require careful monitoring. Nitrates are contraindicated in those patients who have taken sildenafil or similar agents within the previous 24 hours owing to profound vasodilatation and hypotension. They should also be used with extreme caution in patients with fixed cardiac output (e.g. those with severe aortic stenosis or hypertrophic obstructive cardiomyopathy). Although nitrates may also be used topically or sublingually, the intravenous route is preferred in the patient with APO, as dosing can be titrated to effect and therapy ceased promptly if the patient becomes hypotensive. Topical or sublingual therapy is often used as a temporizing measure until intravenous access can be secured. The peak effect of intravenous nitrates occurs after 5 minutes.

The usual dosing regimen is to begin the infusion at 5 to 10 μg/min and rapidly increase the rate by 10 to 20 μg/min every 3 minutes, titrated to clinical effect and limited by falling blood pressure. If a patient has not responded to intravenous glyceryl trinitrate (GTN) in a dose of 400 μg/min, he or she is unlikely to respond to further dose increases. Because higher doses of nitrates lead to greater afterload reduction and coronary blood flows, there is some interest in investigating higher than conventional dosing regimens, with some authorities recommending higher starting doses. Some studies[8,9] have looked at higher-dose bolus intravenous nitrates and have shown good efficacy and safety, with improved results over low-dose nitrates, furosemide and NIV. These studies, however, have limitations of small patient numbers, retrospectivity or non-randomization and these dosing regimens are not currently widely used. A recent observational cohort study[10] examined the use of intermittent higher-dose bolus nitrates versus infusion versus a combination. They found an association between the bolus nitrates and lower ICU admissions and shorter lengths of hospitalization without increased hypotension or other adverse events. This study is limited due to its retrospective and observational format, and it is recommended that these findings be tested in a randomized trial prior to widespread adoption of its recommendations.

Sodium nitroprusside

Sodium nitroprusside is a potent vasodilator with rapid action on both the venous and arterial systems. It has beneficial actions in APO by reducing both preload and afterload. It can lead to rapid improvements in haemodynamic parameters and cardiac output without the renal complications of some other agents. Due to its swift and sometimes profound hypotensive action, invasive blood pressure monitoring should be used. Rebound vasoconstriction can occur if the drug is stopped abruptly, so it should be weaned slowly. In addition, longer duration of use (>72 hours) has been associated with cyanide toxicity, especially in patients with renal or hepatic disease, in whom it should be used with extreme caution. Nitroprusside is a valid vasodilator alternative to nitrates and can be used when nitrates are contraindicated in non-hypotensive patients.

Angiotensin-converting enzyme inhibitors

ACEIs have a clear role in the treatment of chronic heart failure. Their use in APO is more controversial. ACEIs effectively reduce afterload via blockade of the renin-angiotensin-aldosterone system and, in cardiogenic pulmonary oedema, can also improve pulmonary capillary wedge pressure and cardiac output.

In a small prospective study,[11] when added to standard therapy, ACEIs produced a more rapid improvement in haemodynamic parameters and symptoms than placebo. Their use in pulmonary oedema was also associated with reduced intubation rates and ICU length of stay. Unfortunately there are no large randomized trials looking at the use of ACEIs in APO patients.

ACEIs can also produce prolonged first-dose hypotension and can worsen renal function, especially when used in combination with diuretics. Therefore these agents should be used with caution, especially in patients who have renal impairment or are hypotensive. At present it is not recommended that they be initiated as first-line therapy in APO patients, but they should be commenced with appropriate monitoring of blood pressure and renal function once the patient has stabilized.

A large multicentre international randomized trial examining the use of ACEIs or angiotensin receptor blockers (ARBs) in addition to vasodilation with nitrates and hydralazine to achieve maximal vasodilation (systolic blood pressure [SBP] 90 to 110 mm Hg) in APO patients is currently under way. The Goal-directed Afterload Reduction in Acute Congestive Cardiac Decompensation Study (GALACTIC) is due to be completed in late 2019 and will help define the role of these agents in the treatment of APO.

Furosemide

Furosemide was the first-line treatment for patients with APO for many years. Its usefulness is due to venodilatatory properties that lead to reduced preload as well as its diuretic properties. The venodilatation occurs about 15 minutes after intravenous dosing, well before diuresis begins. Furosemide can, however, lead to increased peripheral vascular resistance via reflex sympathetic and renin-angiotensin system actions. As mentioned earlier, fluid overload is not usually a contributing factor in acute heart failure; therefore diuresis is not a necessary end point of therapy. The obvious exception is in patients with APO of iatrogenic origin after intravenous fluid therapy.

Although it is an established therapy, there are no controlled studies that show benefit from the use of furosemide in APO. A 2017 observational cohort study[12] did find an association between early furosemide infusion (<60 minutes from ED arrival) and decreased in-hospital mortality when compared with later dosing. However, the non-randomized observational nature and heterogeneous cohort groups preclude using this study to recommend dose timing in APO. In addition, at least two studies[8] have shown that nitrates are more beneficial than furosemide in relation to haemodynamic and clinical outcomes. High-dose furosemide has also been associated with worsening renal function, more frequent ICU admissions and poor outcomes in patients with acute heart failure. Nevertheless a single dose of furosemide at 1 to 1.5 mg/kg is still commonly recommended in the initial management of this illness.

Morphine

In the past, morphine was one of the major drugs used in the treatment of APO. It can cause vasodilatation and decreased sympathetic activation. However, it has significant adverse effects, including respiratory and central nervous system depression, hypotension and decreased cardiac output, as well as vomiting with risk of aspiration. A small prospective study and a number of large retrospective studies have shown an association between morphine use in APO patients and increased rates of intubation, ICU admission and death.[13] As there is no evidence showing benefit from the use of morphine in the treatment of APO and there is an increasing body of literature associating it with harm, morphine is not recommended in the treatment of patients with APO.[14]

Aspirin

The most common cause of APO in patients presenting to ED is myocardial ischaemia/infarction. Aspirin has been shown to reduce the risk of death and myocardial infarction in patients with myocardial ischaemia. Although it does not directly treat APO, aspirin should be given when the cause is thought to be myocardial ischaemia.

Ventilatory support

Patients with APO should be given high-flow supplemental oxygen using an oxygen delivery system that can meet their minute volume needs, such as a Venturi system. They are hypoxic and, if uncorrected, this condition will worsen APO through direct pulmonary vascular constriction and reduced myocardial oxygen delivery. Prolonged supranormal oxygenation, however, should be avoided, especially in those patients with underlying airways or other chronic lung disease. In these patients, oxygen should be used judiciously and weaned as soon as the patient is improving, aiming for low normal oxygen saturations.

Patients with an impaired level of consciousness, cardiogenic shock, respiratory exhaustion, agonal respirations or respiratory arrest require endotracheal intubation and mechanical ventilatory support. This should be accomplished using rapid-sequence intubation. Delayed-sequence intubation should be considered if adequate pre-oxygenation cannot be obtained with conventional methods in the spontaneously breathing patient.

The introduction of NIV using continuous positive airway pressure (CPAP) or bi-level positive airway pressure (BiPAP) has allowed many patients to avoid endotracheal intubation. Initial CPAP pressures of 5 to 10 cm H_2O are used and then titrated to effect. When using BiPAP, expiratory pressures are usually begun at 3 to 5 cm H_2O, with the inspiratory pressure 5 to 8 cm higher. The benefits of these therapies are due to a number of effects. Oxygen concentration can be accurately controlled and higher percentages can be delivered than via a face mask. By using CPAP (and expiratory positive airway pressure (EPAP) when using BiPAP), functional capacity is increased by alveolar recruitment, with a resultant increase in gas exchange area, improved pulmonary compliance and reduced work of breathing. The addition of inspiratory pressure support with BiPAP further reduces the work of breathing and may be more useful in hypercapnic or tiring patients. Cardiovascular effects result from positive intrathoracic pressures, with reduced venous return and reduced LV transmural pressures. These preload and afterload effects improve cardiac output without increasing myocardial oxygen demand. In general these therapies have few complications and are considered safe. Complications that have been reported include nasal bridge abrasions, patient intolerance, gastric distension and aspiration, pneumothorax and air embolism. The last three potentially serious adverse events are extremely rare and appear to occur in selected populations with other underlying disease processes (e.g. pneumothorax in patients with *Pneumocystis jirovecii* pneumonia).

A number of studies have compared CPAP and/or BiPAP, both with each other and with conventional therapy in APO. Most studies have been small and a number of meta-analyses have analysed their combined data.[15–17] When CPAP was compared with standard medical therapy there were significant improvements in oxygenation, ventilation, respiratory rate and distress and heart rates without significant adverse events. There were also significantly reduced rates of endotracheal intubation, ICU length of stay, and more importantly, reduced mortality. There is also a clear reduction in the rate of intubation and ICU admission when using BiPAP compared with standard therapy. There also appears to be a trend towards a mortality benefit, although, in most analyses, it does not reach significance. BiPAP is associated with a more rapid reduction in symptoms than CPAP and may be particularly useful in patients with coexisting airways disease and acute on chronic respiratory acidosis. In the earliest trials of BiPAP in APO, there appeared to be an unexplained increase in the rate of myocardial infarction among patients in the BiPAP groups. These trials involved very small numbers and had methodological issues. Subsequent trials and meta-analyses have not shown an increase in myocardial infarct rates in the BiPAP groups.

When CPAP and BiPAP were compared, there was no significant difference in intubation, myocardial infarction or death rates. BiPAP is the recommended modality in patients with underlying airways disease or significant acute on chronic respiratory acidosis. Otherwise the treating clinicians should choose the NIV modality with which they are most familiar and that they have the greatest comfort in using.

A relatively new oxygen delivery method is via high-flow nasal cannula (HFNC) devices that deliver heated and humidified gases at up to 100% oxygen. In addition to titratable oxygen delivery, the deliverable high gas flows splint the upper airways and have some CPAP effect. There is some limited literature comparing HFNC with NIV in patients with respiratory failure, with no evidence that it improves outcomes such as intubation or mortality.[18,19] The only controlled trial in ED patients with APO[20] found no difference in patient-orientated outcomes (e.g. intubation and ICU rates, admission rates and mortality) between HFNC and conventional NIV. At present it can be recommended only in those patients intolerant of other NIV modalities or where NIV face-mask fitting is a problem; for example, seal issues from abnormal anatomy or beards.

New pharmacological agents

A number of novel agents have been investigated in patients with acute decompensated heart failure.[21–29] These include *Levosimendan*, a calcium sensitizer that causes increased cardiac contractility and vasodilatation; *Nesiritide*, a recombinant BNP that acts to cause arterial (including coronary) and venous vasodilation and to suppress the renin-angiotensin-aldosterone and sympathetic nervous systems; *Nicorandil*, a hybrid vasodilator that causes combined preload and afterload reduction via activated K_{ATP} channels and a nitrate-like effect; *Rolofylline,* an adenosine A1 receptor antagonist that can improve diuresis; *Serelaxin*, a synthetic hormone that produces systemic and renal vasodilation and increased vascular compliance; *Tezosentan*, an endothelin antagonist that improves cardiac output and decreases SVR; *Tolvaptan*, a diuretic vasopressin antagonist; and *Ularitide,* a NP with both diuretic and vasodilator properties. In general these agents have not demonstrated usefulness in terms of symptom control, hospitalization or decreased mortality as compared with standard care, whilst adverse events such as hypotension, electrolyte abnormalities and arrhythmias also limit their usefulness.[30] None of the new agents have specifically been studied in APO patients; therefore they are not currently recommended for the treatment of APO in the ED.

Hypotensive patients

In general, patients with APO who are hypotensive are at the most severe end of the disease spectrum and have cardiogenic shock. They require both ventilatory and haemodynamic

support. Endotracheal intubation using rapid-sequence intubation (or delayed-sequence intubation if hypoxia cannot be improved with conventional pre-oxygenation techniques), since ventilation maximizes oxygen delivery and minimizes oxygen utilization. A positive end-expiratory pressure of 5 to 10 cm H_2O may be useful. These patients may have a fluid deficit; therefore cautious fluid bolus resuscitation should be titrated against haemodynamic parameters and clinical effect. Inotropic support is also required, with epinephrine (adrenaline) being the first-line agent. Cardiac output may be improved with dobutamine, but it can lead to hypotension, requiring the concomitant use of vasopressors. These drugs will increase cardiac output but do so at the expense of increased myocardial oxygen demand and increased arrhythmogenicity. Invasive monitoring will be required in this group, as it helps guide fluid and inotropic management. Some time may be bought by the use of invasive therapeutic manoeuvres, such as an intra-aortic balloon pump. This device reduces myocardial oxygen demand via afterload reduction and increases coronary flow through diastolic augmentation. Reversible causes should be treated – for example, reperfusion for acute myocardial infarction or surgical correction of acute valvular dysfunction.

CONTROVERSIES

- The use of natriuretic peptide levels as diagnostic aids
- The potential use of changes in natriuretic peptide levels as a guide to patient disposition
- The use of standard-dose infusions versus high-dose bolus nitrates
- The optimal use time of infusion and dosage of furosemide
- The role of new vasodilators and diuretic agents

5.4 Arrhythmias

Marcus Ong Eng Hock • Desmond Mao • Gayathri Devi Nadarajan

ESSENTIALS

1 **Cardiac arrhythmias require urgent attention, as some are life-threatening and can lead to sudden death.**

2 **The most important initial evaluation is for haemodynamic stability. Patients who are hemodynamically stable should have a 12-lead electrocardiogram (ECG), whereas unstable patients require immediate intervention.**

3 **Bradyarrhythmias should always be evaluated in the light of the patient's presenting symptoms as well as the ECG abnormality.**

4 **Patients with wide complex tachycardia should be considered to have ventricular tachycardia unless proved otherwise.**

Introduction

Arrhythmia is the term used to describe an abnormal heart rhythm. The most common arrhythmias are atrial or ventricular ectopic beats. Tachycardia occurs when the heart rate is greater than 100 beats per minute (bpm), and bradycardia is defined as a rate below 60 bpm. The management of cardiac arrhythmias depends on the presentation of the patient, his or her haemodynamic stability, underlying heart disease (if any) and the exact type of arrhythmia. Patients with asymptomatic stable arrhythmias in the absence of underlying heart disease usually do not require emergency treatment. However, patients with symptomatic arrhythmias, especially when associated with underlying heart disease, require more urgent therapy. The key objective is restoration of adequate cardiac output to maintain cerebral perfusion as well as a stable rhythm using interventions least likely to cause harm.

Pathophysiology and pathogenesis

An understanding of cardiac arrhythmia requires knowledge of the normal conduction system (Fig. 5.4.1). In the normal heart, electrical impulses start from the sinoatrial (SA) node and conduct via the atria to the atrioventricular (AV) node. The electrical impulses then conduct down the bundle of His to the right and left bundle branches and subsequently via the Purkinje fibres to the ventricular myocardium.

Different mechanisms—such as re-entry, enhanced automaticity and triggered activity—can result in arrhythmias. Generally arrhythmias are thought of as abnormal impulse generation or abnormal impulse conduction. Abnormal impulse generation in the SA node, as in sick sinus syndrome, can result in failure of impulse formation. Abnormal impulse conduction in the AV node can result in failure of electrical conduction from the atrium to the ventricles, resulting in various degrees of AV block. Ectopic impulses in the atria result in atrial ectopics or atrial tachycardia. Accessory pathways between the atrium and ventricle can result in supraventricular tachycardia (SVT). Abnormalities in ventricular conduction can result in bundle branch blocks or a variety of intraventricular conduction abnormalities. The most dangerous arrhythmias arise from the ventricles, as these, especially in the presence of underlying structural heart disease, may be associated with sudden death.

Re-entry

Re-entry occurs when a closed loop of conducting tissue transmits an electrical impulse around the loop and stimulates atrial or ventricular electrical activity with each pass around the circuit. This pathway can either be an anatomical abnormality such as an accessory pathway or functional abnormality, as in a diseased myocardium caused by ischemia.

Enhanced or abnormal automaticity

Automaticity refers to the generation of an action potential by either the SA node or by abnormal tissue within the myocardium. Automaticity can be enhanced, as during exercise or by drugs. Automaticity can also be abnormal, for example, when action potentials are initiated by tissue other than the SA node, as in ventricular arrhythmias.

Triggered activity

Triggered activity is due to after-depolarizations, which are depolarizations of the myocardium before full repolarization occurs.

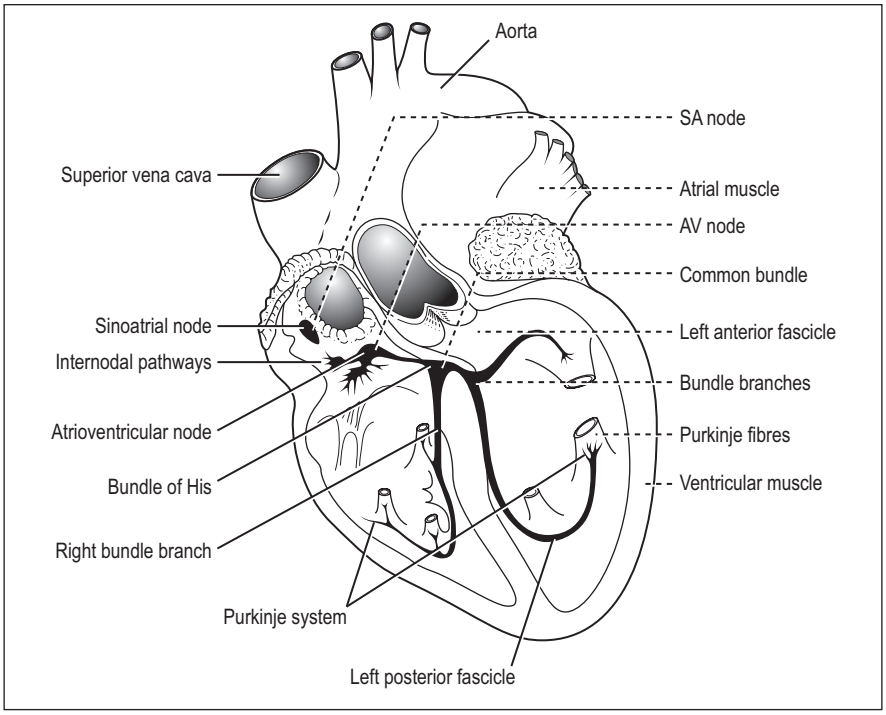

FIG. 5.4.1 Conducting system of the heart. *AV*, Atrioventricular; *SA*, sinoatrial.

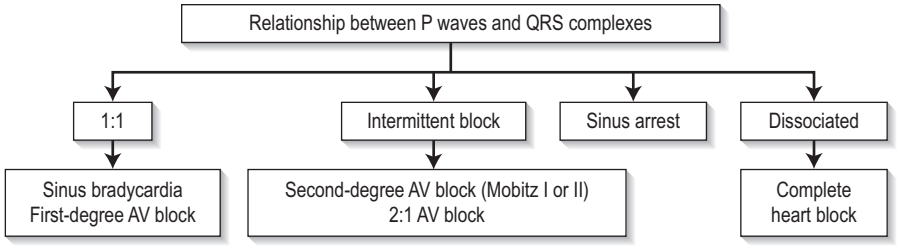

FIG. 5.4.2 Algorithm for electrocardiographic diagnosis of bradyarrhythmias. *AV*, Atrioventricular.

After-depolarizations can be early, as in the case of torsades de pointes VT associated with a prolonged QT, or they can be late, as in the case of catecholaminergic polymorphic VT and idiopathic outflow tract VT.

Principles of assessment and management

Patients with arrhythmias may present with symptoms due to the arrhythmia, such as palpitations or syncope, or they may be asymptomatic and have the arrhythmia noticed during routine examination or investigations. All patients should initially be managed in an area where cardiac and other physiological monitoring is available.

The management of arrhythmias should begin with attention to the airway, breathing and circulation. Management of cardiac arrest is discussed in Section 1. For stable patients, the usual process of history, physical examination and investigations (particularly ECG), is appropriate. Family history of sudden cardiac death should raise the suspicion of ventricular arrhythmia. For unstable patients, urgent intervention is required, with restoration of a stable cardiac rhythm and cerebral perfusion being the priorities. Unstable patients are those with hypotension, dyspnea, chest pain or a decreased level of consciousness. Clinical information—for example, that from a patient with a history of renal failure or heart failure taking spironolactone—should raise the suspicion that a wide complex tachycardia is due to hyperkalemia.

Intravenous access should be obtained and blood drawn for investigations such as full blood counts, electrolytes and cardiac markers (if indicated). A 12-lead ECG is essential, and a chest x-ray may be helpful. Other specific investigations—such as serum digoxin level, thyroid function tests and theophylline levels—may sometimes be indicated, depending on the arrhythmia and the clinical context.

Bradyarrhythmias

Bradycardia is defined as a heart rate of less than 60 bpm. It is important to take into account the patient's underlying clinical state when bradyarrhythmias are being treated. ECG diagnosis of bradyarrhythmias can be simplified by the algorithm in Fig. 5.4.2. Note that denervated transplanted hearts will not respond to atropine; thus, if treatment is required, pacing, catecholamine infusion or both should be used.

Sinus bradycardia

Physiological sinus bradycardia may be associated with good physical conditioning (e.g. marathon runners), drug effects (e.g. β-blockers, calcium antagonists) and vagal stimulation (e.g. vomiting). More serious causes include acute inferior myocardial infarction, raised intracranial pressure, hypothermia and hypothyroidism.

Clinical features

There are often no signs or symptoms. Symptoms may be related to the underlying cause.

Clinical investigations

ECG features are

- Atrial rate equal to ventricular rate
- Normal PR interval
- Normal P-wave morphology

Treatment

Treat the underlying cause. If there is evidence of hypoperfusion, intravenous atropine 0.5 mg may be used while the cause is being investigated. Physiological bradycardia does not require treatment. Disposition will depend on the cause.

Sick sinus syndrome (bradycardia-tachycardia syndrome)

This is most commonly found in elderly patients and results from fibrosis around the sinus node. It can also occur with congenital heart disease, rheumatic disorders, myocarditis, pericarditis, rheumatological disease, metastatic tumours, surgical damage, cardiomyopathies and ischaemic heart disease. It is a heterogeneous disorder that includes a wide variety of intermittent SVTs and bradyarrhythmias. Pathophysiologically, there is sinus bradycardia with intermittent failure of sinus node function, with the prolonged pause interrupted by a temporary escape rhythm. Drugs such as β-blockers, digoxin and antiarrhythmics—as well as conditions such as abdominal pain, thyrotoxicosis and hyperkalemia–can exacerbate the condition.

Clinical features

Typical features are syncope, light-headedness, palpitations, dyspnoea, chest pain, collapse and cerebrovascular accidents.

Clinical investigations

ECG features are

- Sinus bradycardia
- Intermittent cessation of P-wave activity
- Long pauses interrupted by escape rhythms
- Resumption of sinus node activity

Treatment

Unstable patients should be managed with intravenous atropine 0.5 mg IV as a bridge to pacing. If not effective, then consider adrenaline infusion (epinephrine) (2 to 10 μg/min) or dopamine (2 to 10 μg/kg/min) infusion if pacing is delayed. Transcutaneous pacing should be required if drugs are ineffective. Drug treatment for tachyarrhythmia risks aggravating pre-existing AV block or sinus arrest and should be avoided until pacemaker insertion. These patients eventually require a permanent pacemaker.

Heart block

First-degree atrioventricular block

In first-degree AV block, conduction of the atrial impulse to the ventricle is delayed. A P wave precedes each QRS complex, but the PR interval is more than 0.2 seconds. Causes include drug effects, vagal stimulation, inferior myocardial infarction and high vagal tone (especially in young patients). Rarely, it may be a sign of myocarditis, digoxin toxicity, idiopathic fibrosis or underlying structural abnormalities of the AV node.

There are no specific clinical features.

ECG features (Fig. 5.4.3) are

- P wave always followed by a QRS
- Constant PR interval but greater than 200 ms (five small squares on the ECG recorded at 25 mm/s)

Asymptomatic patients require no specific treatment, and first-degree AV block is not itself an indication for hospital admission.

Second-degree atrioventricular block: Mobitz type I (Wenckebach)

In Mobitz type I AV block, conduction of the atrial impulses to the ventricles is intermittently blocked due to impaired conduction in the AV node; therefore the atrial rate is greater than the ventricular rate. There is a progressive increase in the PR interval until a dropped QRS complex occurs. After the dropped QRS, AV conduction recovers, resulting in a normal PR interval; then the progressive increase in PR interval starts again. Anatomically, this block is above the bundle of His in the AV node.

Causes include inferior myocardial infarction, AV nodal blocking medications and high vagal tone. In normal subjects and athletes, the condition is nearly always benign. In patients with underlying heart disease, Mobitz type 1 AV block may progress to complete heart block.

There are no specific clinical features.

ECG features (Fig. 5.4.4) are

- Progressive increase in PR intervals until a dropped QRS complex occurs
- Grouped beating
- Shorter first PR after dropped QRS

No treatment is required for stable patients. Atropine, dopamine/adrenaline infusion or cardiac pacing may be indicated in the haemodynamically unstable patient.

Second-degree Mobitz type II atrioventricular block

Mobitz type II AV block is due to intermittent failure of conduction of atrial impulses to the ventricles. The PR interval remains constant, but there is regular intermittent failure of P-wave conduction. This is usually due to impaired conduction in the bundle of His or bundle branches (i.e. it is infranodal). Advanced second-degree block is the block of two or more consecutive P waves. This condition is rarely seen in patients without underlying heart disease. It may be seen with acute coronary syndrome involving the left coronary artery or, less commonly, idiopathic fibrosis of the bundle branches.

Most patients have some degree of symptoms. Mobitz type II AV block is more likely to be associated with stroke, Stokes-Adams attacks (syncope), a slow ventricular rate and sudden death.

ECG features (Fig. 5.4.5) are

- Atrial rate greater than ventricular rate.
- Regular atrial rhythm (P waves plot through).
- Some P waves not followed by a QRS (more P waves than QRSs).
- PR interval usually prolonged, but constant for each conducted QRS.
- QRS complexes are dropped periodically. They may be narrow or widened.

If the patient is haemodynamically unstable, give intravenous atropine 0.5 mg IV If not effective, consider adrenaline (2 to 10 μg/min) or dopamine (2 to 10 μg/kg/min) infusion. Occasionally pacing may be needed. Patients with this condition should be admitted, as it can deteriorate to complete heart block.

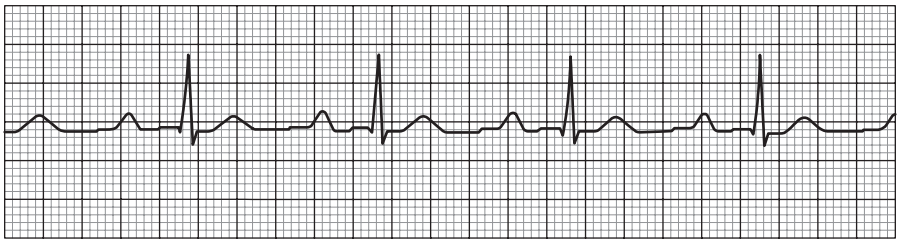

FIG. 5.4.3 Rhythm strip of first-degree atrioventricular block.

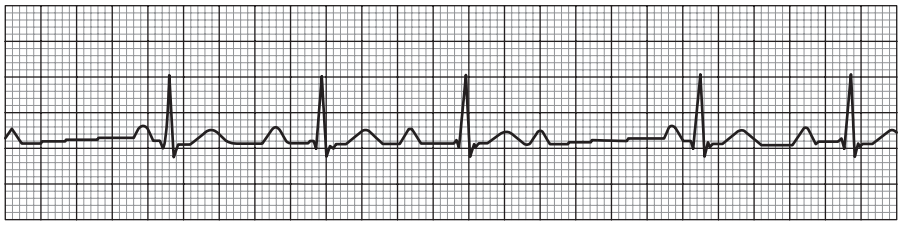

FIG. 5.4.4 Rhythm strip of second-degree atrioventricular block, Mobitz I.

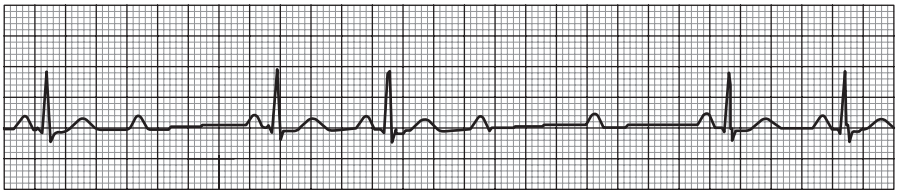

FIG. 5.4.5 Rhythm strip of second-degree atrioventricular block, Mobitz II.

Third-degree (complete) atrioventricular block

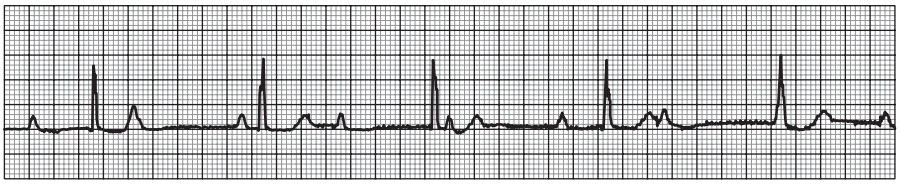
In third-degree or complete AV block, conduction of atrial impulses to the ventricles is completely blocked. Subsidiary pacemakers arise. If they are within the bundle of His, QRS complexes are narrow (Fig. 5.4.6). In contrast, if the block is infranodal, subsidiary pacemakers usually arise in the left or right bundle branches and the QRS complexes are wide (Fig. 5.4.7). The commonest cause of complete heart block is myocardial fibrosis. It is also seen in up to 8% of inferior myocardial infarctions, where it is often transient. Complete heart block is also associated with sick sinus syndrome, Mobitz II block and transient second-degree block with new bundle branch or fascicular block.

Nearly all patients with third-degree AV block will present with some degree of symptoms, and syncope or near syncope is common. Clinically, cannon 'a' waves may be seen in the neck veins and the first heart sound may vary in loudness.

ECG features are

- Complete dissociation of P waves and QRS complexes.
- Ventricular escape pacemaker is at 20 to 50 bpm.
- A block at the bundle of His is typically associated with a narrow QRS complex while an infrahisian block has a wide QRS complex.

Haemodynamically compromised patients should have measures taken to increase ventricular rate to a level that results in adequate perfusion. Judicious use of atropine 0.5 mg IV may be helpful. If this is unsuccessful, dopamine or adrenaline infusions, titrated to effect, may be effective. In ischaemic tissue, adrenaline is preferred, as coronary perfusion is better maintained. External pacing may be required if these measures are ineffective. Admission is required and permanent pacing is often necessary.



FIG, 5.4.6 Rhythm strip of narrow complex third-degree heart block.

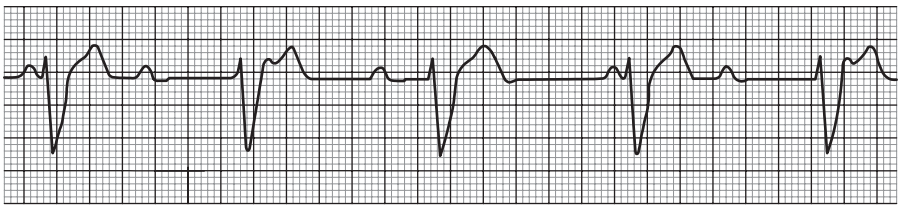


FIG. 5.4.7 Rhythm strip of third-degree heart block.

Never treat third-degree heart block with ventricular escape beats using lignocaine or any agent that suppresses ventricular escape rhythms, as this will suppress the already slow heart rate, resulting in reduced cardiac output.

Tachyarrhythmias

There is a wide range of tachyarrhythmias. Immediate diagnosis may be considered on the basis of the width of the QRS complex and the regularity of the rhythm (Fig. 5.4.8).

Broad complex tachycardias 7

The differential diagnosis of a regular broad complex tachycardia includes VT and SVT with aberrant conduction. Considerable research has been undertaken in an attempt to define ECG criteria that can reliably distinguish SVT from VT. There are various criteria (e.g. Wellens, Verecki, Griffith). Although relatively high sensitivities for some criteria have been reported, the high prevalence of VT in ED patients with broad complex tachycardia (approximately 80% in some studies) lowers the predictive value of those criteria. It is usually safest to treat a broad complex tachycardia as VT unless there is very strong evidence to the contrary. In the older patient with underlying ischaemic heart disease, syncope and hypotension, VT would be the most likely diagnosis.

Ventricular tachycardias 10

The management of ventricular arrhythmia depends on the correct identification of the rhythm, assessment of the risk-benefit ratio of antiarrhythmic drug therapy and an awareness of non-pharmacological modes of treatment. The presence or absence of heart disease and left ventricular function (ejection fraction) also influence the management approach. Risk

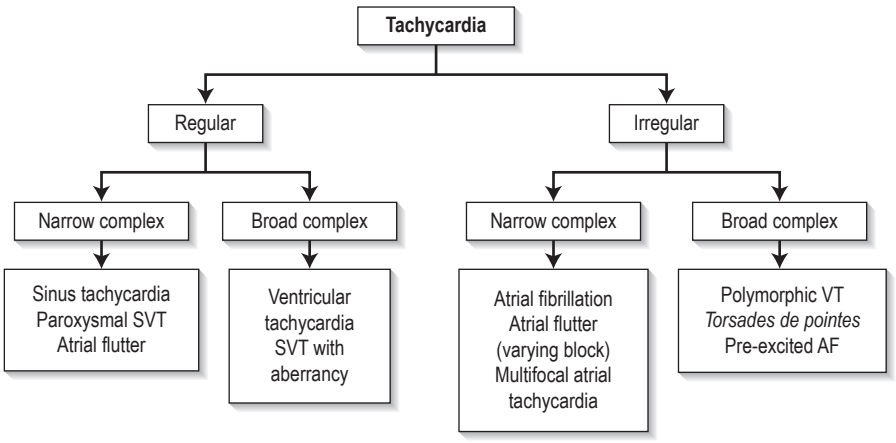

FIG. 5.4.8 Approach to tachyarrhythmias. *AF*, Atrial fibrillation; *SVT*, supraventricular tachycardia; *VT*, ventricular tachycardia.

increases with the severity of structural heart disease and left ventricular dysfunction. However, in the unstable patient, the key priority is to perform synchronized cardioversion to restore a perfusing rhythm. Ventricular arrhythmia with hemodynamic instability and syncope can lead to death if untreated; the shorter the time to synchronized cardioversion, the better the chances of survival.

Mono-morphic ventricular tachycardia Sustained VT is defined as a succession of ventricular impulses at a rate greater than 100 per minute and lasting more than 30 seconds or resulting in haemodynamic compromise. If the patient is haemodynamically stable, a 12-lead ECG should be recorded to characterize morphology.

Patients may be asymptomatic or complain of palpitations, dizziness or chest pain. Cannon 'a' waves may be seen in the neck veins. The patient may lose consciousness.

ECG features (Figs. 5.4.9 and 5.4.10) are

- AV dissociation.
- Fusion beats or capture beats
- Wide QRS complexes greater than 140 ms
- Rate greater than 100 bpm: commonly 150 to 200 bpm
- Rhythm regular, although there is some beat-to-beat variability
- Constant QRS axis, often with marked left axis deviation or northwest axis
- Deep S wave with r/S ratio less than 1 in right bundle branch block (RBBB) morphology VT

AV dissociation, captured beats or fusion beats, if present, are pathognomonic of VT. However, they are rarely seen because the rate of VT must be slow, usually less than120 bpm, for it to be easily visible.

Treatment 1

VT should be managed according to current American Heart Association/American College of Cardiology (AHA/ACC) guidelines. Management of pulseless VT is addressed in Section 1 of this book. All patients with VT require oxygen therapy and IV access, at which time blood for electrolyte and cardiac marker analysis is obtained. Electrolyte imbalances, particularly of potassium, should be corrected.

An unstable patient requires immediate emergency cardioversion with sedation as needed. Caution is necessary, especially as these patients usually have low blood pressure. The first recommended DC shock should be 100 J (synchronized) and increased thereafter (150, 200, 360 J). The equivalent biphasic energy should be used for biphasic defibrillators (e.g. escalating 70 J, 120 J, 150 J, 170 J). Amiodarone is first line for shock-resistant VT. Lignocaine, magnesium and procainamide are considered second-line adjuncts to cardioversion, as there is less evidence to support their efficacy. Nifekalant, which is a pure potassium channel blocker. can also be considered where available. An infusion of either amiodarone or lignocaine should be commenced after cardioversion. If the blood pressure is low, consider the use of inotropic support, for example, dopamine infusion. For patients who are unstable with suspicion of a cardiac aetiology, emergency coronary angiography should be considered. The absence of ST elevation on the ECG or the lack of chest pain should not prevent coronary angiography from being performed as in patients with risk factors for coronary artery disease, VT may be the sign of a diseased myocardium.

Stable patients may be treated with

- Intravenous amiodarone 150 mg as a slow bolus over 10 minutes. This can be repeated a second time if conversion has not been achieved.
- An alternative is IV procainamide 100 mg (where available) every 5 minutes to a maximum dose of 10 to 20 mg/kg body weight.

Table 5.4.1 Features indicating that a broad complex tachycardia is likely to be ventricular tachycardia

History	*Clinical features*	*ECG features*
Age >35 years	Cannon 'a' wave in jugular venous pulse (JVP)	AV dissociation
Smoker	Variable intensity of S1	Fusion beats
Ischaemic heart disease	Unchanged intensity of S2	Capture beats
Previous VT		Extreme left axis
Active angina		QRS morphology in V1
		QRS with >140 ms (<120 ms SVT)
		Concordance of QRS vectors in pericardial leads
If in doubt, treat as VT!		

AV, Atrioventricular; *SVT*, supraventricular tachycardia; *VT*, ventricular tachycardia.

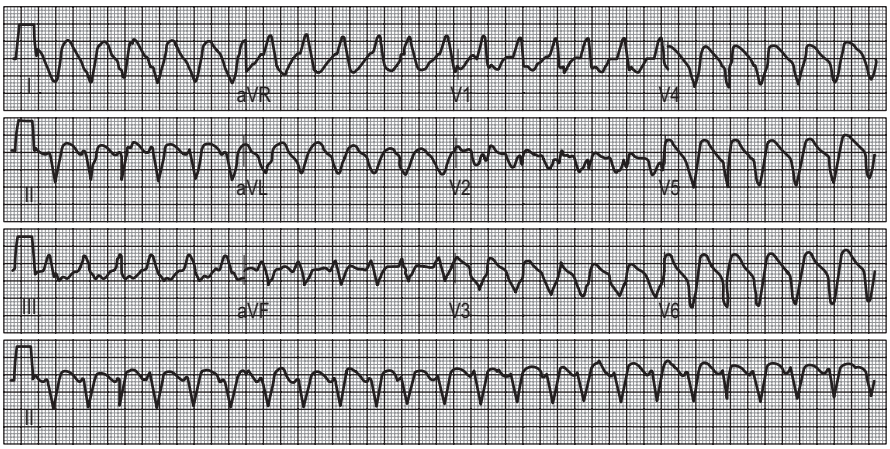

FIG. 5.4.9 Ventricular tachycardia.

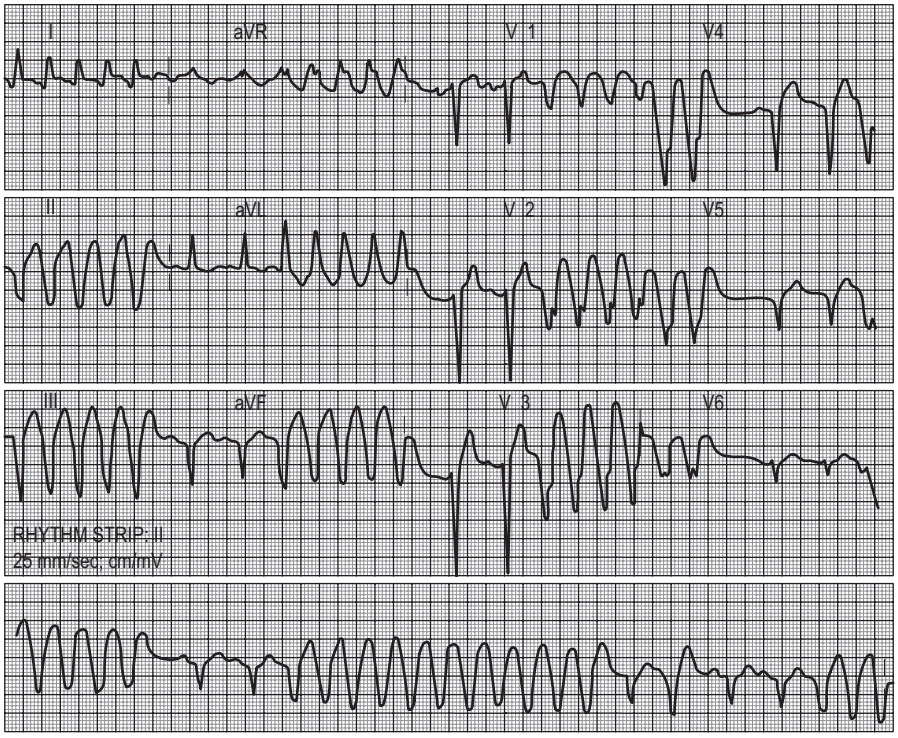

FIG. 5.4.10 Non-sustained ventricular tachycardia.

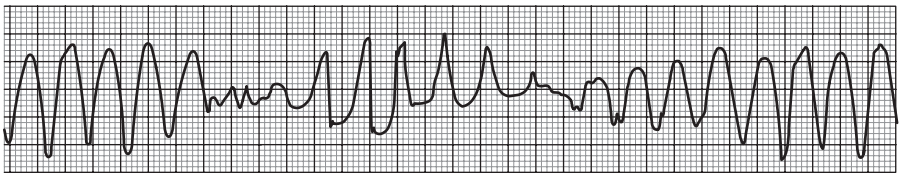

FIG. 5.4.11 Torsades de pointes.

- Lignocaine 50 to 100 mg IV push at a rate not more than 50 mg/min. This can be repeated a second time if conversion is not achieved. It should be noted, however, that lignocaine is relatively ineffective for terminating haemodynamically stable VT of unknown aetiology.

Sotalol 1 mg/kg is used as a second-line agent. Following successful conversion, an infusion of this agent should be commenced for maintenance therapy.

If amiodarone is unsuccessful, a second bolus or an addition of a second antiarrythmic can be used. If pharmacological therapy is unsuccessful, cardioversion under sedation is indicated.

Polymorphic VT VT with a continuously varying QRS morphology is called polymorphic VT. It is often associated with ischaemia and tends to be more electrically unstable than monomorphic VT.

Polymorphic VT includes a specific variant called torsades de pointes, which is associated with a prolonged QT. This is characterized by QRS peaks that twist around the baseline (Fig 5.4.11) and it occurs in the presence of repolarization abnormalities. Causes are summarized in Box 5.4.1.

Syncope is the usual presenting symptom. ECG features include

- Regular or irregular fast, wide QRS complexes
- Continuously varying QRS morphology

Torsades de pointes is sensitive to magnesium. A bolus of 2 g over 1 to 2 minutes followed by an infusion will usually cause reversion. Cardioversion is recommended if the patient is haemodynamically compromised, but torsades de pointes can be resistant; overdrive pacing to a rate of 90 to 120 bpm may be successful. Treatment of the underlying cause is essential. β-blockers can also be considered for congenital prolonged QT syndrome.

Idiopathic ventricular tachycardia Idiopathic VT is a monomorphic VT that occurs in the absence of structural heart disease. The QRS morphology during tachycardia can indicate the site of origin.

The ECG of idiopathic VT can present with

- Left bundle branch block (LBBB) morphology: Inferior axis VT due to right ventricular outflow tract (RVOT)
- RBBB morphology: VT due to idiopathic left ventricular tachycardia (ILVT)
- Either a RBBB or LBBB morphology: Propanolol-sensitive monomorphic VT (IPVT)

Right ventricular outflow tract ventricular tachycardia Right ventricular outflow tract VT has a typical LBBB inferior axis morphology. It typically occurs in young patients and is slightly more common in females. There is usually no evidence of underlying structural heart disease.

ECG features are

- A broad QRS (>120 ms) with a left bundle branch inferior axis morphology.
- AV dissociation is not usually seen as the tachycardia is often very rapid.
- Repetitive monomorphic forms may occur.

As it is catecholamine-sensitive, it is usually responsive to β-blockers as well as verapamil and adenosine. Catheter ablation has a higher success rate. It is important to exclude underlying structural heart disease, especially arrhythmogenic right ventricular cardiomyopathy, as the ECGs for both may look similar.

Idiopathic left ventricular tachycardia Idiopathic left VT is a fascicular VT. The pathophysiology is a re-entrant phenomenon in the posterior fascicle of the left bundle branch.

It occurs in young patients without structural heart disease.

On ECG (Fig. 5.4.12), QRS morphology is broad and shows an RBBB pattern with left axis deviation. The duration of the QRS complex is 100 to 140 ms with an RS interval less than 80 ms. For ischaemic VT, the duration of the QRS complex is usually greater than 140 ms and the RS interval is greater than 100 ms. The ECG may also show capture or fusion beats.

The drug of choice is IV verapamil. Amiodarone and sotalol have been reported to be equally effective. Vagal manoeuvres and intravenous adenosine are ineffective in converting this arrhythmia. Lignocaine is not effective for ILVT. Catheter ablation is highly effective.

Pre-excited atrial fibrillation

Pre-excited atrial fibrillation (AF): Wolff-Parkinson-White (WPW) AF is a differential diagnosis for an irregular wide complex tachycardia.

The patient is usually young (age <50 years) with a previous history of palpitations, rapid heart rate, syncope or documented history of WPW.

Box 5.4.1 Causes of torsades de pointes

Hypomagnesaemia or hypocalcaemia
Class I and class II antiarrhythmic drugs
Phenothiazines
Tricyclic antidepressants
Congenital prolonged QT syndrome
Organophosphates
Complete heart block
Drug interaction of terfenidine with erythromycin

ECG features (Fig. 5.4.13) are

- Rapid ventricular response (>180 bpm; this response rate is much too rapid for conduction down the AV node).
- Broad and bizarre QRS complex, signifying conduction down the aberrant pathway.
- Occasionally a narrow QRS can be seen, representing conduction through the AV node.
- Changing R-R intervals; a QRS complex that changes frequently.

During sinus rhythm, the ECG of patients with WPW shows a PR interval less than 0.12 seconds, a slurred R-wave upstroke (δ wave) and a wide QRS greater than 0.10 seconds (Fig. 5.4.14).

It is important to distinguish WPW AF from other wide complex tachycardias. Certain subtypes of polymorphic VT, such as torsades de pointes, present with an undulating baseline. In contrast, WPW AF usually has a stable ECG baseline with no alteration in the polarity of the QRS complexes.

Haemodynamically unstable pre-excited AF is managed by immediate synchronized cardioversion. Haemodynamically stable pre-excited AF can be treated with

- Procainamide (30 mg/min IV, maximum dose 17 mg/kg) but should be given slowly to avoid severe hypotension. It may not reach therapeutic blood levels for 40 to 60 minutes.
- Ibutilide, a class III antiarrhythmic agent, can also be used. Dosage is 1 mg IV (0.01 mg/kg for patients <60 kg) over 10 minutes, repeated once after 10 minutes if needed. It has a short half-life of 4 hours. Its dosing does not require adjustment for hepatic or renal function and it is safe in elderly patients. It acts rapidly, with a mean conversion time of approximately 20 minutes.
- Administration of IV adenosine, amiodarone, digoxin, diltiazem or verapamil is potentially harmful as they accelerate the ventricular rate and can precipitate ventricular fibrillation. These agents should not be used.

Supraventricular tachycardia with aberrant conduction

SVT with aberrant conduction occurs when a patient with a pre-existing BBB has a rapid ventricular response. In aberrant conduction, the supraventricular impulse is blocked at the bundle branches or in the distal Purkinjie system. Hence the baseline QRS complex is wide. During SVT, this wide complex tachycardia may mimic VT. In AF with aberrant conduction, the ECG has a stable beat-to-beat QRS configuration, contrasting with the variable beat-to-beat QRS configuration in WPW AF.

Narrow complex tachycardias

Sinus tachycardia

Sinus tachycardia is defined as a heart rate greater than 100 bpm. Common causes include shock, hypoxia, cardiac failure, anaemia, drug effects, fever/infection, pain, anxiety, thyrotoxicosis and pregnancy.

Patients may complain of palpitations but are often asymptomatic. Clinical features would be those of the underlying cause.

ECG features are

- Rate: 100 to 160 bpm
- Rhythm: regular
- P waves: uniform and upright in appearance, one preceding each QRS complex

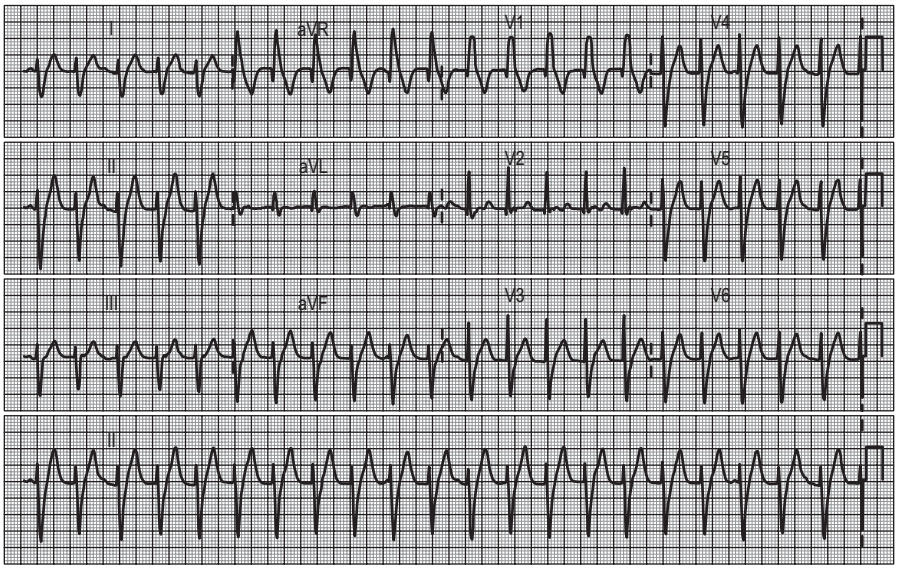

FIG. 5.4.12 Idiopathic left ventricular tachycardia.

FIG. 5.4.13 Pre-excited atrial fibrillation.

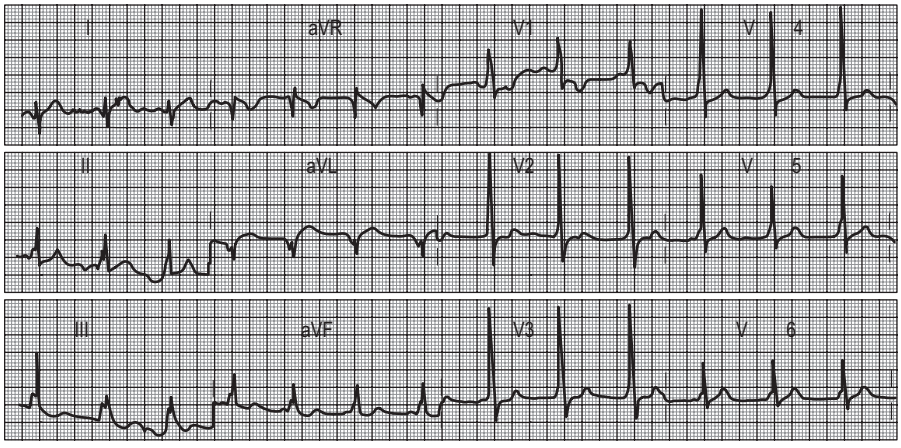

FIG. 5.4.14 Wolff-Parkinson-White syndrome: 12-lead electrocardiogram showing δ waves.

- PR interval: 0.12 to 0.20 s
- QRS: less than 0.10 s

Management focuses on treatment of the underlying cause.

Paroxysmal supraventricular tachycardia

Paroxysmal supraventricular tachycardia (PSVT) originates from either an ectopic atrial focus or a re-entry circuit. Those caused by atrial flutter and fibrillation are considered separately further on.

Re-entry circuits are responsible for pre-excitation, which exists when the whole or part of the ventricular muscle is activated earlier than anticipated. The majority of re-entry circuits involve the AV node (AVNRT). Retrograde conduction may also involve an AV bypass tract

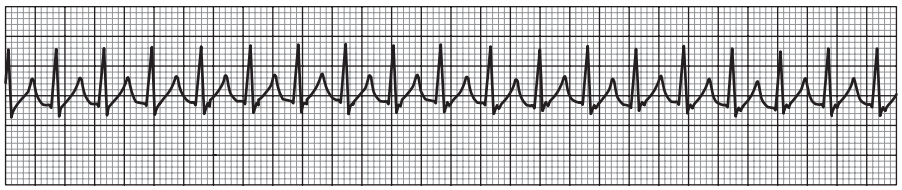

FIG. 5.4.15 Paroxysmal supraventricular tachycardia.

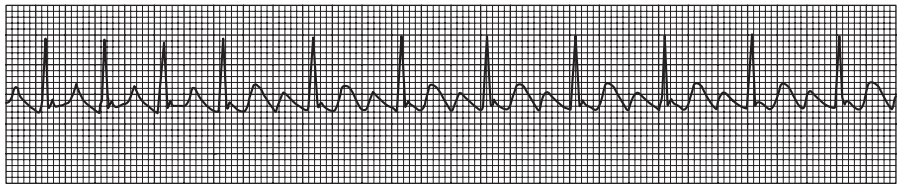

FIG. 5.4.16 Rhythm strip of atrial flutter.

Box 5.4.2 Causes of atrial fibrillation seen in the emergency department

Cardiac
- Ischaemic heart disease
- Pericarditis
- Hypertension
- Rheumatic heart disease
- Pre-excitation syndromes
- Cardiomyopathy
- Atrial septal defect
- Atrial myxoma
- Postoperative

Non-cardiac
Electrolyte imbalances
- Sepsis
- Pulmonary embolism
- Drug and alcohol intoxication
- Chronic obstructive airways disease
- Thyrotoxicosis
- Lung cancer

Intrathoracic pathology

(AVRT). WPW syndrome is the most common of these. It is characterized by an electrically conductive muscle bridge (bundle of Kent) connecting atria and ventricle and bypassing the AV node. ECG when in sinus rhythm may show a PR interval of less than 0.12 s, a δ wave (slurred upstroke) and a wide QRS greater than 0.10 s (see Fig. 5.4.14).

Patients may have palpitations, chest pain or syncope.

ECG features (Fig. 5.4.15) are
- Rate: 150 to 250 bpm
- Rhythm: regular
- P waves: atrial P waves differ from sinus P waves
- P waves are usually identifiable at the lower end of the rate range but seldom identifiable at rates above 200 bpm.
- P waves may be lost in the preceding T wave.
- PR interval: usually not measurable because the P wave is difficult to distinguish from the preceding T wave. If measurable, it is 0.12 to 0.20 s.
- QRS: less than 0.10 s.

Vagal manoeuvres and/or IV adenosine should be used as first-line therapy in the acute treatment of regular PSVT.[2] If unsuccessful and the patient is haemodynamically unstable, cardioversion is indicated. Sedation is usually required. In haemodynamically stable patients, if vagal manoeuvres and/or adenosine are unsuccessful or inappropriate, the choice of drug therapy lies between IV β-blockers, IV diltiazem or IV verapamil (continuous slow infusion of 1 mg/min to a maximum of 20 mg or 5 mg IV slowly, which may be repeated). There is scant evidence to show that one drug is more effective than the other.[2] With adenosine, patients experience a transient sense of impending doom, chest discomfort and shortness of breath that can be very distressing. With verapamil, hypotension may occur, hence the cautious administration. Concurrent use of β-blockers may potentiate this. Flecainide (2 mg/kg over 30 to 45 min) would be considered third-line therapy. Patients who are resistant to chemical cardioversion may require electrical cardioversion.

Atrial flutter

Risk factors for atrial flutter mirror those of AF including thyrotoxicosis, obesity, obstructive sleep apnea, sick sinus syndrome, pulmonary disease and pulmonary embolism.

Patients may have palpitations and chest pain or more commonly are asymptomatic.

ECG features (Fig. 5.4.16) are
- Rate: atrial rate 250 to 350/min, flutter rate usually about 300/min.
- Ventricular rate variable, usually 150/min with 2:1 AV block. Rarely 1:1 or higher-degree AV block (3:1, 4:1).
- Rhythm: atrial rhythm regular; ventricular rhythm usually regular, but may be irregular.
- P waves: sawtoothed 'flutter waves'. Best seen in II, III, aVF.
- PR interval: not measurable.
- QRS: usually less than 0.10 s but may be widened if flutter waves are buried in the QRS complex.

Haemodynamically unstable patients will usually respond to low-energy cardioversion (e.g. 50 J) or rate control with IV amiodarone.[3] In haemodynamically stable patients, synchronized cardioversion, rapid atrial pacing may be used for rhythm control. IV β-blockers, IV diltiazem or IV verapamil may be used for rate control if required. Treatment of the underlying illness, if obvious, may often result in spontaneous reversion.

Atrial fibrillation

AF is the result of chaotic atrial depolarization from multiple areas of re-entry within the atria. Thu, there is a lack of coordinated atrial activity. AF is characterized by an irregular rhythm without discrete P waves and may be acute or chronic. Causes of AF seen in the ED are summarized in Box 5.4.2.

There are three variations of AF,
- Paroxysmal AF
- AF with slow ventricular response
- AF with rapid ventricular response

Clinical features Patients with acute episodes of AF often experience palpitations, dyspnoea, dizziness or angina. Those with chronic AF often have no specific symptoms, especially if their heart rate is less than 100 bpm. Clinically, the pulse is irregularly irregular and S1 varies in intensity.

Clinical investigations Patients with acute-onset AF should have electrolyte studies and thyroid function tests as well as consideration of cardiac marker levels if appropriate to the clinical context. All patients with AF should have echocardiography if not recently performed. This can be done as an outpatient procedure for those successfully treated in the ED.

ECG features (Fig. 5.4.17) are
- Absent P waves
- Chaotic irregular baseline—fibrillatory waves
- Irregularly irregular RR cycles—fast or slow AF
- Wide QRS due to aberrance may occur intermittently (Ashman phenomenon)

Treatment[3] Emergency management depends on the chronicity of the condition, haemodynamic stability, the ventricular

FIG. 5.4.17 Rhythm strip of atrial fibrillation.

Table 5.4.2 CHA_2DS_2-VASc risk stratification scores for subjects with non-valvular atrial fibrillation (where C stands for Congestive heart failure, H stands for Hypertension, A stands for Age >/=75, D stands for Diabetes Mellitus, S stands for stroke, V stands for vascular disease, A stands for age between 65-74 and Sc stands for sex category referring to female.)

Acronym	*Score*	*Total score*	*Adjusted stroke rate (% per year)*
Congestive heart failure	1	0	0%
Hypertension	1	1	1.3%
Age ≥75	2	2	3.2%
Diabetes mellitus	1	3	3.2%
Stroke or transient ischemic attack or thromboembolism	2	4	4.0%
Vascular disease (prior myocardial infarction, peripheral artery disease or aortic plaque)	1	5	6.7%
Age 65–74 years	1	6 7	9.8%. 9.6%
Gender (female)	1	8	6.7%
Maximal score	9	9	15.2%

response rate, the presence of underling structural heart disease and any associated conditions. The aim of treatment for patients with chronic AF is rate control and treatment of any associated illness. Regardless of duration, hemodynamically unstable patients with recent-onset AF and a rapid ventricular response rate require urgent electrical cardioversion.

Anticoagulation should be considered based on the CHADS-VASc score (Table 5.4.2). In recent years, direct oral anticoagulants (DOACs) have become an alternative to warfarin for non-valvular AF.

Most patients presenting to the ED with AF will be alert and have a normal perfusing blood pressure and thus will not require immediate cardioversion.[4] In such patients, the choice lies between cardioversion in the ED (electrical or pharmacological), rate control and anticoagulation with delayed elective electrical cardioversion or rate control alone. There is no evidence that a rhythm-control strategy is superior to a rate-control strategy. That said, a rhythm-control strategy may be preferred for younger patients, those who are symptomatic without structural disease, those presenting for the first time with lone AF and those with AF secondary to a treatable/correctable precipitant. A rate-control strategy may be preferred for patients aged over 65, those with coronary artery disease, those with contraindications to antiarrhythmic drugs, those unsuitable for cardioversion and those with congestive heart failure.

Treatment of AF in the emergency department is summarized in Fig. 5.4.18. Haemodynamically stable patients where onset of AF is within 48 hours may be treated with either pharmacological or electrical cardioversion. Where AF is of a longer duration, a delayed elective cardioversion or rate control-only strategy is indicated.[8]

As part of a rhythm-control strategy, electrical cardioversion may be attempted at 120 to 200 J (biphasic). If cardioversion is unsuccessful, repeated direct-current cardioversion attempts may be made after adjusting the location of the electrodes or applying pressure over the electrodes or following administration of an antiarrhythmic agent.

As part of pharmacological cardioversion, amiodarone, flecainide, dofetilide, propafenone, vernakalant and ibutilide may be used.

Rate control can be achieved with β-blockers (e.g. metoprolol 2.5 to 5 mg IV over 2 minutes, repeated if necessary to a maximum of 15 mg), verapamil (5 to 10 mg IV over 2 to 5 minutes), amiodarone or diltiazem. The target heart rate is controversial but should be below 110 bpm. In patients with signs of heart failure or known LVEF below 40%, the smallest dose of β-blocker should be used to achieve rate control.

In patients with known permanent AF where haemodynamic instability is caused mainly by a poorly controlled ventricular rate, a pharmacological rate-control strategy should be used. β-Blockers or rate-limiting calcium antagonists are the agents of choice or, where these are contraindicated or ineffective, amiodarone should be used. Radiofrequency ablation has been shown in a recent trial to be useful in reducing mortality for patients with AF and concomitant heart failure.

Multifocal atrial tachycardia

This rare arrhythmia is characterized by three distinct P-wave morphologies; a ventricular rate of more than 100 bpm; and variable PP, PR and RR intervals. It is associated with chronic obstructive pulmonary disease, hypoxia, electrolyte disturbance, pulmonary embolus and valvular heart disease. Treatment is directed at improving the underlying condition and controlling the ventricular rate. IV magnesium may be helpful. Cardioversion and anti-arrhythmics are not useful.

Unifascicular blocks

A unifascicular block is a conduction block that affects one of the major infranodal conduction pathways: RBBB, left anterior fascicular block (LAFB) or left posterior fascicular block (LPFB). Conduction blocks can be caused by ischaemia, cardiomyopathies, valvular disease, myocarditis, surgery, congenital disease and degenerative diseases (Lenegre or Lev disease).

Left anterior fascicular block

There are no specific clinical features.

ECG features are

- Left axis deviation
- Normal QRS duration

Usually no treatment needed. Treat the underlying cause.

Left posterior fascicular block

There are no specific clinical features.

ECG features are

- Right axis deviation
- Normal QRS duration

Usually no treatment needed. Treat the underlying cause.

Right bundle branch block

RBBB can be a normal variant. Other causes include pulmonary embolism, right ventricular hypertrophy, ischaemic heart disease, congenital heart disease and cor pulmonale.

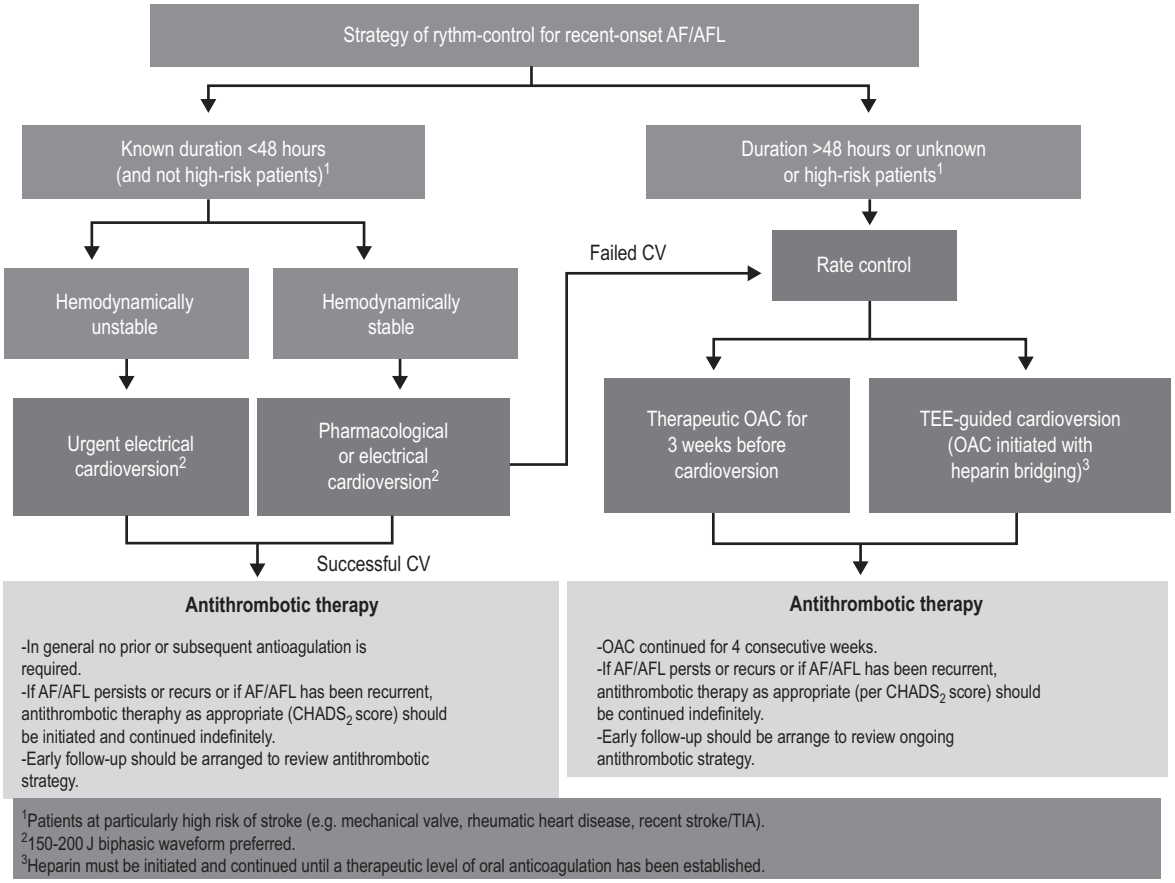

FIG. 5.4.18 Management algorithm for atrial fibrillation *(AF)* in the emergency department. *AFL*, atrial flutter; *CV*, cardioversion; *OAC*, oral anticoagulation; *TEE*, transoesophageal echo; *TIA*, transient ischaemic attack. (Reproduced with permission from Stiell IG, Macle L, CCS atrial fibrillation guidelines committee. Canadian cardiovascular society atrial fibrillation guidelines 2010: management of recent onset atrial fibrillation and flutter in the emergency department. *Can J Cardiol.* 2011; 27:38–46.)

Clinical features will be those of the underlying cause.

ECG features (Fig. 5.4.19) are

- rSR pattern, most noted in V1 and V2
- Broad S wave in left ventricular leads
- QRS greater than 120 ms in complete RBBB and ≤120 ms with incomplete RBBB.

Treatment is of the underlying cause. If there is a new RBBB, the cause should be actively determined.

Left bundle branch block

LBBB is usually pathological. Causes include coronary artery disease, myocardial ischemia, hypertension, myocarditis and cardiomyopathies.

Clinical features will be those of the underlying cause.

ECG features (Fig. 5.4.20) are

- Broad notched or slurred R wave in leads I, aVL, V5 and V6
- QRS >120 ms

Treatment is of the underlying cause. Studies have shown that most patients with chest pain and a 'new' LBBB do not have a ST elevation myocardial infarction (STEMI), and other factors need to be considered in determining the need for immediate reperfusion. The Sgarbossa criteria (Fig. 5.4.21)[5,6] are useful in determining STEMI in the presence of LBBB. The criteria used to diagnose infarction in patients with LBBB are

- Concordant ST segment elevation of 1 mm or more that is in the same direction as the QRS complex in any lead (5 points)
- Concordant ST segment depression of 1 mm or more in any lead from V1-V3 (3 points)
- ST segment elevation of 5 mm or more that is discordant with the QRS complex (2 points)

A total score of 3 or more is specific for infarction.

Combination blocks

A bifascicular block is a conduction block that affects two of the major infranodal conduction pathways. This may be a LBBB or a combination of RBBB and LAFB or LPFB. Trifascicular block is a combination of conduction blocks of all three fascicles. Examples include

- RBBB and LAFB with first-degree AV block
- RBBB and LPFB with first-degree AV block
- LBBB with first-degree AV block
- Alternating RBBB and LBBB

Blocks may be permanent or transient. In the setting of an acute myocardial infarction both bi- and trifascicular blocks may degenerate to complete heart block. Thus admission to a monitored bed is needed and pacemaker insertion may be considered.

Other disturbances of cardiac rhythm and conduction

Atrial ectopics

Atrial ectopics are mostly asymptomatic and may be precipitated by the intake of alcohol, nicotine or caffeine. They may be associated with AF, underlying heart disease or respiratory disease.

ECG features are

- Complexes are usually earlier than normal (premature).
- P-wave morphology different from sinus P. May be lost or deformed.
- PR interval may be short or long.

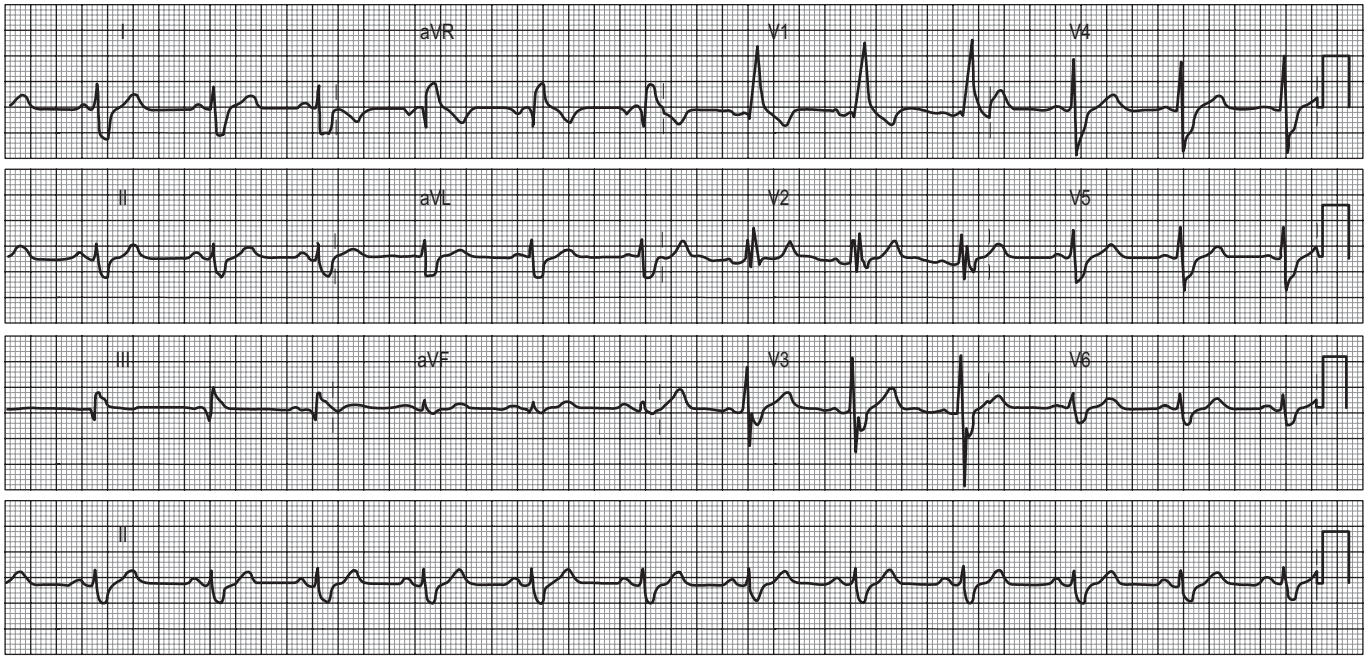

FIG. 5.4.19 Right bundle branch block.

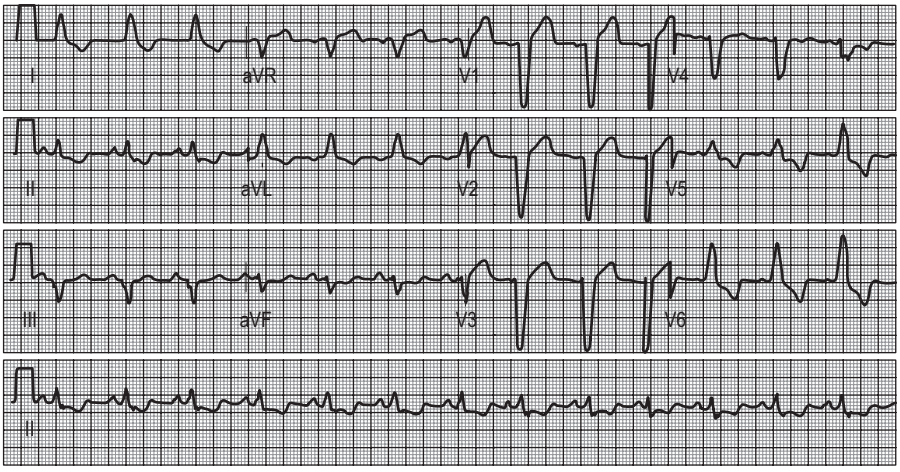

FIG. 5.4.20 Left bundle branch block.

- QRS is usually normal unless aberrantly conducted.
- When early, may be blocked—blocked atrial ectopic.
  Usually no treatment is necessary.

Junctional rhythm

A junctional rhythm is usually asymptomatic.
ECG features are

- Rate is slower than sinus rhythm.
- Rhythm is regular.
- No preceding P wave.
- Infrequently the P wave may precede or be just after the QRS (the P waves are inverted in II, III, aVF).
- QRS usually narrow unless aberrantly conducted.
  Usually no treatment is needed.

Brugada syndrome[9]

The Brugada syndrome is a syndrome with the ECG showing right-bundle-branch morphology and ST-segment elevation in V1 and V2 with terminal T inversion (Fig. 5.4.22) as well as symptoms such as syncope or cardiac arrest. It is important to differentiate Brugada pattern of ECG from Brugada syndrome. The ECG pattern with symptoms may be associated with sudden cardiac death from ventricular fibrillation, and there may be a family history of sudden death. Brugada syndrome is an example of a channelopathy. Occasionally the ECG pattern is seen only during fever or after taking antiarrhythmic drugs, especially class IC antiarrhythmics such as flecainide or propafenone. Patients with the Brugada pattern should be referred for further evaluation and risk stratification.

CONTROVERSIES

- There is not much evidence from randomized controlled trials for the use of many second-line antiarrhythmic drugs.
- Is there a role for a period of observation for minimally symptomatic recent-onset paroxysmal AF?

Concordant ST elevation ≥1 mm in leads where the QRS is predominantly positive (V4–V6, aVL, I) (5 points)	Concordant ST depression ≥1 mm in leads where the QRS is predominantly negative (V1–V3) (3 points)	Discordant ST elevation ≥5 mm in leads where the QRS is predominantly negative (V1–V3) (2 points)	
FIG. 5.4.21 Sgarbossa criteria.

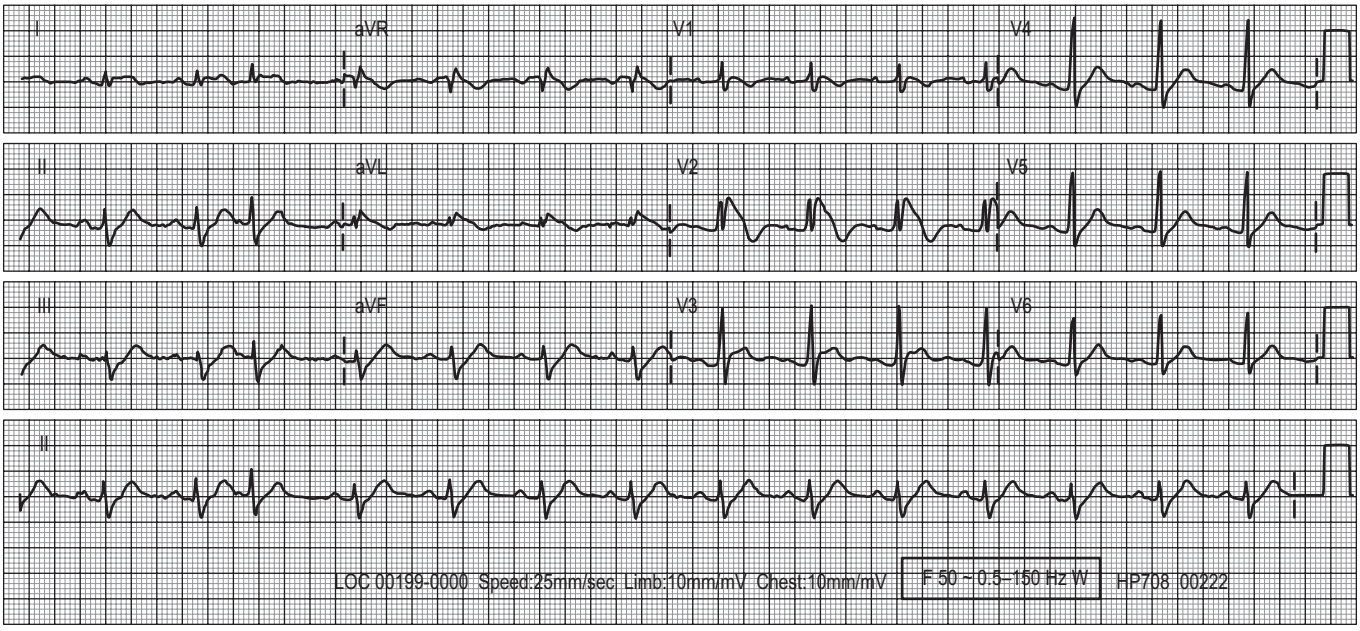

FIG. 5.4.22 Brugada syndrome.

5.5 Pulmonary embolism

David Mountain

ESSENTIALS

1 **Venous thromboembolism (VTE) has protean clinical manifestations and is a continuum from deep venous thrombosis (DVT) to the main life-threatening complication of pulmonary embolism (PE).**

2 **Left untreated, patients with a diagnosis of PE have a significant recurrence rate and mortality; this can be considerably reduced with anticoagulation.**

3 **Diagnostic and treatment decisions rely on good risk stratification, preferably using validated scores such as the Wells scores and the pulmonary embolism rule-out criteria (PERC rule) to avoid excessive investigation and unnecessary therapy as well as to guide the management and disposition of those with PE.**

4 **The investigative algorithm should include electrocardiography (ECG), chest x-ray (CXR) and measures of oxygenation (plus other investigations for alternative diagnoses) to stratify risk, guide radiological testing and search for alternative causes. Computed tomographic pulmonary angiography (CTPA) is the most commonly used diagnostic test. Several further modalities may be utilized—including validated combinations of D-dimer (as well as age-adjusted D-dimer), lower limb ultrasound, ventilation/perfusion (V/Q) scan, single-photon emission computed tomography (SPECT or V/Q SPECT) and CTPA—to refine probability. Which are chosen will depend on local resources.**

5 **The decision to treat is based on reaching a diagnostic threshold (>80% chance of PE), where PE morbidity/mortality outweighs the risks of anticoagulation.**

6 **In massive (clinically unstable) PE, transthoracic or, if available, trans-oesophageal echocardiography is the recommended initial investigation.**

7 **Novel oral anticoagulants (NOACs), now being referred to as direct oral anticoagulants (DOACs), are the recommended first-line treatment for most cases of PE, although in some circumstances sub-segmental PE (SSPE) may be appropriately left untreated.**

8 **Thrombolysis (or embolectomy if thrombolysis is contraindicated or has failed) is indicated only for haemodynamically unstable/shocked PE. Stable patients with evidence of right ventricular strain should be monitored vigilantly, with thrombolysis initiated urgently if they deteriorate clinically.**

9 **Prognosis can be usefully assessed and used to guide disposition and management, with combined clinical and investigation parameters using validated scores, such as the Simplified Pulmonary Embolism Severity Index (SPESI).**

Introduction

Pulmonary embolus (PE) is the third most common cardiovascular disease, more often seen in the elderly with co-morbidity (cancer, trauma, immobility, surgery or severe medical disease). Historically, when diagnosed clinically and untreated, it has a high mortality. Treating PE with anticoagulation reduces in-hospital mortality to between 4% and 12%.

The diagnosis and management of PE is often difficult. It requires careful clinical assessment, documented risk stratification (preferably a validated score such a Wells, PERC, etc.) and appropriate selection of diagnostics, none of which are truly definitive. Possible alternative serious conditions should always be considered. All PE diagnostic tests (including D-dimer) need risk assessment to ensure safe and appropriate usage (see risk assessment, further on). Generally, with PE risk below 5% (most low-risk emergency patients), an alternative diagnosis should be sought, with PE investigation pursued if no definitive alternative is found. Overly aggressive radiological investigation in 5% risk populations potentially finds more false-positive venous thromboembolism (VTE) than real PE/deep venous thrombosis (DVT). The diagnostic threshold is 70% to 80% PE probability, where treatment benefits clearly outweigh treatment risks. Most diagnostic guidelines use Wells, and/or PERC (if low-risk Wells) and/or D-dimer (if low-risk Wells and positive PERC) for most emergency department (ED) patients, followed by computed tomographic pulmonary angiography (CTPA) or occasionally nuclear ventilation/perfusion scan (V/Q) for definitive diagnosis. Venous ultrasound (US or CT venography) may assist after indeterminate imaging. Echocardiography, if available, is useful for PE risk stratification and particularly for managing unstable cases (Fig. 5.5.1).

Almost all cases of diagnosed PE will be anticoagulated, the majority on direct oral anticoagulants (DOACs) or novel oral anticoagulants (NOACs), some with heparin/warfarin. Thrombolysis or embolectomy (when thrombolysis is contraindicated or fails) is indicated in shocked patients (massive PE, blood pressure [BP] <90 mm Hg for >15 minutes or if patient is requiring inotropic support due to PE); thrombolysis is not routinely administered for submassive PE. Disposition decisions (e.g. home therapy, intensive monitoring) are assisted by prognostic decision making based on validated scores (e.g. the Simplified Pulmonary Embolism Severity Index [SPESI]) or PE severity markers (e.g. biomarkers such as brain natriuretic peptide [BNP], troponin, etc.) or echocardiography.

Aetiology, pathogenesis and pathology

Up to 30% of PEs, particularly ED presentations, are idiopathic. Most risk factors act via more than one item in Virchow's triad (e.g. vessel wall injury, venous stasis or hypercoagulable states). The major risk factors associated with secondary (provoked) PE are as follows:

- Surgery or trauma; particularly pelvis/ lower abdomen, lower limb or central nervous system (CNS) (provokes 15% to 30% of PE)
- Cancers (15% to 25%)
- Systemic disease with immobilization (>24 hours bed rest), particularly heart disease/ strokes (15% to 25%)
- A history of DVT/PE (particularly unprovoked, 5% to 15%).

PE incidence rises exponentially with age, with those above 85 years of age having

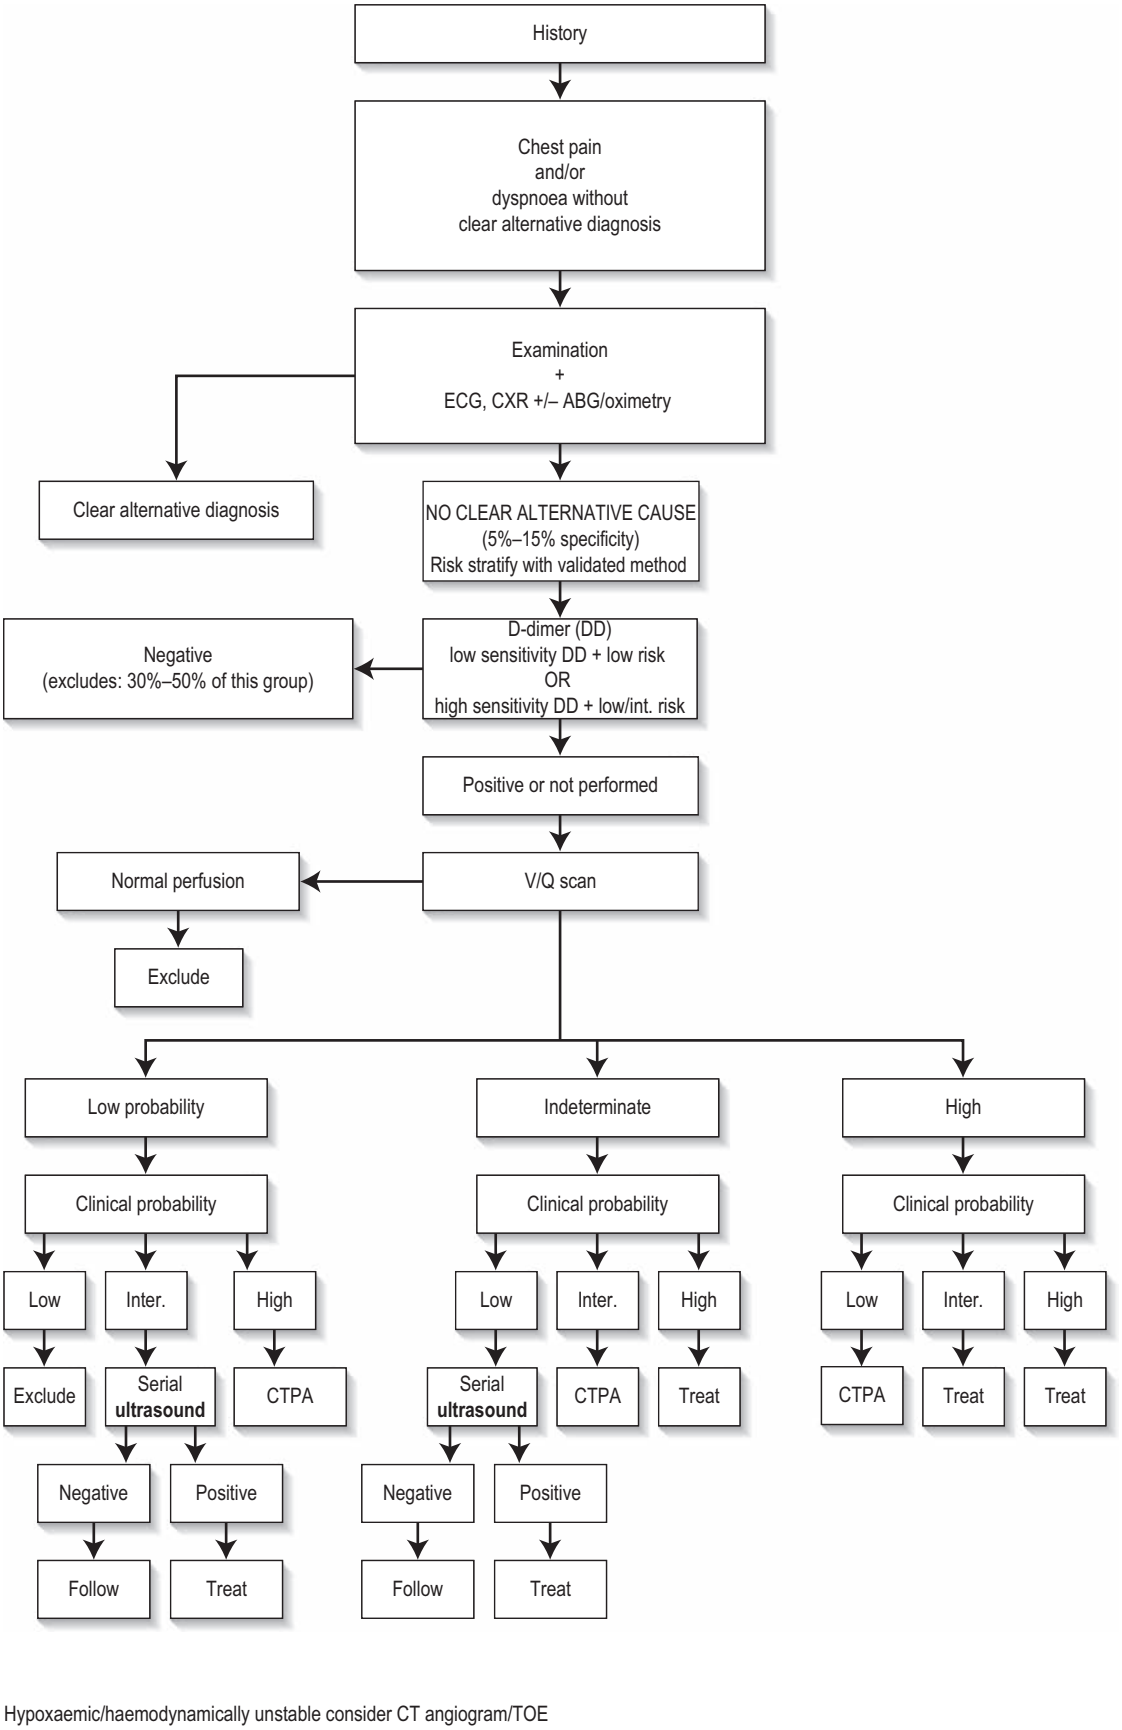

FIG. 5.5.1 Investigation algorithm for pulmonary embolism using V/Q scan as the primary imaging technique. *ABG*, Arterial blood gas; *CTPA*, computed tomographic pulmonary angiography; *CXR*, chest x-ray; *ECG*, electrocardiography; *TOE*, transoesophageal; *V/Q*, ventilation/perfusion.

60 times the incidence of 18- to 25-year-olds, mainly driven by co-morbidity. Hypercoagulable states (e.g. antithrombin III deficiency, factor V Leiden, antiphospholipid syndrome, protein C/S deficiencies etc.), indwelling venous devices, hormone contraception or therapy, obesity, later pregnancy/post-partum, many vasculitic/autoimmune diseases, smoking, use of non-steroidal anti-inflammatory drugs and long-haul air travel increase the risk of PE.

Prevention

The greatest preventable cause of DVT/PE is surgery. Stasis from illness-related bed rest—particularly cancer, stroke and cardiopulmonary disease—are also common. Low-dose preventive low-molecular-weight heparin (LMWH) or NOACs/DOACs make surgery safer and more effective and improve outcomes for high-risk hospitalized medical patients. Thrombo-prophylaxis risk assessment should be performed and started as early as possible.

Clinical Features

History

The history provides important clues for diagnosing PE. Virtually all PE patients present with either recent-onset dyspnoea (particularly if rapid/recurrently episodic), chest pain (any type), or both (sensitivity 97%, specificity 10%). Syncope either with respiratory symptoms or signs (even if transient), where VTE risk is high, often suggests severe disease. DVT symptoms should be sought in all patients. Haemoptysis has some predictive value but is uncommon. Associated risk factors, divided into major and minor, increase PE likelihood and should be documented and incorporated into risk assessments.

Other symptoms (e.g. clear musculoskeletal symptomatology) are less important for diagnosis but may suggest or exclude other causes, particularly in low-risk patients. No single symptom (or sign) has the sensitivity or specificity to either establish or exclude the diagnosis.

Examination

Physical signs confirming PE (e.g. persistent unexplained tachycardia [>100] at rest) are rare but can significantly increase PE diagnostic probability; this is incorporated into most prediction rules. Leg (or arm) DVT signs (e.g. a swollen, oedematous leg with pain in the venous distribution or significant thrombophlebitis) increase PE risk and mandate imaging. Other features include tachypnoea (50% to 80%), cough (10% to 20%), mild fever (<38.5°C), wheeze and pleural effusion/rub; but these are not discriminatory for PE. Occasionally elevated jugular venous pressure (JVP), a loud cardiac S(P)2 heart sound or a pulmonary systolic murmur may suggest right ventricular strain.

Risk assessment for the diagnosis of pulmonary embolism

The pre-test probability (PTP) calculation used to decide on investigation strategies is based on history, examination and investigations, including CXR, arterial blood gas analysis/oximetry, ECG and investigations for alternative diagnoses. For non-experts, this estimate is best made using validated scoring systems. The best validated and most widely disseminated is the Wells rule (Table 5.5.1). If the Wells score is low (<2) the patient should have a PERC score (Table 5.5.2) applied to decide whether D-dimer is indicated; if PERC is negative PE is excluded (<2% PE incidence) without need for D-dimer testing. If PERC is positive in this low-risk Wells group an age adjusted D-dimer is performed followed by CTPA/VQ/SPECT if positive. If Wells is higher (>4), then the D-dimer is not performed and the patient progresses directly to CTPA/VQ/SPECT.

Anticoagulation before diagnosis

The initial screening tests for PE are discussed below. For patients considered high risk for PE (Well's >6) without contraindications to anticoagulation or individual agents, initiate either a DOAC, heparin (LMWH or unfractionated heparin (UFH) or fondoparinux. For intermediate risk ED patients (PE in 15% to 25%) consider bleeding risks versus signs of severity for PE or underlying cardio-respiratory instability when deciding to start anticoagulants before confirmed PE. All unstable patients (including hypoxia, tachycardia/hypotension/lactate excess) should be anticoagulated immediately unless absolute contra-indications exist with heparin in addition to receiving thrombolysis or embolectomy.

Chest x-ray

A normal chest CXR with significant hypoxia is somewhat suggestive of PE. However, the CXR is abnormal in 80% to 90% of PE. If definitely present, an enlarged/plump descending pulmonary artery, pulmonary oligaemia or cut-off (Westermark sign), and particularly a 'Hampton hump' (a semi-circular opacity with the base abutting the pleural surface) are quite specific (70% to 90%). However, these may be subtle (e.g. often identified in retrospect) and have poor sensitivity. Pleural effusion, plate atelectasis, enlarged heart and non-specific consolidation are common but seen no more often than in other cardio-pulmonary conditions. The main role of CXR is to identify alternative diagnoses and to assist in deciding if a V/Q scan will provide adequate discrimination.

Table 5.5.1 Wells clinical criteria for pulmonary embolus

Clinical signs of DVT	3.0
Pulse rate >100 (at rest)	1.5
Immobilized ≥3 days	1.5
Surgery <4 weeks	1.5
Past history PE/DVT	1.5
Haemoptysis	1.0
Current/recent neoplasm	1.0
No alternative diagnosis more likely than PE	3.0[a]
Score[b]	
Low	<2
Moderate	2–6
High	>6

[a]Including information from ECG, ABG, CXR and other tests for alternative diagnoses.
[b]A dichotomized (modified Wells) scale of ≤4 (low) or >4 (high) is also validated and allows lower sensitivity D-dimers (and age-adjusted D-dimer using sensitive latex agglutination tests) to exclude more patients. On line version at http://www.mdcalc.com/wells-criteria-for-pulmonary-embolism-pe/

Electrocardiography

At least 21 potential ECG features have been postulated for PE, but they are insensitive and most lack specificity. The most significant are

tachycardias (particularly atrial), right bundle branch block (often incomplete/transient), right axis deviation (particularly S1-S3), T-wave inversion (especially deep V1-V3) and the S1-Q3-T3 pattern. The more features present, the more suggestive for right ventricular (RV) strain. These changes have been associated with poorer PE outcomes, particularly the rare S1-Q3-T3 pattern.

Arterial blood gas analysis

In recent years, the role of ABG in PE has been challenged. A PaO_2 below 80 mm Hg without other cause makes PE more likely, but 12% of PE patients have PaO_2 greater than 80 mm Hg. An abnormal A–a gradient marginally increases PE risk, but 20% of PE patients have normal A–a gradients. In most patients, oximetry is sufficient to exclude significant hypoxaemia (<92%) and little is gained from ordering a routine ABG/venous analysis.

D-dimer tests

Most modern D-dimers are sensitive (particularly by enzyme linked immunosorbent assay [ELISA]) but non-specific, as many conditions cause raised levels. If used appropriately, they reduce the need for further investigations for significant numbers of patients (20% to 60%). By identifying low-risk patients who can safely forgo further investigation, they increase PE yields in the remaining low-risk patients, making investigation of these patients useful and reducing false positives. D-dimers are really useful when negative, allowing PE exclusion for non-high-risk patients (Wells score 0–4, PERC-positive). Patients with a minimal (<2%) chance of a negative D-dimer should not undergo this test (e.g. <1 week after major surgery, shocked patients, late pregnancy). Patients with prolonged symptoms (>1 week) are likely to have false-negative tests and should not be tested. The test should not be used if PE is not a realistic part of the differential diagnosis. Knowledge of the diagnostic performance of your D-dimer test is required to guide test application and interpretation. High-sensitivity tests, (e.g. VIDAS or the newer validated rapid latex tests [e.g. Lia-Test etc.]) are safe for low- and intermediate-risk ED patients (<25% PE). Low-sensitivity tests (e.g. Simpli-Red, most point-of-care tests) are only appropriate for low-risk patients (<10% to 15% chance of PE).

Age-adjusted D-dimer

D-dimer levels increase with age, meaning that in older populations specificity (utility) is low and negative tests are rarer. Studies have looked to see if using higher D-dimer thresholds with age (age in years × 0.01 ng/mL in those over age 50 is the best validated model) would increase negative testing while maintaining sensitivity. Recent large studies, particularly the prospective ADJUST study, found that lower-risk populations (Wells <6.5) were safely excluded in applying this modification, with 6% to 10% more negative tests and minimal loss of sensitivity. Not all tests are as sensitive as the ELISA tests, like VIDAS, and for most latex-agglutination tests a Wells cut-off of below 4.5 is recommended (dichotomous Wells low risk).

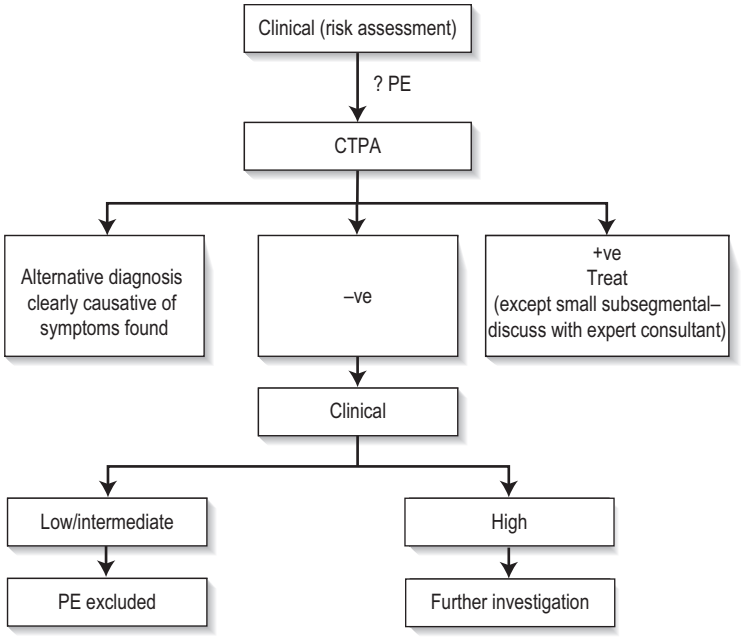

FIG. 5.5.2 Alternative algorithm. *CTPA*, computed tomographic pulmonary angiography; *PE*, pulmonary embolism.

Further investigation

If the D-dimer is positive with no clear alternative diagnosis, further investigation is indicated, CTPA is mainly used, although V/Q or V/Q SPECT are also appropriate, occasionally supplemented by US or CT venography. If either CTPA or V/Q is available, choice is driven by patient-related issues (discussed further on) and logistics. Pulmonary angiography (PA) is now rarely available or used and is not discussed further here. In unstable patients, echocardiography is the preferred initial test, looking for severe RV dilatation and overload signs. Magnetic resonance imaging (MRI) is occasionally used for patients where V/Q and CTPA are contraindicated/unavailable.

Computed tomographic pulmonary angiography and venography

Multi-slice (16 to 300+) CTPA is available in most centres, and after-hours availability is generally better than for V/Q. CTPA is preferable to V/Q in most patients with pre-existing lung disease because intermediate V/Q results are frequent with these patients. CTPA appears accurate in diagnosing main, lobar and most segmental vessel emboli. Sensitivity for SSPEs is low, but the prevalence (around 5% to 15% in Australasia) and their clinical significance is unclear. CTPA with 16 to 300or more slices increases smaller PE sensitivity, with overall sensitivity for all PEs around 90% with good specificity (93% to 99%). The PIOPED2 study suggested sensitivity as low as 85% for PE, although with CT venography (CTV), sensitivity improved to 90%.

Many centres now use CTPA alone to exclude significant PE. This is probably a safe strategy in all but high-risk patients. High-risk patients with negative CTPA should be considered for US to exclude DVT (Fig. 5.5.2).

A major advantage of CTPA is that other thoracic diagnoses may be identified. In some series, abnormalities are seen in up to 60%, with acute serious conditions in 20% to 30%. However, although many of these findings may be incidental, they often lead to prolonged further work-ups and additional radiation. Additionally, with quicker-gated scanners, data on RV size, shape and function may help PE risk stratification.

Some centres use CTV (legs to heart), using CTPA dye run-off instead of separate US testing. Almost all the additional yield (3% to 5% additional PE/DVT diagnosed in some studies) is from leg veins. Radiation doses to gonadal areas from pelvic/abdominal scanning should be avoided unless pelvic pathology is likely.

CTPA has significant problems in clinical practice. Up to 15% of scans are technically inadequate. It requires significant dye loads and therefore is unsuitable for patients with major renal dysfunction or contrast/iodine allergies. The radiation dose is high, particularly for

Box 5.5.1 Pulmonary embolism rule-out criteria

Age <50 years
Pulse <100/min
SaO_2 >94% on room air
No haemoptysis
No exogenous oestrogen
No previous DVT or PE
No surgery or trauma within prior 4 months
No unilateral leg swelling

(From Kline JA, Mitchell AM, Kabrhel C, et al. Clinical criteria to prevent unnecessary diagnostic testing in emergency department patients with suspected pulmonary embolism. *J Thromb Haemost.* 2004;2:1247–1255.)

DVT, Deep venous thrombosis; *PE*, pulmonary embolism.

women with proliferative breast tissues (2 to 4 Gy per breast), conferring significant increased lifetime breast cancer risks (1:1000 per CTPA). V/Q scanning and/or US of the legs should be preferred in all premenopausal (including pregnant) female patients. Fetal radiation doses are minimal in both CTPA and V/Q if proper precautions are taken.

Ventilation/perfusion scan

V/Q scanning is available in most tertiary centres, has low complication rates, moderate radiation exposure and is useful for patients with severe renal dysfunction or dye allergies. However, potentially unwell patients may spend long times in often distant nuclear medicine departments, and most centres do not scan 24/7. Additionally, some critics complain that most V/Q scans are non-diagnostic (>50% in the PIOPED study without risk assessment), thus requiring additional testing to rule PE in or out. Patients with obvious CXR abnormalities (e.g. major collapse, pleural effusions, etc.) or major lung disease frequently have indeterminate V/Q scans and preferably should have CTPA.

Two major studies (PIOPED and McMaster) defined the PE rates with various V/Q results combined with clinical risk assessment. Scans were defined as normal-, low-, intermediate- or high-probability according to the number and/or size of unperfused lung segments matched against ventilation. Further management depends on combining clinical risk and V/Q results as discussed here:

- Normal/near-normal scan (14% in PIOPED). This result excludes significant PE.
- High probability (13% in PIOPED). A high-probability scan gives a greater than 85% chance of PE. However, this means 15% of patients with a high-probability scan may be anticoagulated unnecessarily. The majority of the false positives will be those with a low pre-test probability. Therefore patients with low clinical risk but a high-probability V/Q should have further investigations.
- Low/intermediate (42%/36% in PIOPED). The low- and intermediate-probability groups had 10% to 15% and 35% chance, respectively, of PE. Patients with a low clinical risk assessment and a low-probability V/Q have a less than 5% chance of PE. Most can be safely discharged if other major diagnoses are excluded. However, further leg imaging should occur in patients with critical cardiorespiratory problems, as these individuals have high mortality from even a small PE.

Patients with low clinical pre-test probability and intermediate V/Q (or vice versa) had rates of PE of 16%. However, studies found that after serial or even single negative leg US excluding DVT, recurrent PE and death rates were acceptably low. Patients with dichotomous risk versus V/Q results (low vs high) or intermediate/intermediate results need further alternative investigation with CTPA and/or leg vein imaging.

V/Q single-photon emission computed tomography

V/Q SPECT is a new technique combining V/Q with low-dose computed tomographic scanners (circular arrays) allowing three-dimensional lung imaging. This improves image clarity, better delineates perfusion defects against vascular domains and better images patients with lung disease. Units applying V/Q SPECT give definitive PE diagnosis or exclusion in 90% to 98% of cases and results followed in the same way as CTPA results (see Fig 5.5.2).

There is reasonable evidence that V/Q SPECT gives better imaging and more definitive results than planar V/Q and, in head to head trials, performs with similar accuracy to CTPA. To date, direct comparisons with CTPA have been limited and definitive comparative studies are awaited. It is considered an acceptable alternative to CTPA and preferable to planar V/Q when CTPA is indeterminate/inadequate (10% to 25% of cases) or contraindicated. Small numbers of outcomes studies suggest a good negative predictive value, and V/Q SPECT is probably more sensitive but less specific than CTPA. The specificity issues are probably reduced if V/Q SPECT is combined with low-dose CT (VQ SPECT/CT), allowing lung abnormalities causing perfusion defects to be determined. Many Australasian nuclear medicine departments now offer VQ-SPECT/CT. Caution should be applied when imaging is non-concordant with the clinical picture (e.g. low-risk patient with multiple large perfusion defects, etc.), and cross-over examinations to a CTPA/US may be advisable.

Magnetic resonance imaging

MRI is rarely indicated in PE management.

Echocardiography—transthoracic or transoesophageal

Echocardiography is a rapid, accurate method of diagnosing massive PE in unstable patients. It helps exclude other causes of hypotension and raised venous pressure, such as cardiac tamponade or major valve or myocardial dysfunction. In massive PE, it can demonstrate right heart distension/dysfunction and central pulmonary artery or atrial clot. Importantly, it can be performed during ED resuscitation and used for deciding to initiate thrombolytic treatment in unstable patients. It is insensitive for peripheral emboli and is inadequate to diagnose non-massive PE. However, in stable patients, echocardiography provides prognostic information. If RV strain is seen, there is a higher risk of poor outcomes (5%15% vs. 0% to 2% mortality), which assists disposition and management decisions after a diagnosis of PE.

Pulmonary angiography

PA was the 'gold standard' for PE with very good sensitivity (98%) and specificity (97% to 100%). Because of significant technical, logistical and clinical difficulties, including up to 0.3% mortality and 3% complication rates, it is now rarely used or available.

Further investigation of isolated subsegmental clots

Whenever only SSPEs are reported on imaging, further tests to exclude false positives are recommended. These include

- getting an independent review by an experienced senior CT radiologist
- leg imaging if not already performed for clot load
- using an alternative imaging test to confirm the result if available/feasible
- ensuring senior (treating consultant) review, good documentation and case-by-case decisions, including the patient's wishes/preferences and underlying co-morbidity (e.g. cardiorespiratory status vs. bleeding risks)

Remember, false positives are common in patients with isolated SSPE no matter what imaging is used. Some current guidelines allow for non-treatment in well-assessed low-risk patients after negative leg US.

Treatment

Risk stratification

Patients diagnosed with PE should be risk-stratified for short-term/in-hospital prognosis. There are significant differences in both therapy offered and monitoring requirements for PE patients depending on prognosis. Features determining prognosis are overt haemodynamic instability (particularly

hypotension/shock), syncope or prolonged respiratory failure, with investigations suggesting RV overload/strain, right atrial (RA) thrombus and possibly saddle emboli or severe underlying co-morbidities (cardiopulmonary or bleeding risks).

Cardio-respiratory instability should be clinically obvious, although the use of venous/arterial gases to expose unexpected lactic acidosis/hypoxia is useful and ongoing lactates above 2.0 with resuscitation suggest shock. In patients without overt shock, prognosis may be determined by considering the following:

- Historical features, such as collapse/syncope/arrest or severe co-morbidity and age (>80)
- Physical examination findings, such as borderline perfusion/shutdown, BP, persistent tachycardia-new AF, signs of right ventricular failure/cor-pulmonale
- Bedside and laboratory investigations (e.g. ECG – right ventricular strain patterns, particularly if there are multiple markers of strain), elevated troponin (particularly troponin above ranges for acute myocardial infarction [AMI] diagnosis; 5% to 20% mortality), elevated BNP (>90 pg/mL) or proNT-BNP (>450 pg/mL), persistent lactate above 2.0, hypoxia on oximetry (persistently<93%) or by ABG on room air.
- Echocardiography (still considered the most important prognostic test) or CTPA with signs of right ventricular strain (e.g. RV/LV ratios >1.0, ventricular bowing or signs of RV dysfunction—5% to 15% total mortality) or thrombus in transit (mortality 20% to 60%)

Other features that raise concerns for patients are a demonstration of a massive clot load (e.g. massive DVT, centrally located emboli), recurrent PE on adequate therapy and serious cardiopulmonary co-morbidity.

Prognostic scores

Combinations of various clinical features and/or investigations have been studied to try to define low-risk groups for possible early or immediate discharge. The SPESI score was validated in a large randomized trial confirming safety in selecting patients with PE for home therapy. High SPESI scores are also associated with poor prognosis (e.g. >15% mortality).

General measures

Almost all patients with diagnosed PE need to have a combination of supportive care, including oxygen therapy, analgesia, gentle fluids (250-mL boluses) and careful observation for an initial period while early prognosis is determined and either a licensed DOAC, an LMWH or fondaparinux are initiated (unless there are absolute contraindications).

Heparin therapy

Unfractionated heparin is inferior to LMWH and probably other therapies but should be used for patients being considered for thrombolysis as well as those at high risk of bleeding or severe renal dysfunction.

Dosing for LMWH must be reduced for those with poor renal function (reduced dose and frequency) and the morbidly obese (e.g. 100 kg maximum lean weight) to avoid accumulation or excessive dosing. LMWH is useful if early discharge from inpatient units or even home therapy is being contemplated, although DOACs are increasingly used. Home therapy with appropriate follow-up is now widely used in low-risk PE as defined by the SPESI score.

Warfarin therapy

Warfarin, if used, should be started at the same time as initial heparin therapy and maintained for at least 3 months. Duration of treatment should probably be longer in those at high risk (e.g. cancer patients, unprovoked large PE, etc.). The risk of anticoagulation causing major bleeding may be as high as 10% over 6 months in very high-risk patients (2% to 4% in well-controlled patients), with 1% to 3% intracranial haemorrhage rates reported in some registries and mortality from bleeding of 0.1% to 1% per annum. Risk scores for assessing who is at high risk of bleeding are not validated in the PE population and have limited evidence of discrimination. Elderly, frail, hypertensive, falling, recently bleeding, alcoholic or severely co-morbid patients are at much higher risk.

Direct oral anti coagulants and novel oral anti coagulants

The term *DOAC* is replacing *NOAC* as these agents become less novel with the passage of time; rivaroxaban starts at 15 mg twice daily for 21 days followed by 20 mg once daily. Apixaban starts at 10 mg twice daily for 7 days followed by 5 mg twice daily. Dabigatran requires parenteral anticoagulation (e.g. LMWH) for 5 to 7 days before starting at 150 mg twice daily (or 110 mg twice daily for patients ≥80 years of age). Drug interactions and dosing precautions should be checked before starting on these medications, particularly in the elderly or those with renal dysfunction.

Caval interruption techniques

The use of caval interruption techniques should be considered only in cases of recurrent PE despite adequate anticoagulation, caval thrombosis or possibly if bleeding precludes anticoagulation. There is little evidence for improved outcomes with vena caval filters and they are not recommended routinely in any current guidelines.

Patients at high risk of deterioration

Patients without overt shock but with features of RV strain or major PE, such as a history of syncope/collapse, ongoing hypoxia/tachycardia, elevated lactate, troponins or BNP, very large clot loads, RV strain on CT/echocardiography, high SPESI score or clinician concern, should undergo close observation and continuous monitoring in a high-dependency or critical care area. There is a high rate of deterioration or death in these patients, with up to 25% requiring inotropes, intubation or thrombolysis for instability; mortality rates are up 15% (40% to 50% for RA thrombi). A management plan should have been decided before transfer from the ED, preferably with criteria for initiation of thrombolysis or embolectomy.

Unstable patients

Patients presenting with overt shock, rapidly deteriorating respiratory failure or a history of recovery from cardiorespiratory arrest should be resuscitated, stabilized and, in most cases, strongly considered for thrombolysis (or alternative treatments if thrombolysis is contraindicated; see later). Severe hypoxaemia may require intubation and ventilation, with positive end-expiratory pressure (PEEP) avoided and small tidal volumes to avoid increased intrathoracic pressures. Haemodynamic instability requires gentle intravascular fluid loading with 250- to 500-mL boluses of crystalloids totalling no more than 1 L unless dehydration or hypovolaemia are clearly coexistent. The reason for this is that, in massive PE, the right ventricle is already pressure-overloaded and failing and excessive fluids will further overstretch a failing ventricle (Starling law).

Persistent hypotension will require inotropic support. There is little evidence to support the use of norepinephrine (noradrenaline) over epinephrine (adrenaline) as the inotrope of choice. Patients requiring inotropes should not be treated with isoprenaline as this results in vasodilation, reduced peripheral resistance and increased cardiac output without improving coronary perfusion.

Thrombolysis

The widespread use of thrombolytic therapy for coronary artery disease has led to a reappraisal of thrombolytics in PE. There is definite evidence of earlier reduced pulmonary artery pressures and improved RV function after thrombolysis, although few differences remain at 1 week. Some meta-analyses suggest that shocked PE patients may gain a mortality benefit. Few clinicians would withhold thrombolytics for massive (hypotensive/unstable) PE that is not improving. There has been wider use of thrombolytics for moderate-sized PE

causing RV strain, particularly in Europe, with registry evidence suggesting benefits. However, randomized trial evidence is equivocal, with all current major international guidelines actively discouraging thrombolysis for non-shocked, non-deteriorating patients.

Tissue plasminogen activator (rTPA) is the easiest and quickest thrombolytic to give of those approved for PE and has the fewest side effects (excepting intracranial haemorrhage) compared with urokinase and streptokinase. Alteplase is used providing the first 10 mg as a bolus over 2 minutes followed by 90 mg as an infusion over 2 hours. If the patient weighs less than 65 kg then 1.5 mg/kg is provided as an infusion over 2 hours after an initial bolus of 10 mg over 2 minutes. Bolus reteplase (two doses of 10 units separated by half an hour) or tenecteplase (weight-based infusion) should be effective, but have not been formally evaluated or approved for PE. Patients must receive anticoagulation having received thrombolysis; heparin is the agent of choice aiming to maintain an activated partial thromboplastin time (APTT) of 2 to 2.5 times normal. If the patient received LMWH in advance of thrombolysis, then the heparin infusion should be delayed until 12 hours after LMWH administration. Thrombolysis is associated with major bleeding in up to 20% of patients, with rates of intra-cerebral haemorrhage (ICH) as high as 4% and bleeding deaths in 0.3% to 2%. There is no current evidence that thrombolysis improves late outcomes such as chronic pulmonary hypertension or RV function.

Embolectomy

Patients with arrest, persistent haemodynamic instability or severe hypoxia with contraindications to thrombolysis can be considered for thoracotomy and/or embolectomy. Many are not at hospitals with facilities for cardiopulmonary bypass and alternative therapies have been developed. The use of mechanical clot disruption (catheter embolectomy with or without lysis) for massive PE is reported in case studies/series and small controlled trials, but large studies are difficult because of low frequency and their emergent nature. Unlike other surgical techniques, this procedure is readily available in many larger hospitals. Pulmonary embolectomy without cardiac bypass has been used as a last resort for haemodynamically unstable patients, with reported survival in over 50%. Following cardiac arrest, survival rates are lower, although good survival rates are reported in some large case series.

There is no evidence that mechanical clot removal leads to a better outcome than thrombolysis; in fact, it could be worse. In the pre-arrest/arrested patient, transfer to cardiopulmonary bypass may buy additional time but is a major endeavour. Some hospitals have also used nitric oxide/levomendran to bridge to definitive therapy in deteriorating patients. In general, hospitals should decide on thrombolysis versus thrombectomy as their preferred management of unstable PE to avoid confusion and unnecessary delays or develop rapid decision-making teams, called PE resuscitation teams (PERT) in the United States.

Prognosis

Prognosis is largely dependent on coexistent illness, clot load and eventual position of the initial PE. Patients with arrest or shock have mortality rates of 15% to 50% even with thrombolysis/thrombectomy. Haemodynamically stable patients with RV strain have overall mortality rates of 5% to 15% and are at higher risk of developing chronic thromboembolism and pulmonary hypertension. Patients without significant co-morbidity or RV dysfunction have good outcomes (<1% mortality or poor outcome rates in some studies). Hospital mortality overall may still be high (2.5% to 10%) but is mainly due to co-morbidity, particularly cancer or severe cardio-respiratory disease. Recurrent PE occurs in about 25% of patients by 8 years.

Disposition

Patients with instability, recovery post-arrest, persistent hypoxia (<92% on room air) or evidence of RV strain should be admitted to an intensive care unit or high dependency unit. Most stable PE can be admitted directly to the ward and early discharge on DOAC or NOAC, LMWH/ warfarin (or fondaparinux) should be encouraged for compliant patients, with low bleed risks, low SPESI scores, good home circumstances, good follow-up and at low risk for complications. Some centres manage up to 50% of patients with home discharge. Most patients should have outpatient follow up organized with respiratory, haematology, oncology or general medicine for long-term management and anticoagulation decisions.

CONTROVERSIES

- Is V/Q SPECT-CT equivalent to CTPA for PE diagnosis?
- Will age adjusted D-dimer improve CTPA yield and be used safely and appropriately?
- Should all patients with PE have echocardiography (or equivalent investigations of RV function) and, if positive, how should they be monitored?
- Are BNP/troponins equivalent to echocardiography for RV strain/prognosis?
- Thrombolysis: is generally accepted for use in massive/shocked PE, but is it still very controversial for submassive PE?
- Could thrombectomy/mechanical embolectomy be better than thrombolysis?
- Can we better risk stratify PE for early discharge and also select higher-risk groups for thrombolysis trials?

5.6 Pericarditis, cardiac tamponade and myocarditis

C. Geraldine McMahon

PERICARDITIS

ESSENTIALS

1 **Myocarditis is often associated with pericarditis. This has important clinical implications.**

2 **Pericarditis is diagnosed based on history and findings on both electrocardiography (ECG), and echocardiography. The diagnosis is based on two of the four criteria outlined in Table 5.6.1.[1]**

3 **The majority of cases of pericarditis are idiopathic or viral in aetiology and run a benign course.**

4 **Multimodality imaging for pericardial disease is essential for comprehensive evaluation of the disease condition.**

5 **The correct identification of pericarditis as opposed to ST-segment elevation myocardial infarction (STEMI) is essential. Administration of fibrinolysis in cases of pericarditis may result in life-threatening complications and delay in reperfusion therapy; it is also deleterious to patient outcome.**

6 **Longer-term follow up is important, as a sub-acute or chronic course can develop, with complications such as chronic constrictive pericarditis.**

Introduction

Pericarditis is an inflammation of the pericardium and may be acute, sub-acute or chronic, depending on symptom duration and their recurrence. In the majority of cases there are variable degrees of associated 'epimyocarditis'. The condition is therefore better described as perimyocarditis. It most frequently affects young and middle-aged individuals, is often recurrent and affects men more often than women. It has an overall mortality rate of 1.1%. The causes of pericarditis are listed in Table 5.6.2.

Clinical features

History

Chest pain is the most common presentation (>85% to 90% of cases). It tends to be sharp in nature and is usually localized to the precordial/retrosternal area. The pain is classically worse on inspiration and is often positional. Pain may radiate to the trapezius ridge, neck or shoulder due to involvement of the phrenic nerve. It is typically worse when the patient is supine and improves when he or she is sitting up and leaning forwards. The aetiology is often idiopathic, but a focused history should be directed towards the known causative pathologies, such as post–cardiac injury syndromes, rheumatological manifestations of heart disease (e.g. systemic lupus erythematosus) and complications of malignancy. Dyspnoea is not an expected associated feature unless there are secondary complications, such as cardiac tamponade or constrictive pericarditis.

Examination

A careful history and physical examination should be undertaken in any patient with a suspected pericarditis. Temperature above 38°C is uncommon and may indicate purulent (i.e. bacterial) pericarditis. Sinus tachycardia is common. A pericardial friction rub may be audible when the diaphragm of the stethoscope is placed over the lower left sternal edge with the patient leaning forwards in the left lateral decubitus position (<33% of cases). The rub has a superficial scratching or 'Velcro-like' quality. Pericardial friction rubs may be difficult to detect, as they can be transient and migratory. A raised jugular venous pressure (JVP), hypotension, and pulsus paradoxus are suggestive of cardiac tamponade. Pericardial tamponade, a potentially lethal complication of pericarditis, complicates up to 15% cases of acute idiopathic pericarditis.

High-risk features

The following high-risk clinical features should raise suspicion of serious underlying pathology, such as tuberculosis (TB) or other bacterial infection, malignancy or autoimmune disease:

- Fever
- True dyspnoea
- A sub-acute course
- Significant effusion or tamponade
- Failure to respond to aspirin or non-steroidal anti-inflammatory drugs (NSAIDs)
- Patients on anticoagulant therapy
- Immunosuppression
- Recent trauma
- Patients with suspected significant associated myocarditis indicated by arrhythmias, significantly elevated ST segments or significantly elevated troponin levels

Clinical investigations

Blood tests

- Full blood count: leucocytosis is common, but a markedly elevated white cell count should raise suspicion of bacterial infection.

Table 5.6.1 European Society of Cardiology definition of and diagnostic criteria for pericarditis (2015)

Pericarditis	*Definition and diagnostic criteria*
Acute	Inflammatory pericardial syndrome to be diagnosed with at least two of the four following criteria: 1. Pericarditic chest pain 2. Pericardial rub 3. New widespread ST-segment elevation or PR depression in the ECG 4. Pericardial effusion (new or worsening) Additional supporting findings: • Elevation of markers of inflammation • Evidence of pericardial inflammation by an imaging technique (CT, MRI)
Incessant	Pericarditis lasting for >4 to 6 weeks but <3 months without remission
Recurrent	Recurrence of pericarditis after a documented first episode of acute pericarditis and a symptom-free interval of 4 to 6 weeks or longer
Chronic	Pericarditis lasting for 3 months

CT, Computed tomography; *ECG*, electrocardiography; *MRI*, magnetic resonance imaging.

Table 5.6.2 Causes of acute pericarditis

Idiopathic/viral	Coxsackie viruses, echoviruses, adenovirus, influenza A and B viruses; enterovirus; mumps virus; Epstein-Barr virus; HIV; herpes simplex virus; type I varicella zoster virus (VZV); measles; parainfluenza viruses type II; RSV; CMV; hepatitis A, B and C; parvovirus B 19
Bacterial	Gram positive and gram negative species (streptococci, *Staphylococcus, Pneumococcus), Mycobacterium tuberculosis*. Less common—*Legionella, Norcardia, Actinobacillus, Rickettsia, Borrelia burgdorferi* (Lyme disease), *Listeria, Leptospira, Chlamydophila psittaci, Treponema pallidum* (syphilis), *Coxiella burnettii*, *Meningococcus* species, *Haemophilus* species, *Mycoplasma* species
Fungal	*Histoplasma*, *Blastomyces*, Coccidia, *Aspergillus, Candida*
Parasitic	*Toxoplasma*, *Entamoeba*, *Echinococcus*
Autoimmune/ connective tissue	Systemic lupus erythematosus, Sjogren syndrome, rheumatoid arthritis, scleroderma, vasculitides (eosinophilic granulomatosis) (Churg-Strauss syndrome), Takayasu disease, Behcet syndrome, sarcoidosis, familial Mediterranean fever, inflammatory bowel disease, Still disease, mixed connective tissue disorder, Reiter syndrome, Wegener granulomatosis, ankylosing spondylitis, giant cell arteritis, dermatomyositis, serum sickness
Trauma, iatrogenic	Coronary interventions, permanent pacemaker/ICD implantation, radiofrequency ablation, penetrating, non-penetrating trauma, oesophageal perforation, rupture
Other	Dissecting aneurysm, radiation injury
Myocardial infarction	Acute: days to weeks following transmural myocardial infarction Dressler syndrome: weeks to months following myocardial infarction
Drugs	Daunorubicin, doxorubicin, cyclophosphamide, 5 fluorouracil, amiodarone, cyclosporine, mesalazine, clozapine, methysergide, anti–tumour necrosis factor, hydralazine, procainamide, methyldopa, phenytoin, isoniazid, reserpine. Hypersensitivity syndromes (e.g. penicillin)
Metabolic causes	Uraemia, myxoedema, cholesterol pericarditis
Malignancy	Primary (e.g. sarcoma and mesotheliomas) Secondary (e.g. haematological, breast, lung and melanoma)

CMV, cytomegalovirus; *RSV*, respiratory syncytial virus; *HIV*, Human immunodeficiency virus; *ICD*, implantable cardioverter-defibrillator.

- Serum biochemistry: may identify underlying renal failure.
- Erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) provides confirmatory evidence of an inflammatory process and can be used to follow resolution.
- The troponin level can be minimally elevated in patients with acute pericarditis. Usually the troponin level returns to normal in 1 to 2 weeks. Sustained elevations are suggestive of concomitant myocarditis.
- Other blood tests will be dictated by the clinical assessment and the degree of clinical suspicion for any given causative pathology.

Chest x-ray

The chest x-ray is usually normal in acute pericarditis unless there is a large pericardial effusion. This investigation has a class 1 indication in the European Society of Cardiology (ESC) guidelines for pericardial disease.

European Society of Cardiology guidelines

The ECG is a critical investigative tool and will show abnormalities in 90% of patients with acute pericarditis. ECG changes are the result of the associated epimyocarditis.[2] The pericardium is electrically neutral and does not produce ECG changes. Therefore, in the occasional 'pure' case of pericarditis, the ECG will be normal.

The typical ECG pattern of pericarditis follows four stages:

- Stage 1: hours to days
- Widespread concave upwards ST elevation (60% of cases). This may occur in all leads apart from AVR and VI (Fig. 5.6.1).
  - PR depression.
  - 'Spodick' sign (down-sloping TP segments) seen in 80% of patients with acute pericarditis. It is not usually observed in patients with acute coronary syndrome or early repolarization.[3]
- Stage 2: the PR and ST segments normalize, which can lead to a transiently normal ECG.
- Stage 3: days to weeks: T-wave inversion occurs.
- Stage 4: normalization of the ECG: over a period of up to 3 months; however, in some cases the T-wave changes may be permanent.

Atypical ECG findings may include the following:

- A normal ECG in cases of pure pericarditis (remembering that during stage 2 the ECG may also be transiently normal during a typical evolution).
- The PR-segment depression may occur in isolation, without any ST-segment elevation.
- Stages 1 and 2 without progression to stage 3.
- Localized as opposed to diffuse ECG changes.

Echocardiography

As per ESC guidelines for pericardial diseases, routine transthoracic echocardiography (TTE) is recommended in all patients with acute pericarditis (class 1, level C). It is a crucial imaging technique for detecting pericardial fluid and its haemodynamic effects on the heart if cardiac tamponade or constrictive physiology is suspected. It is also helpful to differentiate from acute myocardial ischaemia by excluding wall motion abnormality. A normal echocardiogram does not rule out a diagnosis of pericarditis. Transoesophageal echocardiography (TOE) is better at measuring thickness of the pericardium than TTE.

Computed tomography scan/magnetic resonance imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) should be considered as further imaging modalities in patients with underlying aetiologies such as malignancy, TB or systemic inflammatory conditions. In most patients, they provide excellent images of the pericardium, including thickness, the presence of effusion and any pericardial lesions. In patients with myopericarditis, MRI shows late gadolinium enhancement in the pericardium.[4] Pericardial uptake of F-fluorodeoxyglucose (FDG) tracer is found in patients with solid cancers and lymphoma and is indicative of malignant pericardial involvement.[4] Positron emission tomography (PET)/CT is also of value in identifying the nature of inflammatory pericarditis. In particular, TB pericarditis yields a higher FDG uptake than idiopathic forms.

Pericardiocentesis and biopsy

Rarely required, pericardiocentesis and biopsy may be indicated in suspected bacterial, tuberculous or neoplastic pericarditis, when cardiac tamponade is present or in chronic or recurrent cases for diagnostic purposes.

Criteria for diagnosis

The clinical diagnosis is based on the presence of two out of four diagnostic criteria in the ESC guidelines. These include (1) typical clinical history, (2) the presence of a pericardial friction rub, (3) typical ECG changes, (4) pericardial effusion.

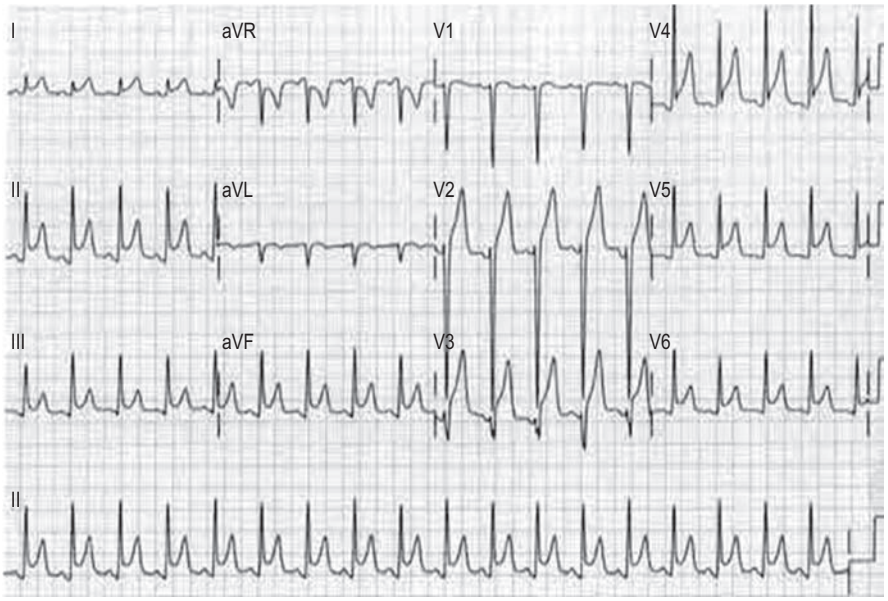

FIG. 5.6.1 Typical electrocardiogram in pericarditis.

Table 5.6.3 Pericarditis vs acute myocardial infarction vs benign early repolarization

ECG feature	*Acute pericarditis*	*STEMI*	*BER*
ST-segment morphology	Concave upwards ST elevation	Convex upwards ST elevation	Concave upwards ST elevation
ST segment elevation	Usually <5 mm	If >5 mm, more suspicious	Usually <5 mm
ST-segment changes distribution	Diffuse	Anatomic	Precordial only
Reciprocal changes	No, mild depressions only in AVR, V1	Deep reciprocal changes opposite ST-elevated segments	No
Q waves	No (unless associated with infarction)	Yes	No
PR segments	PR-segment depressions (may be elevated in AVR and V1)	No	No
T-wave inversion	T-wave inversion after ST segments normalize	T waves may invert concurrently with elevation of ST segments	No
ST/T ratio	>0.25	N/A	<0.25
Usual pattern of evolution of changes	Days to weeks	Minutes to days	Stable over many years

AMI, Acute myocardial infarction; *AVR*, augmented vector right; *BER*, benign early repolarization; *ECG*, electrocardiography; *STEMI*, ST-elevation myocardial infarction.

Convenient diagnoses— such as 'muscular', 'fibrositis', 'costochondritis' and 'viral'—should be avoided until more important conditions such as pericarditis, pulmonary embolus and pneumothorax are excluded.

The most difficult clinical decision in the ED is differentiating between pericarditis, ST-elevation myocardial infarction (STEMI) and benign early repolarization (BER). These ECG features assist in distinguishing between the possible diagnoses are summarized in Table 5.6.3.

Classification of pericarditis

The ESC Task Force has classified pericarditis into three broad categories based on clinical behaviour. The term 'acute' should be adopted for new-onset pericarditis. The term 'incessant' refers to cases with persistent symptoms without a clear-cut remission after the acute episode. The term 'chronic' refers to disease processes lasting more than 3 months. *Incessant* refers to pericarditis with symptoms persisting for more than 4 to 6 weeks (that is generally the approximate length of conventional anti-inflammatory therapy and its tapering). Finally, 'chronic' refers to pericarditis lasting longer than 3 months.

Clinical management and treatment

It is no longer considered mandatory to search for an aetiology in all patients, particularly in areas with a low prevalence of TB. This is because of the relatively benign course and low diagnostic yield. There are some high-risk clinical features that are associated with increased risk of complications. These include a high fever (>38°C), a sub-acute clinical course, evidence of a large pericardial effusion (i.e. diastolic echo-free space of >20 mm), cardiac tamponade and failure to respond within 7 days to NSAIDs. Other risk factors include pericarditis in association with myocarditis, immunodepression, trauma and anticoagulation.

Any clinical presentation that suggests an underlying aetiology such as a systemic inflammatory disease or with any of the high-risk criteria should be admitted to hospital for further assessment and monitoring; patients with none of these conditions can be managed in an ambulatory setting with close follow-up to assess response to treatment and monitor for complications.

Non-steroidal anti-inflammatory drugs

The goals of therapy for acute pericarditis are relief of symptoms, decrease in inflammation, and prevention of recurrences. Aspirin or NSAIDs are the mainstay of therapy. Treatment duration should be based on the resolution of symptoms and normalization of CRP. ESC 2015 guidelines recommend aspirin or ibuprofen as first-line therapy. Results of multiple cohorts and one randomized cohort study suggest that NSAIDs are effective in approximately 70% to 80% of viral/idiopathic pericarditis. Patients who fail to respond or have worsening of symptoms should be evaluated for other aetiologies. The recommended dose of aspirin is 750 to 1000 mg every 8 hours for 1 to 2 weeks, decreasing the dose by 250 to 500 mg every 1 to 2 weeks. The dose for ibuprofen is 600 mg every 8 hours for 1 to 2 weeks and then decreases by 200 to 400 mg every 1 to 2 weeks. In patients with history of acute myocardial infarction and pericarditis, aspirin is the drug of choice. NSAIDs should be avoided as they may hamper myocardial healing and scar formation.

Colchicine

Colchicine is an important component of therapy and has been shown to be effective not only in reducing symptoms but also leading to a 50% reduction in recurrence.[5] It should be given with aspirin and NSAIDs. The ESC 2015 guidelines suggest 0.5 mg once daily for patients weighing <70 kg or 0.5 mg twice a day for those weighing more than 70 kg for 3 months. The initial dose should be maintained until resolution of symptoms and normalization of biomarkers when tapering should be considered.

Corticosteroids

There is some evidence that steroids are associated with increased rates of future relapses in patients with idiopathic pericarditis and therefore should not be used as first-line therapy. The ESC guidelines recommend steroids as second-line therapy in patients who are refractory to NSAIDs and colchicine in whom specific causes of pericarditis requiring other therapies have been excluded. Specifically, steroids may be required first line in patients with systemic inflammatory disease uraemia, or in those who have a contraindication to the use of NSAIDs. Corticosteroids should be used in conjunction with colchicine in these circumstances. The recommended prednisone dose is 0.2 to 0.5 mg/kg per day. This initial dose should be maintained until resolution of symptoms and normalization of CRP are achieved; then tapering should be initiated.[6]

Idiopathic pericarditis in pregnant women is preferably treated with corticosteroids, especially in the last trimester, when NSAIDs are contraindicated because of the risk of premature closure of the ductus arteriosus. Also, colchicine is not recommended in pregnancy because of the potential risk of teratogenicity.

Interventional technique and surgical therapy

Interventional and surgical therapies should be considered in patients with cardiac tamponade, in symptomatic patients who are refractory to medical therapy and those with effusive or constrictive pericarditis, as well as in those with suspected neoplastic or bacterial pericarditis (human immunodeficiency virus [HIV] or TB). Bacterial cultures can be important in evaluating the underlying aetiology in patients with recurrent/relapsing pericarditis and high suspicion for bacterial infection.

Prognosis

Most patients with a diagnosis of acute viral or idiopathic pericarditis have a good long-term prognosis. Cardiac tamponade is not common in this group and constrictive pericarditis is also rare. Constrictive pericarditis complicate up to 30% of cases of TB and purulent pericarditis. Furthermore, up to 20% of patients with idiopathic pericarditis who are not treated with colchicine will develop either recurrent or incessant disease.

NON-TRAUMATIC CARDIAC TAMPONADE

ESSENTIALS

1 **Cardiac tamponade is a life-threatening condition.**

2 **The signs and symptoms of cardiac tamponade can be difficult to elicit. A high index of suspicion is essential to ensure that the condition is not overlooked.**

3 **The gold standard investigation is echocardiography.**

4 **Treatment will depend on the aetiology, speed and volume of accumulation of pericardial contents.**

5 **Needle pericardiocentesis is reserved as a drainage procedure of last resort. The preferred methods are ultrasound-guided drainage performed in the cardiac catheterization laboratory if the clinical situation allows. In cases where cardiac tamponade is the result of myocardial rupture or complicates aortic dissection, thoracotomy with drainage and definitive repair is first-line management. Pericardiocentesis in these situations may be harmful.**

6 **Intubation and mechanical ventilation should be avoided if at all possible in this group as the change from a negative intrathoracic pressure to positive-pressure ventilation decreases preload further and can precipitate and abrupt cardiovascular collapse.**

Introduction

The pericardium consists of two layers; the parietal layer and the fibrous pericardium. Pericardial fluid drains via the right lymphatic duct and the thoracic duct into the right pleural space. A pericardial effusion is defined as the accumulation of fluid (exudate, transudate, blood or chylus) within the pericardial cavity. Normally, this cavity contains 25 to 50 mL of fluid and serves as a lubricant between the visceral and parietal layers of the pericardium. More fluid can be accommodated in the short term, up to about 200 mL. The pericardial sac can accommodate up to 2 L with little clinical consequence if this fluid accumulates slowly. Above these values, the physiological process of cardiac tamponade will occur.

Cardiac tamponade is defined as an accumulation of pericardial fluid that inhibits the diastolic filling of the atria and ventricles and, if left untreated, will result in a clinical state of shock. The diagnosis is confirmed by echocardiography, which can also diagnose an early 'compensated' stage of this process.

The simplest classification for cardiac tamponade is traumatic (dealt with elsewhere in this book) and non-traumatic (Fig. 5.6.2), as not only the aetiology but also the clinical course and approach to management of these clinical scenarios are very different.

Clinical features

History

The symptoms of cardiac tamponade can be non-specific and their onset and course depend on whether the condition is acute or gradual. A high index of suspicion for the condition and a thorough knowledge of the clinical settings in which

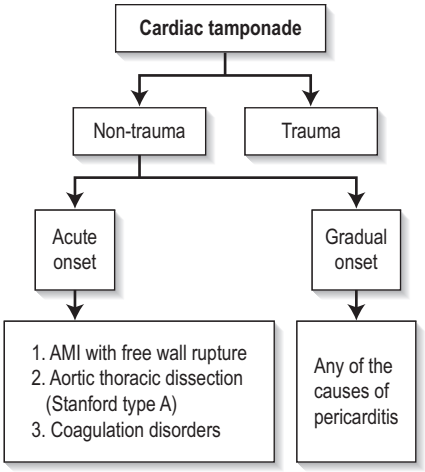

FIG. 5.6.2 Causes of pericardial effusion and cardiac tamponade. *AMI*, Acute myocardial infarction.

tamponade can occur is important. The commonest symptom of cardiac tamponade is dyspnoea (sensitivity 87% to 89%). Other symptoms relate to those of diminished cardiac output (e.g. faintness, dizziness, apprehension) or to the underlying disease process (e.g. pain of pericarditis).

Examination

Generally clinical signs are difficult to elicit and non-specific. The classic signs are those of the Beck triad: hypotension, diminished heart sounds and elevated JVP. It should be noted that cardiac tamponade may be present in the absence of an elevated JVP in conditions of significant hypovolaemia and that diminished heart sounds are a subjective finding. Furthermore, the absence of hypotension does not rule out cardiac tamponade—and, in some cases, hypertension may be present.

The most common clinical features are dyspnoea (sensitivity 87% to 89%), tachycardia (sensitivity 77%), pulsus paradoxus greater than 10 mm Hg (sensitivity 82%) and elevated JVP (sensitivity 76%). Loss of the apical impulse or, if present, an area of cardiac dullness extending beyond the apical impulse may give a clinical clue to the presence of an effusion. If cardiac function is otherwise normal, the lung fields are typically 'clear'. There may be associated pleural effusions and signs of pericarditis (e.g. fever, pericardial rub). Pleuropericardial rubs may still be heard even in the presence of a large effusion.

Differential diagnosis

The differential diagnosis of cardiac tamponade is given in Box 5.6.1.

Box 5.6.1 The differential diagnosis of cardiac tamponade

Massive pulmonary embolism
Tension pneumothorax
Superior vena cava obstruction
Chronic constrictive pericarditis
Air embolism
Right ventricular infarct
Severe congestive heart failure/cardiogenic shock
Extrapericardial compression: haematoma, tumour

Clinical investigations

Chest x-ray

The cardiac silhouette is often normal in cases of acute tamponade. At least 250 mL of fluid must be present within the pericardial cavity before an increase in the cardiac silhouette can be appreciated. In sub-acute or chronic cases, cardiomegaly is common, but it is a non-specific finding and of limited practical use. Classically, the cardiac silhouette is globular or shaped like a water bottle. The best indicators of a possible effusion are cardiomegaly where there has been a relatively acute increase in size and cardiomegaly with clear lung fields, The larger the cardiac silhouette, the greater should be the index of suspicion.

Electrocardiography

This may provide clues to the presence of an effusion, with low voltages and electrical alternans but, again, does not indicate whether tamponade is occurring.

Point of care ultrasound

Point-of-care ultrasound (POCUS) performed in critical care areas is an excellent screening test if tamponade is suspected; it is reported to have a 75% sensitivity for detecting pericardial effusion.[7] Although tamponade cannot be proven, the presence of pericardial fluid provides supportive evidence for the diagnosis.

Echocardiography

Echocardiography is the current 'gold standard' investigation for the diagnosis of cardiac tamponade. It is the most specific and sensitive investigation for the detection of an effusion and of the process of tamponade. It can be performed rapidly and non-invasively (in the case of TTE). In patients in whom a transthoracic study is difficult to perform or in whom the result is equivocal, then a transoesophageal (TOE) study may be performed. This technique may also detect occult loculated effusions missed by TTE and can be performed in the intubated patient during cardiopulmonary resuscitation (CPR). Furthermore, echocardiography can provide valuable information about associated cardiac function. It may also detect the process of tamponade before significant clinical signs develop.

It is important to remember that clinically significant tamponade is a clinical diagnosis and that 'echocardiographic signs of tamponade' are not in themselves an indication for acute intervention.

Computed tomography and magnetic resonance imaging

CT and MRI are sensitive and specific for the detection of pericardial fluid and are good alternatives if echocardiography is not available. Neither is suitable in the critically ill patient.

Haemodynamic monitoring

In the intensive care unit (ICU) setting, pulmonary artery catheter findings of 'equalization' of the right heart diastolic pressures (i.e. right atrial, right ventricular end-diastolic, diastolic pulmonary artery and pulmonary artery wedge pressures) suggest the diagnosis of cardiac tamponade.

Treatment

The treatment for cardiac tamponade is drainage of the pericardial fluid.

General measures

Medical management aims to improve the clinical condition while arrangements for drainage are being made. Oxygenation should be optimized. Fluid loading may provide some minor 'temporizing' support of the cardiac output. Inotropic agents are usually ineffective. Mechanical ventilation may cause a sudden drop in blood pressure as the positive intrathoracic pressure further impairs cardiac filling.

Drainage procedures

Pericardiocentesis is best performed in the cardiac catheterization laboratory under fluoroscopic or ultrasound guidance.[8,9] Surgical drainage is required for purulent or recurrent effusions and when tissue is required for diagnosis; a subxiphoid approach is preferred.

'Blind' needle pericardiocentesis should be considered a method of last resort, particularly as POCUS becomes more widely established.[9] It is best reserved for the peri-arrest patient, as it can be technically difficult and has significant complications, especially when smaller volumes of fluid are involved. If it is to be carried out, it should be followed up with the insertion of an indwelling 'pigtail'-type catheter for ready aspiration should the patient's condition deteriorate. CPR in the arrested patient will not be effective in cases of cardiac tamponade without immediate needle drainage followed by thoracotomy.

Thoracotomy without attempts at drainage should be performed when definitive surgical repair of the causative pathology is necessary—for example, in trauma, rupture of the myocardium and dissecting thoracic aneurysm causing cardiac tamponade. Attempts at drainage before definitive repair in the case of dissecting aortic aneurysm may be lethal.

Disposition

Pericardial effusion may, with time, lead to cardiac tamponade. All cases of cardiac tamponade will lead to shock and death if left untreated, the rapidity of which will depend on the amount of fluid present, the rate at which it accumulated and the compliance of the pericardium.

Patients with clinically 'compensated' non-traumatic cardiac tamponade should be closely monitored pending urgent definitive drainage under image-guided techniques. In cases of decompensated tamponade, urgent drainage is required and the choice of management will depend on the aetiology, clinical urgency and expertise available.

CONTROVERSIES

- The distinction between clinical and echocardiographic tamponade with the advent of more sensitive imaging
- The type and timing of drainage procedures in the critically ill

MYOCARDITIS

ESSENTIALS

1 **Myocarditis is most commonly caused by viral infection and the majority of cases run a benign course with full recovery.**

2 **Acute fulminating myocarditis can occur with life-threatening arrhythmias, cardiac failure and death. Survivors of these episodes may, however, make a full recovery with supportive treatment.**

3 **Myocarditis may present in a similar manner to myocardial infarction, including similar chest pain, ECG changes and elevation of cardiac biomarkers.**

4 **Long-term follow-up is important in patients who have had myocarditis, as some may progress to a chronic form with the development of dilated cardiomyopathy.**

Introduction

The World Health Organization's (WHO) definition of myocarditis is an inflammatory disease of the myocardium diagnosed by established histological, immunological and immunohistochemical criteria.[10] It is frequently associated with pericarditis, resulting in a myopericarditis. Prognosis varies according to the underlying aetiology. The treatment of many forms of myocarditis is symptomatic, but immune, histo-chemical and molecular biological analysis of endomyocardial biopsy (EMB) as well as autoantibody serum testing is important to identify those in whom specific therapy is appropriate.

Pathogenesis and pathophysiology

A wide range of viral, fungal, bacterial, protozoal and parasitic pathogens as well as toxins, drugs and immune-mediated diseases cause myocarditis. The more common of these are shown in Table 5.6.4. Molecular techniques, mainly reverse transcriptase (RT)–polymerase chain reaction (PCR) amplification, suggest that viral infections are the most common cause of myocarditis. The exact mechanism by which viral myocarditis and its longer-term complications develop is unknown. It is considered to involve an interplay of several factors including direct damage by the virus itself, damage by the host's immune responses and individual genetic predisposition.

Table 5.6.4 Commoner causes of myocarditis

Viral	Adenovirus Coxsackie B virus Cytomegalovirus Human herpesvirus 6 Human immunodeficiency virus Influenza A Herpes simplex virus 1 Parvovirus Respiratory syncytial virus
Toxin or drug	Anthracyclines Trastuzumab Ethanol Clozapine Snake or scorpion bite Ionizing radiation
Immune-mediated	Chagas disease Sarcoidosis Scleroderma Systemic lupus erythematosus Alloantigen (heart transplant recipient) Kawasaki disease
Bacteria	*Rickettsia* species *Leptospira* *Coxiella burnetii* *Corynebacterium diphtheriae* *Mycoplasma pneumoniae*
Protozoa, fungi and parasites	*Toxoplasma*, *Cryptococcus* species

Epidemiology

Given its highly variable clinical presentation, the real incidence of myocarditis is unknown. It accounts for up to one-third of cases of dilated cardiomyopathy (DCM).

Clinical features

The clinical spectrum of myocarditis may manifest as any of the following:

- Asymptomatic/subclinical
- Fever with 'viral' illness, with minimal cardiac features
- Acute myopericarditis
- Unexplained arrhythmias, including conduction delays
- Unexplained cardiac failure, ranging from mild to cardiogenic shock
- Sudden unexpected cardiac death
- Delayed (years later) DCM

History

Many cases of myocarditis are asymptomatic. There may be a history of an antecedent viral illness, and 10 to 14 days later symptoms relating to cardiac involvement develop, such as arrhythmias causing palpitations or dizziness or cardiac failure causing shortness of breath. Pleuritic-type pain may be a feature owing to an associated pericarditis. Myocarditis may also present similarly to acute myocardial infarction, with chest pain, ischaemic ECG changes and elevated cardiac biomarkers. This presentation is more common in younger patients with few cardiac risk factors, a preceding viral illness and subsequent normal coronary angiography.

Examination

A fever may be present; however, patients are often afebrile. Sinus tachycardia is often found and is said to be 'out of proportion' to the degree of fever. Other arrhythmias may also occur. A pericardial rub due to an associated pericarditis may be present. There may be signs of heart failure, ranging from mild to pulmonary oedema or cardiogenic shock.

First-line clinical Investigations

A definitive diagnosis of acute viral myocarditis cannot be made in the ED and must, in the first instance, be presumptive. Presentation scenarios may include the young patient who presents with cardiac failure, shock or arrhythmias for which there is no obvious aetiology. Testing may provide supportive evidence for the diagnosis.

Laboratory tests

A number of investigations can give supporting evidence to a diagnosis of myocarditis. These include elevation of the white cell count, ESR and/or CRP as well as cardiac biomarkers including troponin and brain natriuretic peptide (BNP). These parameters can also be used to assess response to treatment.

Chest x-ray

This may show cardiomegaly with changes of congestive heart failure in severe cases but may also be normal.

Electrocardiography

In most cases, the ECG will be abnormal; however, the changes are not specific for myocarditis. The most common finding is sinus tachycardia and non-specific ST-T-wave changes. ST- elevation is usually concave and diffuse without reciprocal changes. Rhythm disturbances of any type may occur, including conduction delays. A-V block in the presence of mild left ventricular dilation is suggestive of Lyme disease, cardiac sarcoidosis or giant cell myocarditis.

Echocardiography

This can give supportive evidence but is not diagnostic. Global wall motion abnormalities are a characteristic finding but, in some cases, more regional abnormalities will be seen. An associated effusion may be found. Evidence of myocardial failure can be found with ventricular cavity dilation and reduced ejection fraction.

Cardiac magnetic resonance imaging and electrocardiography-gated multidetector computed tomography

Cardiac MRI is being increasingly used to assist in the diagnosis of myocarditis and monitoring disease progression. Regions of myocarditis are reported to correlate closely with regions of abnormal signal on MRI. It may also be used to identify target sites for biopsy. ECG-gated multidetector CT (MDCT) is likely to show abnormal myocardial late hyper-enhancement, either transmural or sub-epicardial. The ESC task force on myocarditis strongly recommends EMB as the gold standard for the diagnosis of myocarditis.

Coronary angiography

Coronary angiography may have to be performed to exclude significant coronary artery disease.

Endomyocardial biopsy

This is currently the only way to make a definitive diagnosis. Despite endomyocardial biopsy being considered the gold standard, the following problems may be encountered:

- Acute myocarditis may be patchy and diagnosis may be missed on a single specimen.
- False-positive results are possible.
- It may overestimate more minor cases of myocarditis.

There has long been debate about patient selection for EMB, particularly after the negative results of the Myocarditis Treatment Trial.[10] Patient selection remains controversial, even with case reports of treatment of myocarditis with interferon after PCR detection of adenovirus and enterovirus on EMB. Complications include venous injury, arrhythmias and cardiac perforation.

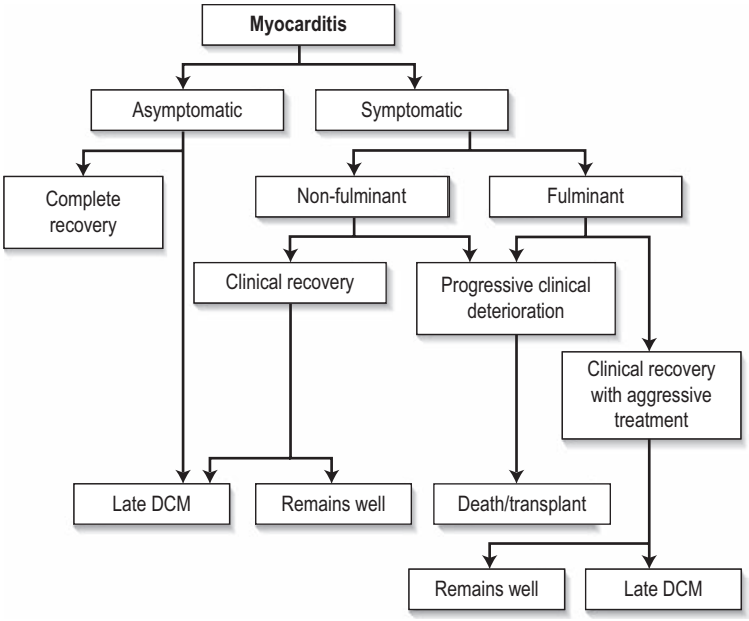

FIG. 5.6.3 Natural history of myocarditis. *DCM*, Dilated cardiomyopathy.

Treatment and disposition

Treatment consists of therapy for heart failure and supportive care, progressing to implantable defibrillators and aggressive mechanical assist devices as bridging therapy and, in severe cases, heart transplantation.

Supportive treatment should attend to airway, breathing and circulation. Oxygenation is important and, in cases of pulmonary oedema, ventilatory support (non-invasive or invasive) may be necessary. Analgesia will be required if pain is a significant feature. Strict bed rest is advised, as exercise has been shown to increase the degree of myocyte necrosis. Diuretic therapy, vasodilators and inotropic support are used to optimize cardiac filling and increase cardiac output. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs) should be initiated early. Complicating arrhythmias are treated along conventional lines. In patients who develop cardiogenic shock, intervention should be early and aggressive. The use of inotropes, extracorporeal membrane oxygenation (ECMO) or ventricular assist devices is recommended as a bridge to transplant or recovery. In severe refractory cases, cardiac transplantation may ultimately be required. Immunosuppression trials have to date been largely disappointing, with no randomized trial showing sustained clinical or mortality benefit. Preliminary data suggest that administration of interferon-β (INF-β) to patients with persistent depression of left ventricular ejection fraction (LVEF) and PCR-positive genome expression for enteroviral or adenoviral DNA may enhance viral clearance and improve LVEF. Multicentre trials are yet to be conducted.

Survivors of myocarditis must be followed up for the possible future development of DCM. Patients should not undertake any competitive sport for 6 months after the onset of clinical myocarditis. Athletes may return to training if left ventricular function, wall motion and dimensions return to normal, arrhythmias are absent, serum markers of inflammation have resolved and the ECG has normalized.

All patients with suspected acute myocarditis should be admitted to the cardiac care unit (CCU)/ICU.

Prognosis

Prognosis or acute myocarditis depends on the severity of symptoms and signs, histological classification and biomarkers. Clinical predictors of a fatal outcome include hypotension and elevated pulmonary wedge pressure. Biochemical markers associated with poorer outcome include serum Fas, Fas ligand, anti-myosin autoantibodies and interleukin-10 (IL-10) levels. Increased tumour necrosis factor-α (receptor 1) expression and persistent viral genome expression for selected viruses have also recently been associated with progressive failure of recovery of LVEF.

Complications at presentation are usually the result of arrhythmias and heart failure; however,

the majority of cases will run a benign course with a full recovery. Occasionally an acute fulminant course may occur, with intractable arrhythmias or, more often, with acute heart failure rapidly progressing to cardiogenic shock and death. However, survivors of this fulminant course will often make a complete recovery.

The whole spectrum of asymptomatic through to fulminant cases may progress to a chronic course. Myocarditis is thought to be the cause of up to one-third of cases of DCM. It may also explain some instances of recurrent unexplained arrhythmias and sudden unexpected cardiac death, especially in younger age groups. See Fig. 5.6.3 for a summary of the natural history of myocarditis.

CONTROVERSIES

- The role of interferon, immunoglobulin and corticosteroids in the management of viral myocarditis
- Optimal diagnostic strategy, in particular the place of MRI
- The role of EMB in patients suspected of having autoimmune disease

5.7 Heart valve emergencies

Kevin K.C. Hung • Colin A. Graham

ESSENTIALS

1 Infective endocarditis is effectively a multiorgan disease and is an often missed diagnosis.

2 There has been a shift in the predominant organism in infective endocarditis from *Streptococcus viridans* to *Staphylococcus aureus*, and nosocomial infections are becoming more common.

3 Degenerative heart disease and the presence of prosthetic valves are currently the high-risk factors for infective endocarditis in developed countries.

4 Antibiotic prophylaxis in patients with valvular or congenital heart disease is an important consideration in the appropriate clinical context.

5 The causes of acute deterioration in chronic valve lesions must be recognized and treated expeditiously to prevent life-threatening haemodynamic instability.

Introduction

Heart valve emergencies are a cause of sudden deterioration in cardiac function. The underlying cause depends on the valve involved.

Infective endocarditis

This is a commonly missed diagnosis. A high index of suspicion must be maintained, as delays in diagnosis will increase the mortality and morbidity.

Epidemiology

The incidence of infective endocarditis is 3 to 10 episodes/100,000 person-years, of which prosthetic valve endocarditis (PVE) accounts for 20% to 30%. The male-to-female ratio is ≥2:1, and it is more common in the fifth and sixth decades of life.

In the developing countries, rheumatic heart disease is the commonest risk factor for infective endocarditis. Despite a fall in the incidence of rheumatic fever in developed countries, the prevalence of infective endocarditis has not fallen. In the developed world, the risk factors include the following:

- Host-related factors
  - Poor oral hygiene
  - Intravenous drug use (IVDU)
  - Severe renal disease, on haemodialysis
  - Diabetes mellitus
  - Mitral valve prolapse—particularly in the presence of valve incompetence or thickening of the valve leaflets
  - Degenerative valve sclerosis associated with age (mitral valve most common, then aortic, tricuspid and pulmonary valves, respectively)
- Procedure-related factors
  - Infected intravascular device
  - Post–genitourinary procedure
  - Post–gastrointestinal procedure
  - Surgical wound infection

Pathology and pathogenesis

In infective endocarditis, the interactions between host and organism are complex. Platelet-fibrin deposits form at sites of endothelial damage;

Table 5.7.1 Bacterial pathogens associated with host categories

IVDU	*Staphylococcus aureus*; 80% of tricuspid valve involvement is due to this pathogen Streptococcal species *Pseudomonas aeruginosa* Multiple organisms
IVDU with HIV infection	Unusual organisms, such as *Salmonella*, *Listeria*, *Bartonella*
Insulin-dependent diabetes mellitus	*Staphylococcus aureus*
Prosthetic heart valves, within 2 months of valve surgery	*S. epidermidis* *S. aureus* *Enterococcus* species
Prosthetic valves, more than 2 months after valve surgery	*S. aureus* *Streptococcus viridans*
Pre-existing malignancy or procedures involving the genitourinary or gastrointestinal tract	*Enterococcus* species

HIV, Human immunodeficiency virus; *IVDU*, intravenous drug use.

this is known as non-bacterial thrombotic endocarditis. Invasion and multiplication by a virulent microbe lead to enlargement of these vegetations, which become infected. The consequences of this are the basis of the clinical complications of infective endocarditis. The vegetations can fragment and embolize, leading to distal foci of infection, called septic emboli. Obstruction of vessels by these fragments can also result in tissue ischaemia and infarction. Seeding from these fragments perpetuates the bacteraemia. Local destruction of the valve may produce intracardiac complications, such as rupture of the chordae tendineae, abscess of the valve annulus and conduction problems.

Staphylococcus aureus, entering through a breach in the skin, has surpassed *Streptococcus viridans* as the commonest bacterial pathogen in both native valve endocarditis (NVE) and PVE. This change reflects better dental care and an increased incidence of nosocomial infections, although significant geographical variation exists. In proven *S. aureus* bacteraemia, the incidence of infective endocarditis is 13% to 25%. Overall, three major pathogens account for more than 80% of cases: *S. aureus*, *Streptococcus* species and *Enterococcus* species.

Nosocomial infective endocarditis is defined as endocarditis occurring after 72 hours of hospital admission or within 4 to 8 weeks of an invasive procedure performed in a hospital. Organisms responsible for nosocomial endocarditis are *Staphylococcus* species (>75%, mainly *S. aureus*) and *Enterococcus* species in genitourinary and gastrointestinal tract procedures. Organisms associated with particular host categories are shown in Table 5.7.1.

Fungal infections account for less than 10% of cases and are most common in IVDU, the immunocompromised and those with prosthetic valves. The gram negative HACEK group (*Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae*) are growing in importance and lead to large vegetations that may result in large vessel embolization or cardiac failure. Endocarditis caused by the HACEK group is often culture-negative, as these bacteria are fastidious.

Prevention

The decision to administer a procedural prophylactic antibiotic to at-risk patients depends on the assessment of the risk of endocarditis in the abnormal valve coupled with the risk of bacteraemia of the procedure being undertaken. High-risk valve lesions are prosthetic valves, mitral valve prolapse with significant incompetence and acquired dysfunctional valves in indigenous patients (because of the high incidence of rheumatic heart disease). The indications for antibiotic prophylaxis have been significantly reduced in major infective endocarditis prophylaxis guidelines, and many now recommend against prophylaxis for gastrointestinal or genitourinary tract procedures. Prophylaxis for dental procedures that involve manipulation of either gingival tissue or the periapical region of teeth or perforation of the oral mucosa is reasonable for those with the highest risk of adverse outcomes from endocarditis (Box 5.7.1). These changes are due to the changes in the risk-benefit ratio of prophylactic treatment. It is believed that infective endocarditis is much more likely to result from frequent exposure to random bacteraemias associated with daily activities than from those listed procedures.

When indicated, a single-dose antibiotic 30 to 60 minutes before the procedure is now recommended. Current recommendations from the European Society of Cardiology (ESC) suggest

- KH amoxicillin or ampicillin 2 g orally or intravenously for adults (50 mg/kg for children) or
- clindamycin 600 mg orally or intravenously if patient is allergic to penicillins

Box 5.7.1 Highest-risk cardiac conditions for which prophylaxis with dental procedures is recommended

Antibiotic prophylaxis is reasonable before dental procedures that involve the manipulation of gingival tissue, manipulation of the periapical region of teeth or perforation of the oral mucosa in patient with

1. Prosthetic cardiac valves
2. Prosthetic materials used for cardiac valve repair
3. Previous infective endocarditis
4. Unrepaired cyanotic congenital heart disease or those repaired but with residual defects
5. Cardiac transplant with valve regurgitation due to a structurally abnormal valve

(Adapted with permission from Nishimura RA, Otto CM, Bonow RO, et al. 2017 AHA/ACC focused update of the 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Circulation*. 2017;135(25):e1159–e1195.)

Clinical features

Infective endocarditis should be considered a multisystem disease. The symptoms and signs are non-specific, compounding the difficulty of diagnosis. Symptoms usually occur within 2 months of the event responsible for the initiation of bacteraemia, although this may be difficult to identify in retrospect. It is important to suspect infective endocarditis in patients with an unexplained fever and a predisposing factor.

The two most frequent systemic features are fever and malaise. Fever is present in 80% to 85% of cases; usually above 38°C but rarely above 39.4°C. It can be absent in the severely debilitated, the elderly and those with cardiac failure, chronic renal failure, liver failure, recent antibiotic use and if the infection is by a low-virulence organism.

Malaise is reported in up to 95% of cases. Other symptoms are variable and non-specific and may include headache, confusion, cough, chest pain (more common in IVDU), dyspnoea, abdominal pain, anorexia, weight loss and myalgia.

Other clinical features include immunological phenomena as well as those related to the lesion itself and systemic embolization. Immunological phenomena include glomerulonephritis, Osler nodes, Roth spots and an elevated rheumatoid factor.

A new or changed incompetent murmur may be found on clinical examination of the heart. However, in 70% to 95% of cases, a murmur is already present; hence the discovery of an acute murmur is an uncommon but highly significant finding. The absence of a murmur does not exclude the diagnosis of infective endocarditis. A new murmur or a change of murmur is more likely in patients with a prosthetic valve or congestive cardiac failure.

Petechiae are commonly found in the palpebral conjunctivae and are also present in the mucosal membranes. Splinter haemorrhages under the fingernails, Osler nodes (painful tender swellings of the fingertips or

Table 5.7.2 Complications of infective endocarditis

Organ system	*Complications*
Cardiac	Congestive cardiac failure Valvular incompetence Perivalvular abscess Arrhythmias Cardiac rupture/tamponade Pericarditis Myocardial infarction Cardiac fistulae
Neurological	Stroke or TIA Cerebral abscess Intracranial haemorrhage from aneurysm rupture Meningitis/encephalitis
Renal	Renal infarction/abscess following septic embolization Immune-mediated glomerulonephritis
Other	Mycotic aneurysm of any artery Emboli to any organ, e.g. spleen, liver, skin

TIA, Transient ischaemic attack

toe pads), Janeway lesions (small haemorrhages with a slightly nodular character on the palms and soles) and Roth spots (oval retinal haemorrhages with a clear pale centre) are uncommon.

Complications

Congestive cardiac failure may occur and is usually a result of infection-induced valvular damage. Involvement of the aortic valve is more likely to cause congestive cardiac failure than mitral valve damage. The other cause is extension of the infective process beyond the valvular annulus. Involvement of the septum produces atrioventricular, fascicular and bundle-branch blocks. Cardiac rupture and tamponade have been reported but are rare. Pericarditis can result from extension into the sinus of Valsalva. Myocardial infarction can also occur as a result of infective embolism to the coronary arteries but is rare.

Neurological manifestations, the result of embolic events from left-sided lesions, are present in approximately 15% of patients and are more likely if the pathogen is *S. aureus*. These include meningoencephalitis, focal deficits, transient ischaemic attacks and stroke. Embolic stroke is the most frequent event, but intracranial haemorrhage may occur as a result of rupture or leak of a mycotic aneurysm, septic arteritis or bleeding into an infarct. The mortality is high.

Systemic embolization occurs in 40% of cases and gives rise to the peripheral manifestations of infective endocarditis. The embolization usually precedes the diagnosis. Its incidence falls with the administration of appropriate antibiotics. Embolization may involve any organ but skin; splenic, hepatic and renal emboli are most common. Notably, systemic emboli are absent in infective endocarditis of the tricuspid valve, but multiple pulmonary abscesses are characteristically present.

Renal dysfunction may be due to altered renal haemodynamics, immune complex–mediated glomerulonephritis or nephrotoxicity from medications. Splenomegaly is present in 30% of cases. This is due to splenic abscesses arising from direct seeding from the bacteraemia or from an infective embolus. It leads to persistent fever, abdominal pain and diaphragmatic irritation. Tender hepatomegaly may also be present. Anaemia is common.

Complications are summarized in Table 5.7.2.

Diagnosis

The diagnosis of infective endocarditis requires a high degree of suspicion along with integration of data from various sources. This is due to the non-specific nature of the clinical manifestations. The Duke criteria for infective endocarditis are a useful diagnostic tool that has good specificity and a negative predictive value above 92%. These combine patient risk factors, isolates from blood cultures, the persistence of bacteraemia, echocardiographic findings and other clinical and laboratory data. It has been regularly updated and the version in the latest 2015 European Society of Cardiology guidelines is shown in Boxes 5.7.2 and 5.7.3.

Severely ill patients with obvious sepsis should be treated without delay according to the 'Surviving Sepsis' guidelines. However, infective endocarditis commonly presents in a more insidious way. When fever is persistent and unexplained, infective endocarditis must be considered, particularly in situations such as the following:

- Patients with acquired or congenital valvular heart disease, a pre-existing prosthetic valve, hypertrophic cardiomyopathy, congenital heart disease (patent ductus arteriosus [PDA], ventricular septal defect [VSD], coarctation of the aorta), intracardiac pacemakers, central venous lines or intra-arterial lines or a new or changed cardiac murmur
- Patients with known bacteraemia. In *S. aureus* bacteraemia, the risk of infective endocarditis is higher if it is community acquired, there is no primary focus of infection, there is a metastatic complication and, in the context of an intravascular catheter being a possible focus of infection, if fever or bacteraemia is present for greater than 3 days despite removal of the catheter
- Cases with features of an embolic event, especially if recurrent
- Young patients with unexpected stroke or subarachnoid haemorrhage
- Patients with a history of IVDU, especially if there are pulmonary features, such as cough and pleuritic chest pain

Box 5.7.2 Duke criteria for the diagnosis of infective endocarditis: definition

Definite infective endocarditis
Pathological criteria

- Microorganisms demonstrated by culture or on histological examination of a vegetation, a vegetation that has embolize, or an intracardiac abscess specimen
- Pathological lesions; vegetation or intracardiac abscess confirmed by histological examination showing active endocarditis

Clinical criteria

- 2 major criteria or
- 1 major criterion and 3 minor criteria or
- 5 minor criteria

Possible infective endocarditis

- 1 major criterion and 1 minor criterion or
- 3 minor criteria

Rejected infective endocarditis

- Firm alternate diagnosis or
- Resolution of symptoms suggesting infective endocarditis (IE) with antibiotic therapy for ≤4 days or
- No pathological evidence of IE at surgery or autopsy with antibiotic therapy for ≤4 days or
- Does not meet criteria for possible IE as above

(From Li JS, Sexton DJ, Mick N, Nettles R, Fowler VG Jr, Ryan T, Bashore T, Corey GR. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis.* 2000;30: 633–638.)

Box 5.7.3 Definition of the Duke criteria for the diagnosis of infective endocarditis

Major criteria

1. Blood cultures positive for IE
   a. *Typical* micro-organisms consistent with IE from two separate blood cultures:
      - *Viridans* streptococci, *Streptococcus gallolyticus (Streptococcus bovis)*, HACEK group, *Staphylococcus aureus* or
      - Community-acquired enterococci, in the absence of a primary focus or
   b. *Microorganisms* consistent with IE from persistently positive blood cultures:
      - ≥2 positive blood cultures of blood samples drawn >12 h apart or
      - All of 3 or a majority of ≥4 separate cultures of blood (with first and last samples drawn ≥1h apart) or
   c. *Single* positive blood culture for *Coxiella burnetii* or phase I IgG antibody titre >1:800
2. Imaging positive for IE
   a. *Echocardiogram* positive for IE:
      - Vegetation
      - Abscess, pseudoaneurysm, intracardial fistula
      - Valvular perforation or aneurysms
      - New partial dehiscence of prosthetic valve
   b. Abnormal activity around the site of prosthetic valve implantation detected by FDG PET/CT (only if the prosthesis was implanted by >3 months) or radiolabelled leukocytes SPECT/CT.
   c. Definite paravalvular lesions by cardiac CT.

Minor criteria

1. Predisposition such as predisposing heart condition or injection drug use.
2. Fever defined as temperature >38°C.
3. Vascular phenomena (including those detected by imaging only): major arterial emboli, septic pulmonary infarcts, infectious (mycotic) aneurysm, intracranial haemorrhage, conjunctival haemorrhages, Janeway lesions.
4. Immunological phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor.
5. Microbiological evidence: positive blood culture but does not meet a major criterion as noted above or serological evidence of active infection with organism consistent with IE.

CT, computed tomography; *FDG PET-CT*, fluorodeoxyglucose positron emission tomography/computed tomography; HACEK, *Haemophilus, Actinobacillus, Cardiobacterium, Eikenella, Kingella;* SPECT, single photon emission computed tomography.
(From Li JS, Sexton DJ, Mick N, Nettles R, Fowler VG Jr, Ryan T, Bashore T, Corey GR. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis.* 2000;30:633–638.)

- Cases of persistent bacteraemia or fever despite treatment, congestive cardiac failure or new ECG features of atrioventricular heart block, fascicular block and bundle branch block

Clinical investigations

Blood cultures

In the stable patient without evidence of complications, three sets of blood cultures should be collected from different vascular puncture sites at least 1 hour apart over a 24-hour period prior to the start of empirical antibiotics. Timing of venipuncture does not need to coincide with fever, as bacteraemia is continuous. Both aerobic and anaerobic media should be used for each set. Arterial and venous blood samples are equally likely to be infected.

In unwell patients, empirical antibiotics should not be delayed and the timing between blood cultures can be truncated.

Full blood count

Anaemia (usually normochromic and normocytic) is demonstrated in most patients. There is often a leucocytosis in acute infective endocarditis, but this may be absent in subacute cases. Thrombocytopaenia is rare.

Inflammatory markers

The erythrocyte sedimentation rate (ESR) is a non-specific test; however, the ESR is raised in almost all patients to a magnitude of greater than 55 mm/h. A normal ESR makes infective endocarditis unlikely.

C-reactive protein (CRP) is also non-specific but has been reported to be more sensitive than ESR. Procalcitonin levels are also raised in patients with infective endocarditis, although this test may not be as sensitive as CRP.

Urinalysis

The urinalysis is abnormal in 50% of cases, with proteinuria and microscopic haematuria. Normal renal function may be maintained.

Echocardiography

Echocardiography provides morphological confirmation of the diagnosis by visualizing heart valves and vegetations, assessing haemodynamic impact and identifying complications (such as perivalvular involvement and abscesses). Transthoracic echocardiography (TTE) is now recommended as the first-line imaging modality in suspected infective endocarditis and must be performed rapidly, as soon as infective endocarditis is suspected. In NVE, TTE has a specificity for vegetations of 95% and a sensitivity of 70%. The reason for the low sensitivity is the technical difficulties in those with chest-wall deformity, chronic airway limitation and obesity. In PVE, the sensitivity of TTE for vegetations is 50% overall, but sensitivity is especially poor for mitral valve vegetations. However, TTE has the benefit of being non-invasive. The indication for TTE in infective endocarditis is suspected NVE with no technical hindrance to imaging. If the result is negative and coupled with a low clinical suspicion, subsequent transoesophageal echocardiography (TOE) is not warranted.

TOE is invasive and more difficult to obtain. It has a specificity of 90% and the sensitivity is 92% to 96% for vegetations. In particular, it is more likely to detect perivalvular lesions and abscesses. The indications for TOE in suspected infective endocarditis are

- prosthetic valves/intracardiac device
- poor-quality TTE
- negative TTE but high clinical suspicion of infective endocarditis

In patients with positive TTE, subsequent TOE should be considered due to its better

sensitivity and specificity, particularly for the diagnosis of abscesses and measurement of vegetation size.

Despite the qualities of TOE, a negative study does not exclude the diagnosis.

Treatment

Management involves the use of antibiotics to eradicate the pathogen and other interventions to deal with the intracardiac and distal complications of the infections. Cardiac surgery may be required, the timing of which is difficult to judge. Early specialist referral is critical, particularly if signs and symptoms of congestive heart failure are present.

Antibiotic therapy

A microbiological diagnosis is not possible in the emergency department (ED). Toxic patients must start empirical antibiotics after the collection of three sets of cultures at three separate vascular puncture sites. These do not need to be separated in time if patients are clearly septic.

Antibiotic penetration of vegetations is difficult; these are a mixture of fibrin, platelets and bacteria and it is hard to achieve local bactericidal drug levels. The principles of antibiotic therapy are to use antibiotics in combination, with empirical therapy determined by the most likely group of organisms in a given patient and to employ a long duration of therapy, usually 4 to 6 weeks. Antibiotic choice is tailored once the pathogen and its sensitivities are known. The choice of empirical antibiotics depends on local epidemiology, especially antibiotic resistance, and whether patients have received prior antibiotic therapy.

The current ESC recommendations for empirical antibiotic treatment are outlined here.

For community-acquired NVE or late prostatic valves (>12 months post-surgery) endocarditis:

- ampicillin 12 g/day IV in 4 to 6 doses with
- (flu)cloxacillin or oxacillin 12 g/day IV in 4 to 6 doses with
- gentamicin 3 mg/kg IV or IM daily

For penicillin-allergic patients:

- vancomycin (30 to 60 mg/kg/day IV in 2 to 3 doses) with
- gentamicin 3 mg/kg IV or IM daily

For early PVE (<12 months post-surgery) or health care–related endocarditis:

- vancomycin (30 mg/kg/day IV in 2 doses) with
- gentamicin 3 mg/kg IV or IM daily with
- rifampin 900 to 1200 mg IV or orally in 2 to 3 divided doses

Local advice should be sought on appropriate empirical therapy depending on local bacterial endocarditis epidemiology and antibiotic sensitivities.

Surgery

Native-valve endocarditis Patients with congestive cardiac failure, evidence of embolization to major organs and vegetations greater than 10 mm in size have been shown to have poor outcomes on medical management alone.

For haemodynamically unstable patients, the indications for surgery are

- cardiac failure, aortic incompetence or mitral incompetence
- complications including heart block, annular or aortic abscesses or the presence of perforating lesions (e.g. perforated valve leaflets)
- virulent organisms resistant to treatment or
- fungal endocarditis

The indications in haemodynamically stable patients are less clear, but early specialist support should be obtained.

Prosthetic valve endocarditis The indications for surgery include cardiac failure, valve dehiscence, valve dysfunction (increased stenosis or incompetence) and complications such as abscess formation.

Anticoagulation

Anticoagulation with aspirin or warfarin has not been shown to reduce the risk of embolic events and may contribute to an increased risk of bleeding, especially intracranial bleeding. Anticoagulants should be used with caution only where there is a clear indication for them distinct from endocarditis (e.g. presence of a prosthetic valve).

Prognosis

The overall mortality for native and PVE is 20% to 25% at 1 year and 50% at 10 years. The major causes of death are congestive cardiac failure, haemodynamic deterioration and embolic complications. Nosocomial endocarditis has a higher inpatient mortality (24% to 50%) compared with community-acquired endocarditis (16% to 20%). In right-sided endocarditis in IVDUs, the mortality is 10%. The most important determinant of mortality is congestive cardiac failure.

Mortality is also related to the organism isolated. It is greater than 50% in *Pseudomonas aeruginosa*, *Enterobacteriacae* or fungal infection. *S. aureus* infection has a mortality of 25% to 47%.

The rate of relapse varies with the causative organism and occurs usually within 2 months of stopping antibiotics. The rate of relapse in NVE is less than 2% for *S. viridans*, 11% for *S. aureus* and 8% to 20% for enterococci. In PVE, the relapse rate is 10% to 15%.

Long term, approximately 50% of these patients require heart valve replacement.

Acute aortic incompetence

Aetiology and pathophysiology

The causes of acute aortic valve incompetence are infective endocarditis, proximal aortic dissection, blunt chest trauma and spontaneous rupture of an abnormal valve.

The result is an acute and progressive volume overload within the left ventricle that has not had time to compensate. The consequently elevated left ventricular end-diastolic pressure is transmitted to the left atrium and pulmonary venous bed, leading to pulmonary oedema. Cardiac output is diminished as the stroke volume is shared between forward and regurgitant flow into the left atrium. The compensatory mechanisms via the sympathetic nervous system result in positive inotropy and chronotropy. However, the rise in systemic peripheral vascular resistance impedes left ventricular outflow and worsens the regurgitation. Ventricular oxygen demand is also increased and myocardial ischaemia is a major risk even if coronary artery disease is not present.

Clinical features

Acute aortic incompetence is poorly tolerated. Severe congestive cardiac failure and hypotension are typical. Ischaemic chest pain may be reported. The diastolic murmur is soft and extends only to mid-diastole. The first heart sound is also of low intensity. The pulse pressure is large, and tachycardia is almost always present.

Clinical investigations

The chest x-ray (CXR) may reveal the underlying cause. Pulmonary congestion is often present without cardiac enlargement. Echocardiography is diagnostic and provides useful data especially in the selection of timing for surgery. TTE/TOE is required if aortic root dissection is thought to be the cause and, in most EDs, urgent computed tomographic imaging will lead to a more rapid diagnosis, and this should be the key diagnostic tool. Cardiac catheterization can be considered before surgery but is usually not performed in acutely unstable patients requiring emergency cardiac surgery for aortic dissection.

Treatment

Valve replacement is crucial to survival, as severe left ventricular failure is the commonest cause of death. Medical treatment with an inotropic agent (dopamine or dobutamine) and concurrent vasodilatation (with nitrates or nitroprusside) can be used, but these are only temporizing measures prior to surgery.

Intra-aortic balloon counterpulsation is contraindicated. β-Blockers should be used with caution, as the compensatory tachycardia will be prevented.

Acute deterioration in chronic aortic incompetence

Pathophysiology

In chronic aortic valve incompetence, the pathophysiology is dictated by the combination of pressure and volume overload. The initial stage of compensation is achieved by hypertrophy of the left ventricle. The left ventricular ejection fraction (LVEF) is never in the normal range even in the compensated stage. However, patients can be asymptomatic for decades. This is followed by the decompensated stage, where there is a significant reduction of the left ventricular ejection fraction, defined as an LVEF of 50% or less at rest. This results predominantly from volume overload. It is reversible initially, with full recovery of left ventricular function if aortic valve replacement (AVR) is performed. The decompensated phase eventually becomes irreversible with enlargement of the left ventricle. Symptoms become severe and surgery is less effective.

Decompensation can be the result of decreased myocardial contractility due to progressive left ventricular dilatation, myocardial ischaemia or excessive volume overload.

Apart from intrinsic abnormalities of the aortic valve, aortic root dilatation from various causes must be considered.

Clinical features

The clinical features are those of cardiac failure and angina. The patient is usually hypertensive. Clinical findings of severe disease are a wide pulse pressure, a displaced apical impulse, a diastolic murmur in the left third to fourth intercostal space, a third heart sound and an Austin-Flint murmur.

Clinical investigations

The aim of investigations is to identify those who will need surgery. Serial investigations are usually performed. The most important is the assessment of ejection fraction and left ventricular systolic and diastolic volumes by echocardiography. This also allows assessment of the aortic root and its size.

Treatment

Medical management

For symptomatic patients, medical management is aimed at improving left ventricular function as a temporizing measure prior to surgery. This is achieved by using vasodilators. The dose is titrated to the blood pressure, aiming to reduce it to a level tolerated by the patient. Medication options include nitrates, sodium nitroprusside and hydralazine. All of these reduce end-diastolic volume and increase forward flow. Nifedipine in a single dose does not consistently produce this result but may do so when used over a longer term.

Surgical management

Indications for AVR are

- symptomatic patient: angina or significant dyspnoea
- asymptomatic patients with ejection fraction ≤50%
- asymptomatic patients with severe left ventricular dilatation and left ventricular end-systolic volume of less than 55 mm or greater than 75 mm.

Prognosis

Patients with evidence of angina or cardiac failure have a poorer outcome. Mortality for those with angina is 10% per year; for those with cardiac failure, annual mortality rates approach 20%.

Acute deterioration in critical aortic stenosis

Patients with severely stenosed aortic valves can remain asymptomatic for many years. Medical treatment can achieve a 5-year survival of 40% and a 10-year survival of 20%. The risk of sudden death in the asymptomatic patient is 2%, even when critical stenosis is present. With the development of syncope and angina, the survival falls to 2 to 3 years. When complicated by cardiac failure, 50% of patients will die within 18 months if there is no surgical intervention.

Pathophysiology

Aortic valve stenosis restricts left ventricular outflow and imposes a pressure load on the left ventricle. The latter is hypertrophied, with consequent poor compliance, and it is at risk of ischaemia and dysrhythmia. Cardiac function is delicately balanced between preload and afterload. Preload on the hypertrophied ventricle is elevated to support the stroke volume, but not high enough to lead to pulmonary congestion. Systemic vascular resistance is elevated but does not cause an increase in the oxygen demand that cannot be met. The increased demand during exercise causes abnormal distribution of flow leading to vulnerability of the subendocardium to ischaemia. The reserve margin is slim. A small and sudden alteration in any of these factors will precipitate pump failure.

Causes of aortic stenosis include

- congenital bicuspid valve
- calcification of a normal valve, common in the elderly
- rheumatic heart disease, usually with associated mitral valve disease

Pathophysiology of acute deterioration

Causes of acute deterioration include the following:

- An acute fall in preload: hypovolaemia, excessive diuresis and vasodilatation.
- Atrial flutter or fibrillation: both of these are uncommon and should raise suspicion of associated mitral valve disease.
- Acute afterload reduction: this leads to a reduction in coronary artery perfusion and places the hypertrophied left ventricle at risk of ischaemia. It does not improve the left ventricular stroke volume, as the problem lies in the stenotic valve and not the systemic vascular resistance.

Clinical features

Patients with aortic stenosis may be asymptomatic for many years. Presentations to the ED may be for angina, syncope, left ventricular failure or hypotension. At worst, acute decompensation will result in acute pump failure, with shock and pulmonary oedema.

The murmur will have the expected features including aortic area location, systolic timing and radiation to the carotids. It will be less obvious and may be impossible to hear if cardiac output is poor. The most important finding consistent with critical stenosis is the paradoxical splitting of the second heart sound.

Clinical investigations

Electrocardiography, chest x-ray and cardiac markers

Indications for these are dictated by the clinical presentation.

Echocardiography

Echocardiography is the key diagnostic tool and allows assessment of transvalvular flow, transvalvular pressure gradients and the effective valve area.

Treatment

Medical therapy aims to relieve symptoms and optimize left ventricular function prior to definitive surgical management. Rapid reversal of the precipitant is essential.

Practice points

- Expedient treatment of atrial dysrhythmias may necessitate cardioversion. This helps by maximizing the contribution of atrial systole to left ventricular filling.
- Excessive reduction in preload will reduce stroke volume and hence cardiac output.
- Diuretics, digoxin and angiotensin converting enzyme inhibitors (ACEIs) should be used only with caution.
- Angina treatment requires aggressive treatment of the precipitating cause and possibly cautious use of nitrates and β-blockers.
- AVR is indicated for patients with severe aortic stenosis who are symptomatic or with left ventricular systolic dysfunction or an ejection fraction less than 50%.

- Aortic balloon valvotomy may be a reasonable bridge to surgery in haemodynamically unstable patients who are at high risk for AVR or to palliation in cases where AVR cannot be performed.
- Transcatheter aortic valve implantation (TAVI) is a percutaneous procedure developed for patients with a poor prognosis without treatment but who are at high risk if treated by open heart surgery. The procedure aims to implant a bioprosthetic aortic valve at the site of the native aortic valve with access usually achieved via the femoral artery. It was approved by the US Food and Drug Administration (FDA) in 2011. Experience is growing with this procedure and it is gaining in popularity, but for now it should be restricted to high-volume centres with experience in both patient selection and the performance of the procedure. Early referral to a specialist centre is important.

Acute deterioration in mitral stenosis

Pathophysiology

The size of the adult mitral orifice is 4 to 6 cm^2. Symptom onset occurs when the valve orifice is less than 2.5 cm^2 and critical stenosis occurs when it is reduced to 1 cm^2. However, the patient may remain asymptomatic for many years. A pressure load is imposed on the left atrium, with consequent pulmonary congestion and pulmonary hypertension.

The predominant cause of mitral stenosis is rheumatic carditis. Other causes include atrial myxomas, severe annular calcification and ball-valve thrombi. Congenital malformations are rare.

Pathophysiology of acute deterioration

Acute deterioration can be precipitated in two ways. When the heart rate is increased, the ventricular filling time in diastole is reduced. The atrial pressure rises and is transmitted retrogradely to the pulmonary vascular bed, leading to acute dyspnoea and pulmonary oedema. Atrial fibrillation with a rapid ventricular response is a common example of this. Loss of atrial systole in atrial fibrillation leads to a 20% decrease in cardiac output, leading to major haemodynamic instability.

The second cause of acute deterioration is related to flow across the stenosed valve. When the flow is increased, the transvalvular pressure gradient is increased by a factor equal to the square of the flow rate. The left atrial pressure rises and can precipitate pulmonary congestion. Common clinical contexts in which the transvalvular flow is increased include sepsis, exercise, pregnancy, hypervolaemia and hyperthyroidism.

Clinical features

Patients may be asymptomatic for many years but will have an abnormal physical examination. Symptomatic patients present with dyspnoea, fatigue, thromboembolic events, atrial fibrillation or pulmonary congestion. The onset of symptoms is usually followed by a period of minimal disability that may last many years. Pulmonary congestion, pulmonary hypertension or systemic or pulmonary emboli herald rapid deterioration. Auscultatory findings include a loud first heart sound, an opening snap and a mid-diastolic murmur with presystolic accentuation.

Signs of critical stenosis are small pulse pressure, soft first heart sound, early opening snap, long diastolic murmur, diastolic thrill and evidence of pulmonary hypertension (right ventricular heave and loud P2). Acute pulmonary oedema may be present. Atrial fibrillation with a rapid ventricular rate is frequently the cause. Evidence of systemic embolization of a left atrial thrombus should be actively sought.

Clinical investigations

Chest x-ray and electrocardiography

The CXR features are those of an enlarged left atrium, pulmonary congestion and pulmonary hypertension. The heart size is usually normal. Left atrial enlargement on the ECG is found in 90% of patients in sinus rhythm.

Echocardiography

Echocardiography will confirm the diagnosis, exclude other causes of mitral valve obstruction, identify associated or coexisting structural heart disease, determine the severity of mitral stenosis and estimate pulmonary artery pressure.

Treatment

Medical management aims to reduce symptoms and prevent complications. It does not change the course of mitral valve deterioration, which requires surgery for definitive management. This is usually indicated when symptom severity is rated at New York Heart Association (NYHA) functional class III.

Medical management for pulmonary oedema includes diuretics or long-acting nitrates (see Chapter 5.3). If atrial fibrillation with rapid ventricular response is a contributing factor, rate control is the first priority, either with drugs or with cardioversion (see Chapter 5.4). Anticoagulation is indicated for patients in atrial fibrillation.

Percutaneous mitral balloon valvotomy should be the first treatment to consider in patients with moderate or severe mitral stenosis in the absence of left atrial thrombus or moderate to severe mitral regurgitation. Mitral valve surgical commissurotomy or mitral valve replacement may be required for patients with unfavourable valve morphology or severe stenosis.

Prognosis

In asymptomatic or minimally symptomatic patients, average 10-year survival is greater than 80%. In those with significant symptoms, 10-year survival is 0% to 15%. In untreated patients, mortality is due to pulmonary congestion, right heart failure, systemic emboli, pulmonary emboli and infective endocarditis.

Acute mitral incompetence

Pathophysiology

Acute volume overload into the left atrium by the regurgitant stream is the crucial factor in acute mitral incompetence. The left atrium has a limited capacity to accommodate the excess volume and pulmonary oedema occurs. There is an associated rise in pulmonary vascular resistance, and right ventricular failure may result. Cardiac output is reduced owing to a low stroke volume. The consequent elevation in the systemic vascular resistance impedes cardiac output. Tachycardia occurs but confers no benefit as the diastolic filling time is reduced.

Aetiology

The causes of acute mitral valve incompetence are as follows:

- Infective endocarditis
- Papillary muscle disorder
  - Myocardial ischaemia or infarction
  - Trauma
  - Infiltrative disease
- Rupture of the chordae tendineae
  - Acute rheumatic fever
  - Infective endocarditis
  - Chest trauma
  - Balloon valvotomy
  - Myxomatous degeneration
  - Spontaneous rupture
- Mitral leaflet disorder
  - Infective endocarditis
  - Myxomatous degeneration
  - Atrial myxoma
  - Systemic lupus erythematosus
  - Trauma

Clinical features

Acute mitral valve incompetence is poorly tolerated and such patients are always symptomatic. There is reduced perfusion with concurrent acute pulmonary oedema. The blood pressure is variable and can be normal or low. The precordial findings do not correlate with the severity of the pathology; in fact, a third heart sound may be the only finding. The apical mitral murmur is soft and occurs in early systole and does not become pansystolic. It radiates to the axilla and

is commonly accompanied by a short apical diastolic murmur.

Clinical investigations

Chest x-ray and electrocardiogram

The CXR will show pulmonary oedema but not cardiomegaly. The ECG may show a recent infarct if this was the precipitant.

Echocardiography

Echocardiography is diagnostic and provides valuable information on left ventricular function. It demonstrates the lesion and assesses its severity. In a patient with acute heart failure but with hyperdynamic systolic function of the left ventricle on TTE, suspicion for acute mitral valve incompetence is high. Both TTE and TOE may be required for adequate assessment.

Treatment

Surgery is urgently required. Medical treatment is usually only a temporizing step.

Medical treatment

Mortality in patients with severe left ventricular failure in this setting is high. Medical treatment is directed at reducing the regurgitant volume and hence diminishing pulmonary congestion. It also aims to improve the forward output of the left ventricle. The modalities used depend on the blood pressure.

In normotensive patients, sodium nitroprusside may achieve all of the above-mentioned objectives. In hypotensive patients, a combination of sodium nitroprusside and an inotrope, such as dobutamine, is required. Aortic balloon counterpulsation can be used to improve left ventricular ejection volume and further assist in the reduction of the regurgitant volume, but there is no clinical evidence to suggest that it improves outcomes.

In infective endocarditis, appropriate antibiotics are required.

Surgery

Valve repair should be considered before valve replacement owing to the lower perioperative mortality, improved survival, better preservation of postoperative left ventricular function and lower long-term morbidity.

Acute deterioration in chronic mitral incompetence

Pathophysiology

Chronic mitral valve incompetence may be asymptomatic for many years.

In the decompensated phase, left ventricular systolic dysfunction occurs due to failure of contractility. This causes further left ventricular dilatation and increased left ventricular preload. A fall in cardiac output and pulmonary congestion may result. However, the factors are often still in favour of the left ventricle and the ejection fraction may be in the lower range of normal (i.e. 50% to 60%).

Causes of chronic mitral incompetence include rheumatic carditis, ischaemic heart disease, mitral valve prolapse, collagen vascular disease and dilatation of the valvular annulus. Ischaemic causes have the worst prognosis, as myocardial dysfunction is often coexistent.

Clinical features

Features of decompensation may be subtle. A history of reduced exercise tolerance is an important clue. Symptoms are those of pulmonary congestion and reduced cardiac output. Examination findings indicating severe disease include displacement of the apical impulse and evidence of pulmonary congestion. A third heart sound is commonly found and is not necessarily evidence of congestive heart failure.

Clinical investigations

CXR and ECG may provide useful information regarding cardiac size and heart rhythm. Echocardiography will confirm the diagnosis of mitral incompetence and document left ventricular and left atrial sizes. The integrity of the tricuspid valve is also important (E-Figs. 5.7.1 and 5.7.2).

Treatment

Medical treatment

Atrial fibrillation is a common problem in chronic mitral valve incompetence; however, the embolic risk is lower than for mitral stenosis with atrial fibrillation. AF is also an independent predictor of poor outcome after surgery. The ventricular rate requires control (see Chapter 5.4). Anticoagulation can be used as prophylaxis for embolic complications.

In functional mitral incompetence, preload reduction is beneficial if there is left ventricular dysfunction. Useful agents include ACEIs and β-blockers, especially carvedilol, which is the only vasodilating β-blocker due to its additional α-1 blocking effects.

Surgical treatment

Surgical options include mitral valve repair, replacement with preservation of the mitral apparatus (papillary muscles and chordae tendineae) or replacement with the removal of the apparatus (which has poorer outcomes). Surgery is indicated for the following:

- Symptomatic patients in NYHA functional class II to IV with
  - Left ventricular ejection fraction equal to or greater than 30% or
  - Left ventricular end systolic dimension equal to or less than 55 mm
- Asymptomatic patients with
  - Left ventricular ejection fraction between 30% and 60%
  - Left ventricular end-systolic dimensions equal to or greater than 40 mm

Prognosis

The risk of death is related to the degree of left ventricular decompensation.

Prosthetic valve complications

Prosthetic valve complications are common. As discussed, they are prone to infective endocarditis, so appropriate antibiotic prophylaxis is essential when indicated.

Antithrombotic therapy

Antithrombotic therapy is given to prevent embolic complications. The risk is greater for mitral compared with aortic prostheses regardless of the type. It is also highest in the first few months, when the prosthesis has not yet been fully endothelialized. Warfarin is the anticoagulant of choice. Novel antithrombotic agents such as dabigatran have been shown to have worse outcomes than warfarin for patients with mechanical prosthetic valves, so they should not be used in this group of patients.

Mechanical valves

Target international normalized ratio (INR) values for mechanical valves are summarized in Table 5.7.3.

Table 5.7.3 Target international normalized ratio values for prosthetic valves

Position	*Valve*	*Target INR*
Aortic	Bileaflet or current-generation single-tilting-disc AVR and no risk factors for thromboembolism	2.5
	Bileaflet or current generation single-tilting-disc AVR with additional risk factors for thromboembolism	3
	Starr–Edwards or other older-generation mechanical AVR	3
Mitral	Any mechanical MVR	3

AVR, Aortic valve replacement; *MVR*, mitral valve replacement.

(Modified from Nishimura RA, Otto CM, Bonow RO, et al. 2017 AHA/ACC focused update of the 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Circulation*. 2017;135(25):e1159–e1195.)

Aspirin in the dose range of 75 to 100 mg/day is recommended in addition to warfarin in all patients with mitral valve replacement (MVR). This has been shown to reduce the risk of thromboembolism and cardiovascular mortality, but it does increase the risk of major haemorrhage. The data refer to only aspirin doses within this range.

Biological valves

The increased risk of thromboembolism is in the first 3 months, with the incidence at its greatest during the initial few days. There is some evidence to suggest that the use of aspirin 75 to 100 mg/day for all patients with a bioprosthetic aortic or mitral valve may be beneficial.

Heparin therapy, followed later by warfarin, is started as soon as surgical bleeding has been controlled. Warfarin therapy is stopped in two-thirds of the patients at 3 months. The remaining one-third stay on lifetime treatment with an INR in the range of 2.0 to 3.0. Patients requiring lifetime warfarin therapy include those with atrial fibrillation, a past history of thromboembolism, a risk of hypercoagulability and those with severe left ventricular dysfunction (LVEF <30%). Novel anticoagulant drugs may have a role to play in bioprosthetic valve patients but this is not yet clear.

CONTROVERSIES

- Anticoagulation requirements in infective endocarditis
- Indications for and timing of surgery for haemodynamically stable patients with infective endocarditis
- The use of intra-aortic balloon counterpulsation in patients with cardiogenic shock from non-ischaemic causes
- The role of novel anticoagulant drugs in the care of patients with prosthetic (mechanical and biological) heart valves

5.8 Peripheral vascular disease

Kevin K.C. Hung • Colin A. Graham

ESSENTIALS

1 With the continuing rise in the elderly population, the incidence of peripheral arterial and venous disease in the developed world continues to increase significantly.

2 Claudication is the most important symptom of arterial disease in an extremity, although a well-developed collateral circulation will delay the onset of symptomatic extremity ischaemia.

3 Acute arterial occlusion is usually associated with a number of classic symptoms and signs. It is a time-critical emergency requiring urgent access to an experienced vascular surgeon.

4 If venous thrombosis is suspected, detailed assessment is essential. Unfortunately the presence or absence of signs and symptoms of deep venous thrombosis (DVT) does not correlate well with the presence or absence of venous clot.

5 Optimal assessment for DVT consists of defining a pre-test probability of disease and then performing appropriate non-invasive investigations in the first instance.

6 Compression ultrasonography is the investigation of choice for the diagnosis of DVT.

7 Anticoagulation is the recommended treatment for DVT above the level of the popliteal vein. Treatment of below-knee DVT remains controversial, but increasing evidence suggests that these patients should also receive anticoagulation treatment to prevent complications.

8 Extensive ilio-femoral thrombus or thrombus of the upper limb may require early surgical and/or thrombolytic treatment to minimize the risk of post-thrombotic syndrome.

Arterial disease

Extremity ischaemia may be acute, chronic or acute on chronic. The onset and severity of symptoms may be modified by the development of collateral circulation.

Chronic arterial ischaemia

Epidemiology, pathogenesis and pathology

The prevalence of peripheral arterial disease increases with age (most symptomatic patients are over 60 years old); although it is twice as high in men as in women between the ages of 50 and 70 years, it almost identical after the age of 70 at around 15% to 20%.

Peripheral arterial disease is usually due to atherosclerosis of the lower abdominal aorta or the iliac, femoral and/or popliteal arteries. In common with carotid and coronary artery disease, the disease processes that exacerbate peripheral arterial disease include diabetes mellitus, hypertension, smoking, hyperlipidaemia and previous limb surgery or trauma. A significant collateral circulation may develop. If so, it is made up of pre-existing pathways arising from the distributing branches of large and medium-sized arteries. It develops over time when there is an increase in the velocity of flow through these arteries secondary to arterial occlusion that has developed in a main vascular pathway. Collateral flow can usually provide an adequate supply to the resting limb but may be insufficient to meet additional requirements associated with moderate exercise.

Clinical features

Presentation may be acute or chronic. Symptoms consist of pain, ulceration or changes in appearance, with swelling or discoloration. Lower limb ischaemia usually manifests as claudication, the most important symptom of extremity arterial occlusive disease. Chronic critical lower limb ischaemia is defined by either of the following two criteria:

- Recurring ischaemic rest pain persisting for more than 2 weeks and requiring regular analgesics. This is diagnosed with an ankle systolic pressure of below 50 mm Hg and a toe systolic pressure of less than 30 mm Hg or both.
- Ulceration or gangrene of the foot or toes, with similar haemodynamic parameters.

The classic description of claudication is of pain in a functional muscle unit that occurs as a result of a consistent amount of exercise and is promptly relieved by rest. Limp may also be pronounced. The commonest site of occlusion leading to claudication is the superficial femoral artery, resulting in pain in the calf. This occurs on walking upstairs or slopes and is relieved by rest. Less commonly, occlusive aortoiliac disease produces symptoms of pain in the thigh or buttock. Night pain experienced in the foot, relieved by either dependency or, paradoxically, by walking around, implies a reduction in blood flow to a level below that required for normal resting tissue metabolism. Typically rest pain tends to be distal to the metatarsals, severe, persistent and worsened by elevation.

Detailed examination of the peripheral vascular system is essential. Abnormalities tend to be related to changes in the peripheral arteries and tissue ischaemia. Distal pulses may be absent or diminished in amplitude and bruits (commonly femoral) may be present. Capillary return, atrophic changes and foot colour are poorly discriminatory for the diagnosis of peripheral vascular disease. Pallor may be apparent on exercise and is usually associated with pain. There may be pallor on elevation of the foot, with reactive hyperaemia on dependency: the more limited the elevation resulting in pallor, the greater the degree of stenosis (Buerger test).

As ischaemia becomes more advanced, the skin often becomes shiny and scaly, with associated atrophy of the subcutaneous tissues and muscle. In advanced stages of ischaemia, there may be red discoloration, caused by capillary blood stasis and high oxygen extraction. There may also be tissue necrosis and non-healing wounds or ulcers secondary to trauma, which may progress to gangrene.

Clinical investigations

Routine blood tests should be carried out to derive baselines for renal and hepatic function as well as to exclude anaemia, polycythaemia, hyperglycaemia, thrombocythaemia and hyperlipidaemia. In patients below 50 years of age, a thrombophilia screen should be done.

The ankle–brachial pressure index (ABPI) should be measured to confirm the clinical diagnosis. This is calculated (for each leg) by dividing the highest systolic pressure recorded at the respective ankle by the highest systolic brachial pressure obtained in recordings from both arms. Resting ABPI is normally greater than 1 and a figure of less than 0.9 indicates arterial disease. Values between 0.5 and 0.9 may be associated with claudication and below 0.5 with rest pain. Normal ABPI values may be recorded in diabetic patients, even though they have claudication, owing to the presence of medial arterial calcification and small vessel rather than large vessel disease.

Duplex ultrasound is initially used to assess the vascular tree non-invasively. Digital subtraction angiography (DSA) has now been superseded by computed tomography angiography (CTA) or magnetic resonance angiography (MRA), as they are both non-invasive and give a three-dimensional image of the disease extent. MRA is generally considered a first-line investigation if available, with CTA being used if there is a contraindication to MRA; DSA is still required if intervention (e.g. angioplasty) is planned.

Treatment

In patients with chronic stable disease, treatment is focused on preventing progression of the disease. This is usually co-ordinated by the patient's primary care physician and consists of regular exercise (ideally a supervised exercise program), control of associated medical diseases and cessation of smoking, which is absolutely essential. Specific measures should be taken to address hyperlipidaemia, diabetes mellitus and hypertension. A low-dose antiplatelet agent (usually aspirin) should be given if there is no contraindication, but there is no benefit from warfarin therapy or dual antiplatelet therapy. Statins should be given to all patients with arterial disease. Beta blockers have been shown to be safe in patients with peripheral arterial disease.

In more advanced progressive disease, strategies to minimize other complications, including lower limb ulcers and gangrene, should also be considered. Patients presenting to the emergency department (ED) at this stage or with debilitating symptoms merit early referral for a multidisciplinary vascular assessment with a view to operative or radiological (endovascular) intervention.

Acute arterial ischaemia of the lower limb

Pathogenesis and pathology

Acute lower limb ischaemia, or 'limb-threatening' ischaemia, is associated with significant morbidity and mortality. Early recognition of the signs and symptoms is critical. Arterial occlusion will cause symptoms most obviously when there is inadequate collateral circulation. Causes may be embolic, thrombotic, traumatic or iatrogenic in nature, of which emboli are the most common. Most arterial emboli originate from thrombus formed in the heart (85%), the vast majority of these from left atrial or atrial appendage thrombus related to chronic atrial fibrillation. Other uncommon causes include arterial thrombosis due to endothelial injury or alterations in the blood flow to the limb. Iatrogenic causes may be secondary to intra-arterial cannulation, recent cardiac catheterization or angiography or ischaemic limb anaesthesia (such as a Bier block).

Clinical features

Sudden occlusion of a previously patent artery is a dramatic event. Unfortunately recognition can be difficult, particularly in the elderly or those

with chronic cognitive impairment or dementia; careful examination is therefore essential. Occlusion may be portrayed by one or more of the classic signs of pulselessness, pain, pallor, paraesthesia, paralysis and 'perishing cold' (the '6 Ps'). However, none of these, either alone or in combination, is sufficient to establish or exclude the diagnosis of an acutely ischaemic limb. Loss of a palpable pulse in the symptomatic limb compared with the other side should raise significant concern.

The pain is a severe, constant ache that requires intravenous opiates for relief. The ischaemic periphery is pale, white or cadaveric in appearance and feels cold to the touch. Progression occurs with blotchy areas of cyanosis and further discoloration. Pain, tense swelling and acute tenderness of a muscle belly are late findings. If these findings persist for longer than 12 hours, irreversible ischaemia with gangrene is highly likely.

Clinical investigation

Doppler ultrasound should be used in all patients where there is concern about the arterial circulation of a limb. A handheld Doppler probe will confirm the presence or absence of a pulse and give some quantification of flow. Ultrasound may also be used to rapidly establish the level of arterial occlusion. Other investigations, including basic haematology and biochemistry profiles as well as electrocardiography and chest radiography, help to identify other diagnostic possibilities (e.g. low cardiac output state, polycythaemia, aortic dissection) and other contributing factors (such as atrial fibrillation) and establish fitness for urgent surgical intervention.

Differential diagnosis

It is important (but can be difficult) to differentiate between an embolic event and acute progression of a thrombus. The embolic event will tend to be sudden in onset and exhibit some combination of the '6 Ps'. In situ progression of thrombus will occur in patients who have long-standing significant peripheral arterial disease and a well-developed collateral circulation. Other diagnoses that must be considered include aortic dissection and phlegmasia cerulea dolens. The latter is a massive ilio-femoral DVT. The initial symptom may be an acutely swollen and painful leg. As the swelling continues, there may be secondary arterial insufficiency. An acute embolus, on the other hand, tends to produce pallor and a sharp demarcation, whereas with phlegmasia cerulea dolens there is a swollen cyanotic-appearing limb.

It is important to consider other medical causes that can mimic acute embolism of the upper or lower limb. These include neurological disorders (spinal subarachnoid haemorrhage) and low-output states, such as septic shock, cardiogenic shock secondary to myocardial infarction or pulmonary embolus with obstructive shock.

Treatment

The key to management is rapid diagnosis and access to definitive care. Irreversible changes begin to occur within 4 to 6 hours of symptom onset and revascularization is reported to be less effective after 8 to 12 hours of ischaemia. Intravenous heparin should be given immediately (in the absence of any contraindication) along with opioid analgesia. Other correctable aggravating factors (dehydration, sepsis, arrhythmias, myocardial infarction) should be considered and addressed appropriately.

Urgent revascularisation is critical if acute limb ischaemia has occurred. Different revascularization modalities include percutaneous catheter-directed thrombolytic therapy, percutaneous mechanical thrombus extraction and thrombo-aspiration (with or without thrombolytic therapy) and surgical thrombectomy/embolectomy, bypass and/or arterial repair. According to the 2017 European Society of Cardiology (ESC) guidelines, thrombus extraction, thrombo-aspiration and surgical thrombectomy are the preferred options if a neurological deficit is associated with the acute ischaemic limb. Angiography is not necessary in such circumstances as it introduces unnecessary delay; it can be done intraoperatively if necessary. Catheter-directed thrombolytic therapy is more appropriate in less severe cases without a neurological deficit after appropriate imaging.

In patients with acute limb ischaemia of less than 14 days' duration due to thrombosis or intra-arterial thrombolytic therapy has been shown to have similar efficacy to surgical arterial reconstruction, both in terms of mortality and limb salvage. However, intracranial haemorrhage does appear to be more common in the thrombolytic-treated group.

Patients with acute arterial ischaemia ideally should be referred to an experienced vascular surgeon as early as possible; a multidisciplinary approach with vascular surgeons and interventional radiologists is likely to give the best outcomes.

Acute arterial ischaemia of the upper limb

Epidemiology, pathology and pathogenesis

Symptomatic vascular disease of the upper limb is relatively rare compared with the lower limb. Presentation to the ED is usually due to acute pain, coldness or colour changes in the upper limb or digits.

Acute arterial obstruction may arise secondary to emboli or from penetrating, blunt or iatrogenic trauma. Less commonly, acute occlusion may be associated with thoracic aortic dissection. Emboli affecting the upper limb most frequently involve the brachial artery. Radial and ulnar artery emboli tend to arise from atherosclerotic plaques, aneurysms of the subclavian and axillary arteries and from complications of thoracic outlet syndrome rather than from a cardiac source. The diagnosis may be obvious (e.g. trauma) or suggested by the presenting history and clinical findings.

Acute occlusion of a digital artery results in profound ischaemia of the involved digit. Diagnosis is made on clinical grounds, with sudden onset of pain, pallor, coldness and numbness in the affected digit. A chest x-ray may identify a cervical rib. Referral to a vascular surgeon is indicated for further investigations to identify the cause.

Clinical features

Examination of the limb, comparing it with the other side, palpation of the pulses and assessment of capillary return—as well as detailed examination of the neck—may help to localize the level of occlusion. Use of handheld Doppler ultrasound may negate the need for preoperative angiography.

Management

When emboli are thought to be the cause (e.g. atrial fibrillation), embolectomy is the treatment of choice, usually under local anaesthesia. In some cases thrombolysis may be considered. In the presence of acute ischaemic symptoms of the forearm and hand due to trauma, urgent operative repair is mandatory. In the case of injuries to the radial or ulnar arteries, if only one vessel is damaged and collateral flow is satisfactory, the injured vessel may be ligated.

Venous disease: lower limb

In contrast to arterial disease, chronic peripheral venous disease most commonly gives rise to cosmetic concerns (varicose veins) only. However, thrombosis in the deep venous system is a life-threatening emergency requiring urgent treatment.

It is important to understand that the venous drainage of the lower limb comprises superficial and deep systems connected by perforating veins. A complex system of valves and muscle pumps ensures that blood is carried up from the feet back to the heart. Venous pathology, such as valvular destruction, results in directional flow change and venous pooling.

Venous insufficiency and varicose veins

Primary varicose veins develop in the absence of DVT. The main underlying physiological defect in varicose veins is venous valvular incompetence. Varicose veins may also arise secondary to venous outflow obstruction plus valvular incompetence, or there may be primary venous outflow obstruction only.

Acute complications of varicose veins leading to a visit to an ED are uncommon. However, the skin overlying varices can become thin and erosion can occur spontaneously or with minor trauma alone, resulting in bleeding. The essentials of treatment include elevation of the limb and gentle digital pressure on the site. Ligation of the offending vein may be necessary. Surgical treatment or injection of the varicosities is usually required as a later procedure.

Superficial venous thrombosis

Superficial venous thrombosis is a benign, self-limiting disease in most cases. Exclusion of DVT is usually required, although occasionally the diagnosis is obvious. Patients usually present with pain, tenderness and induration along the course of the vein, which may feel firm, cord-like and have associated erythema. There are usually no signs of impaired venous return. Underlying causes include varicose veins, surrounding cellulitis or a history of preceding trauma. In the upper limb, the commonest cause is recent intravenous cannulation.

Treatment depends on the extent, aetiology and symptoms. Superficial, mildly tender and well-localized thrombophlebitis may be treated with mild analgesics, usually oral non-steroidal anti-inflammatory drugs (NSAIDs), topical NSAID creams, elastic supports and continued daily activity. More severe thrombophlebitis with marked pain, tenderness and erythema may require a period of rest and elevation of the limb. Antibiotics are not indicated. Anticoagulation is necessary only if the process extends into the deep venous system or approaches the sapheno-femoral junction. The prognosis is usually good and there is no associated tendency for the development of DVT. The process may take 3 to 4 weeks to resolve. If associated with a varicose vein, superficial thrombophlebitis may recur unless the varix is excised.

Deep venous thrombosis

DVT is a condition characterized by active thrombosis in the deep venous system of one or both lower limbs. Depending on the thrombus load and the level of extension of the thrombotic process, embolism proximally into the central pulmonary circulation can lead to sudden collapse and death. Early recognition and treatment is therefore essential. The diagnosis and management of acute DVT has become more evidence based in recent years, with a move towards structured assessment, non-invasive investigations and more aggressive treatment for patients with distal clots.

Table 5.8.1 Wells criteria for deep venous thrombosis

Criterion	*Score*
Active cancer	1
Bedridden recently for more than 3 days or major surgery within 4 weeks	1
Calf swelling greater than 3 cm compared with the other leg	1
Collateral (non-varicose) superficial veins present?	1
Entire leg swollen	1
Localized tenderness along the deep venous system	1
Pitting oedema, greater in the symptomatic leg	1
Paralysis, paresis or recent plaster immobilization of the lower extremity	1
Previously documented DVT	1
Alternative diagnosis to DVT as likely or more likely	−2

DVT, Deep venous thrombosis.

Clinical features

Symptoms and signs vary, with one-third of patients having no clinical signs at all. A small number may have classic manifestations. Pain may be located in the calf and/or thigh, ranging from a dull ache to a tight sensation, and is sometimes related to exercise. Examination findings include calf swelling, calf tenderness, tenderness over the popliteal or femoral veins and oedema, but the leg may occasionally be entirely normal. Circumferential limb measurements may be helpful, but differences up to 1 cm occur naturally. The Homan sign is non-specific and unreliable and has no clinical utility. In addition, it is important to incorporate an objective assessment of risk factors for DVT.

One validated prediction model for assessment resulting in the generation of a pre-test probability of lower limb DVT has been developed and validated by Wells et al. (Table 5.8.1). A pre-test probability score of 2 or more means that DVT is 'likely' and that compression ultrasonography should be performed. If the score is less than 2, then DVT is 'unlikely' and a D-dimer assay should be performed (see further on).

Clinical investigation

If the derived pre-test probability of DVT is 'likely', compression ultrasonography is recommended. It is the imaging method of choice to diagnose DVT. Local protocols and expertise will determine whether this is done by a radiologist or an emergency physician. If necessary, patients who are haemodynamically stable and are otherwise fit for outpatient care can be therapeutically anticoagulated for the treatment of presumed DVT and allowed to go home, to return during office hours the following day for their compression ultrasound investigation. The overall sensitivity of ultrasound for any lower limb DVT is around 94% to 99%, with 89% to 96% specificity. A negative ultrasound result in the setting of persistent clinical suspicion or continuing symptoms of DVT warrants repeat testing at 5 to 7 days, but alternative diagnoses should also be actively sought. Venography is no longer recommended for the routine diagnosis of DVT.

If the pre-test probability of DVT is 'unlikely', a D-dimer assay is performed to determine the need for imaging to exclude DVT. D-dimers are degradation products of cross-linked fibrin blood clots typical of those found in DVT. The level therefore rises in acute DVT, but it also rises in other acute conditions, such as infection and following trauma. Therefore a positive test does not rule in DVT, but a negative test has a high negative predictive value for DVT and can therefore rule out disease. The combination of a low pre-test probability of disease and a negative D-dimer effectively excludes DVT and the patient can be safely discharged without the need for further investigation. However, D-dimer test characteristics vary greatly depending on whether the method used is an enzyme-linked immunosorbent assay (ELISA) or a variant of a whole blood latex agglutination study. Local expertise in the interpretation of these markers is essential in such circumstances.

Differential diagnosis

These include cellulitis, superficial thrombophlebitis, a ruptured Baker cyst, chronic leg oedema, chronic venous insufficiency, postoperative swelling and arthritis.

Treatment

The standard treatment for established DVT is anticoagulation.

Outpatient treatment is preferred by patients and appears to be cheaper. Hospital-based treatment is indicated if there is severe oedema of the whole of the lower limb or if there is thrombus above the groin.

An approved alternative to low-molecular-weight heparin (LMWH) and warfarin treatment is the direct factor Xa inhibitor rivaroxaban. Oral rivaroxaban 15 mg is taken twice daily for the first 3 weeks after diagnosis, followed by 20 mg once daily for the duration of anticoagulation. It is contraindicated in severe hepatic and renal failure and doses should be reduced in moderate renal impairment. The anticoagulant activity of rivaroxaban is not reflected by the international normalized ratio (INR) and there is no commonly available method of monitoring activity. Oral apixaban can also be used as an alternative to rivaroxaban. The American College of Chest Physicians Antithrombotic Guideline (10th edition, 'CHEST AT10') recommends dabigatran, rivaroxaban, apixaban or edoxaban over vitamin K–antagonist therapy. The major benefit for patients is the removal of the need for injections and lack of requirement to monitor anticoagulation status, in contrast to warfarin therapy, which requires frequent monitoring and dose adjustment. Andexanet alfa (inactivated recombinant factor Xa) has recently been shown to reverse the bleeding effects of rivaroxaban and apixaban (these are both direct factor Xa inhibitors). Cancer patients may benefit from 3 to 6 months of LMWH treatment instead of warfarin therapy, but again this should be guided by local protocols. Irrespective of the initial anticoagulation regimen employed, all patients require ongoing anticoagulation for 3 to 6 months, although the optimal duration continues to be debated. Patient care should be continued by referral to a haematologist or vascular physician according to local practice.

The use of below-knee graduated elastic compression stockings has been thought to reduce the incidence of post-phlebitic (or post-thrombotic) syndrome, but benefits are evident only after 2 years' use and they are poorly tolerated.

For patients with an extensive ilio-femoral thrombus, consideration should be given to thrombolysis, especially if there are haemodynamic changes suggestive of multiple pulmonary emboli. Thrombectomy may be indicated if the vital functions of the lower limb are threatened, with the aim of reducing the risk of post-thrombotic syndrome. Occlusive lower extremity venous thrombi respond poorly to systemic thrombolysis and the risks of bleeding may outweigh the potential benefits. Catheter-directed thrombolytic therapy, however, has been used to treat large symptomatic ilio-femoral thrombi with some success.

Pregnant women with suspected DVT have not been extensively studied with respect to excluding DVT, so caution must be exercised when assessing these patients. In general, they should all undergo compression ultrasonography and there should be a low threshold for treatment with LMWH.

A dilemma arises when there is an isolated DVT below the level of the popliteal vein or when there is an equivocal finding in the calf and negative findings above the knee. Options include withholding anticoagulation and following the patient with serial ultrasound studies or implementation of anticoagulation. The CHEST AT10 guidelines recommend that distal DVTs with the following risk factors should receive anticoagulation: (1) positive D-dimer; (2) extensive thrombosis (>5 cm in length, involves multiple veins >7 mm in maximum diameter); (3) thrombosis close to proximal veins; (4) no reversible provoking factor for DVT; (5) active cancer; (6) history of VTE; (7) inpatient status. In the setting of an infra-popliteal or calf-vein clot where anticoagulation is not commenced, repeat ultrasound at 1 to 2 weeks will determine with a high degree of sensitivity whether the clot has propagated above the knee. As the risk of subsequent extension to the popliteal vein and the risk of pulmonary embolism from untreated calf DVT is of the order of 15%—and given the safety of LMWH treatment—it is probably prudent to treat confirmed below-knee DVT and to investigate equivocal cases further with serial ultrasound studies. (See Chapter 5.5 for the diagnosis and management of pulmonary embolism.)

Venous disease: upper limb

Thrombosis of the subclavian and axillary veins is much less common than thrombosis of the lower extremity veins. It is usually associated with the presence of an indwelling venous catheter, active cancer or mechanical compression of the vein. It can follow upper extremity exertion such as weightlifting—the so-called effort thrombosis—but this is very uncommon.

Clinical features

Patients present with swelling of the extremity, developing either rapidly or slowly over a period of weeks. Severe pain is uncommon: the usual symptoms are arm heaviness and discomfort exacerbated by activity and relieved by rest.

Clinical findings may include an increased prominence of hand and forearm veins, venous patterns over the shoulder and hemithorax, skin mottling or cyanosis and non-pitting oedema. There may be tenderness to palpation of the axillary vein within the axilla. The ipsilateral internal jugular vein is not usually enlarged. If it is, the possibility of a superior vena cava obstruction should be considered.

Clinical investigation

The diagnosis should be made by duplex ultrasound scanning, which has a high sensitivity and specificity for upper limb DVT.

Treatment

Standard treatment consists of anticoagulation to prevent the progression of thrombosis. Rest, heat and elevation of the arm in a sling will give good symptomatic relief. Catheter-directed thrombolytic therapy, anticoagulation and possibly venous angioplasty may be considered to restore vein patency and reduce the risk of re-thrombosis (although this is very low in the absence of other risk factors). Thoracic outlet decompression should be considered if mechanical compression of the upper limb veins is diagnosed.

The use of long-term anticoagulation should be considered only if the patient has risk factors predisposing to recurrent thrombosis (e.g. thrombophilia).

Likely developments over the next 5 to 10 years

- The impact of statin therapy and other types of secondary prevention of vascular disease may lead to changes in the incidence and presentation of peripheral arterial disease in developed countries. On the other hand, the increasing incidence of smoking and atherogenic dietary habits in developing countries, along with the increasing age of the population, will lead to an increase in the incidence of arterial and cardiovascular disease in those countries.
- New developments in anticoagulant drug therapy and their reversal agents are likely to change the initial and ongoing management of venous disease.
- In the future, all emergency physicians will be trained to diagnose or exclude DVT definitively by compression ultrasound, thus enabling immediate treatment decisions for patients with suspected DVT. As a result, D-dimer testing may become less important.

CONTROVERSIES

- The evolving role of systemic or intra-arterial thrombolysis for acute arterial occlusion
- Lack of clear-cut optimal drug regimens, costs and duration of anticoagulation therapy for DVT
- Anticoagulation for below-knee DVT
- Inadequately researched investigative protocols and treatment algorithms for DVT in pregnant women

5.9 Hypertension

Francis O'Keeffe

ESSENTIALS

1 **Hypertension is defined as a systolic blood pressure ≥140 mm Hg and/or a diastolic blood pressure ≥90 mm Hg.**

2 **Hypertensive crises include both hypertensive emergencies and hypertensive urgencies.**

3 **A hypertensive emergency is characterized by end-organ damage (brain, cardiovascular system and kidney) and requires immediate treatment and admission.**

4 **Most patients presenting with a hypertensive emergency have chronic hypertension, although it can present in those previously normotensive.**

5 **Management depends on the clinical syndrome, the presence of complications or coexisting conditions and the risks of intervention.**

6 **Hypertensive encephalopathy mandates urgent control of the blood pressure.**

7 **There is insufficient evidence to support aggressive blood pressure control in the setting of acute stroke except in the case of proposed thrombolytic therapy.**

Introduction

Hypertension is a highly prevalent condition worldwide, carrying significant risk for cardiovascular, renal and neurological morbidity and mortality. Normal blood pressure is defined as <120/<80 mm Hg. Hypertension is defined as a systolic blood pressure ≥140 mm Hg and/or a diastolic blood pressure ≥90 mm Hg. However, the distinction between normotension and hypertension is arbitrary. In practice, the cut-off values are used to aid diagnosis and management decisions allowing an agreed level for screening patients with hypertension and for diagnostic evaluation and initiating therapy. The spectrum of hypertension is shown in Table 5.9.1.

Hypertensive crises, which include hypertensive urgencies and hypertensive emergencies, are uncommon and occur in 1% to 2% of the hypertensive population. They are generally defined by a diastolic blood pressure greater than 120 mm Hg. The magnitude of the blood pressure may not be important, as patients with chronic hypertension can often tolerate higher blood pressure levels than can previously normotensive individuals. The defining factor in a hypertensive crisis is the presence of symptoms and/or end-organ dysfunction. The term 'malignant hypertension' is now outdated. It was first coined in 1928 when mortality rates from hypertensive emergencies were up to 80% (down to <10% now).

One of the first tasks in the emergency department (ED) evaluation is to determine whether the patient's condition represents a hypertensive emergency or an urgency. A hypertensive emergency is defined as severe elevation in blood pressure (systolic blood pressure >180 mm Hg and/or diastolic blood pressure >120 mm Hg) associated with evidence of new or worsening end-organ damage (i.e. cardiovascular, renal or neurological). When these complications are clinically apparent or suspected due to concomitant signs and symptoms, treatment is required immediately in the ED to lower the blood pressure (not necessarily to normal).

In contrast, hypertensive urgency is when there is no evidence of end-organ dysfunction with a similarly elevated blood pressure. Many of these patients have withdrawn from or are noncompliant with antihypertensive therapy. Urgent, aggressive treatment is not required; instead, the majority are managed with re-institution, intensification or initiation of oral antihypertensive drug therapy and early follow-up within 24 to 48 hours.

Epidemiology

Current studies show that hypertension affects 1 billion people worldwide. Three percent of all

Table 5.9.1 Spectrum of hypertension

Hypertension category	*Systolic (mm Hg) Diastolic (mm Hg)*
Optimal	<120 and <80
Normal	120–129 and/or 80–84
High normal	120–139 and/or 85–89
Grade I (mild)	140–159 and/or 90–99
Grade II (moderate)	160–179 and/or 100–109
Grade III (severe)	≥180 and/or ≥110
Isolated systolic	>140 and <90

adults develop hypertension each year, and it is more common in males. Australian indigenous peoples and African Americans have a predisposition to hypertension. It is estimated that 30% of hypertensive patients are undiagnosed and 29% of those with known hypertension are inadequately controlled.

Hypertensive emergencies

Hypertensive emergency syndromes

Hypertensive emergencies encompass a spectrum of clinical features representative of the target organ and/or system involved, including the brain, heart, kidney and large arteries.

Neurological hypertensive emergencies

Severe hypertension with acute neurological signs or symptoms are usually the most complicated and difficult clinical scenarios because the differential diagnosis is varied, with only some individuals requiring active emergent blood pressure management. Neurological hypertensive emergencies include those listed in the following paragraphs.

Hypertensive encephalopathy

Normal autoregulation in the brain occurs between a mean arterial pressure (MAP) of 60 and 120 mm Hg; cerebral blood flow is constant within this range. As blood pressure rises, there is compensatory vasoconstriction to prevent hyperperfusion. When the upper limit of compensation is reached (~MAP 180 mm Hg), vasodilatation occurs, resulting in cerebral oedema (due to endothelial damage). In previously normotensive patients, this can occur at a BP of 160/100 mm Hg (i.e. a MAP of 120 mm Hg). In chronically hypertensive individuals, encephalopathy may not occur until the blood pressure is much higher, probably because of a shift in the range of cerebral autoregulation.

The classic clinical triad of hypertensive encephalopathy is severe hypertension, altered level of consciousness (confusion, coma, seizures) and retinopathy (retinal haemorrhages, exudates, papilloedema). Symptoms may include headache of gradual onset and blurring of vision.

If hypertensive encephalopathy is not recognized, cerebral haemorrhage, oedema and death result. Patients at higher risk include those with untreated or inadequately controlled hypertension, renal disease, thrombotic thrombocytopenic purpura, pre-eclampsia and eclampsia and those on medications, such as erythropoietin and certain immunotherapy treatments.

Ischaemic stroke

Elevated blood pressure is common and occurs in up to 80% of individuals with acute ischaemic stroke, declining spontaneously in most patients within the acute phase (often within 90 minutes). Several major studies have emphasized the effect of elevated blood pressure on outcome after stroke, but the results are inconsistent with no clear consensus on an optimal blood pressure range.

Haemorrhagic stroke—intracerebral and subarachnoid

Over one-third of patients with a haemorrhagic stroke continue to have haematoma expansion in the first few hours after onset. Elevated blood pressure is also common and is associated with haematoma expansion and death (especially with a systolic blood pressure >200 mm Hg). However, conclusive evidence of whether actively reducing blood pressure is useful is still not available.

Cardiovascular hypertensive emergencies

Acute pulmonary oedema

Acute heart failure in a hypertensive crisis is likely a result of diastolic dysfunction secondary to ischaemia. It is the most common clinical manifestation of a hypertensive emergency. The acute blood pressure rise leads to increased mechanical stress on the left ventricular wall and, consequently, a rise in myocardial oxygen demand.

Acute coronary syndrome

Elevated systemic vascular resistance increases left ventricular myocardial wall tension and oxygen demand. In severely elevated blood pressure, myocardial perfusion may not be able to adequately maintain the increased oxygen demand, thus leading to ischaemia. In patients with pre-existing hypertension, coronary artery disease may already be present, which in itself increases oxygen demand.

Acute aortic dissection

Aortic dissection is rare but also the most rapidly deteriorating and devastating hypertensive emergency, with high mortality. It should be suspected in the setting of hypertension associated with chest pain. This is discussed in detail in Chapter 5.10.

Renal hypertensive emergencies

Severe hypertension can occasionally cause direct injury to the kidneys (hypertensive nephrosclerosis), but it is more likely that the kidney impairment is the result of intrinsic renal disease rather than the cause of renal dysfunction.

Additionally, renal insufficiency may itself be the cause of the hypertensive emergency. This creates a vicious cycle of deterioration in renal function leading to an elevation of the blood pressure, which, in turn, compounds the renal dysfunction. Risk groups include patients with chronic renal failure, especially those requiring dialysis, and patients who have had a kidney transplant.

Hypertensive emergencies in pregnancy

Pre-eclampsia is a multi-system disorder characterized by hypertension (≥140/90 mm Hg) and involvement of one or more target organ systems after 20 weeks of gestation and up to 4 weeks post-partum. It carries a significant risk for maternal and/or fetal morbidity and mortality (see Chapter 19.6).

Clinical evaluation of hypertensive crisis

History taking focusses on the presence of end-organ dysfunction, whether there is pre-existing hypertension (including medication compliance) and any obvious aetiology.

Examination also concentrates on assessing for end-organ dysfunction, including blood pressure measurement (both arms), a careful cardiovascular examination (peripheral pulses, cardiac failure, renal bruits), neurological examination and fundoscopy. The presence of retinal haemorrhages, exudates or papilloedema is associated with a high risk of stroke and carries a poor prognosis despite treatment.

Clinical investigation

Investigations should be tailored to the clinically apparent signs and/or symptoms invariably associated with specific end-organ dysfunction.

Bedside tests

- Electrocardiography (ECG), particularly in the setting of chest pain and hypertension, looking for left ventricular hypertrophy and/or ischaemia.

- Urinalysis, looking for haematuria and proteinuria.
- Urine drug screen for the presence of suspected sympathomimetic drugs

Blood tests

- Full blood examination to detect anaemia and haemolysis.
- Renal function tests.
- Serum electrolytes may reveal a secondary cause of hypertension.

Imaging

- Chest x-ray: a routine chest x-ray is of little diagnostic value unless pulmonary oedema is suspected.
- Cerebral computed tomography (CT) may be useful if there is evidence of neurological impairment. This will rule out haemorrhagic stroke and may show the characteristic posterior leucoencephalopathy indicative of hypertensive encephalopathy.

Other investigations will be dictated by the clinical presentation.

Treatment

The primary aim of treatment is to stop progressive deterioration of target-organ function. This must be tailored to the individual patient and not on the basis of the absolute blood pressure values; instead, it should be determined by the type of hypertensive clinical syndrome, the presence of end-organ damage and any co-existing conditions. Caution must be taken when lowering the blood pressure too quickly, risking target-organ hypoperfusion as well as ischaemia in vascular beds, which have become habituated to chronic hypertension.

Reduce MAP by no more than 25% within the first hour, often to a target of <180/120 mm Hg. Over the next 23 hours, cautious reduction to a target of approximately <160/110 mm Hg is appropriate. The exceptions include life-threatening conditions such as aortic dissection, severe pre-eclampsia and phaeochromoytoma crisis, where immediate BP control within minutes is desirable. Parenteral antihypertensive agents should be used and the patient placed in a resuscitation area with intra-arterial BP monitoring.

There is a lack of high-quality evidence supporting the treatments of hypertensive emergencies; practice guidelines are consensus based.

Neurological emergencies

Acute ischaemic stroke

Blood pressure is reduced at the risk of causing hypoperfusion of the peri-ischaemic area, which may result in an extension of the stroke. In the absence of other end-organ dysfunction or intention to treat with thrombolysis, current American Heart Association and Australian Clinical Guidelines for Stroke Management recommend treatment if the systolic blood pressure exceeds 220 mm Hg and/or the diastolic blood pressure exceeds 120 mm Hg over 24 hours. For patients suitable for thrombolysis in the ED, blood pressure should be reduced to below 185/110 mm Hg. If there is evidence of other organ dysfunction, treatment should be tailored to reduce damage to that organ while balancing the risk of further cerebral ischaemia.

Haemorrhagic stroke

Hypertension is part of the reflex response to the resultant intracranial hypertension and is usually transient. The rationale for the treatment of hypertension is that it would reduce further bleeding and hence haematoma expansion. This has not been proven for primary intracranial haemorrhage, and evidence to support treatment of hypertension in this clinical scenario is lacking. Recommendations regarding the treatment of intracranial haemorrhage-associated hypertension are largely based on consensus and—given the suggestive and consistent data linking high blood pressure with poor clinical outcomes—early lowering of high blood pressure seems sensible. The most current guidelines from the American Heart Association recommend treatment with a continuous intravenous infusion of antihypertensive medication such as labetalol if systolic blood pressure is above 220 mm Hg. Australian guidelines recommend a target systolic blood pressure of around 140 mm Hg (but not substantially below). Labetalol can be started at an initial dose of 0.3–1.0 mg/kg (maximum 20 mg) slow IV injection every 10 mins. Alternatively an IV infusion can be started at 0.4–1.0 mg/kg/hr up to 3 mg/kg/hr. The rate should be adjusted to a total dose of 300 mg which can be repeated every 4–6 hours.

Hypertensive encephalopathy

The divide between the risks and benefits of treatment in hypertensive encephalopathy is small. The clinical manifestations characteristically respond dramatically to acute lowering of the MAP. The consensus is that a fall in MAP by 10% to 15% or to a diastolic blood pressure of 100 to 110 mm Hg, whichever value is greater, in the first hour. Vigilant monitoring is essential, as any deterioration in clinical status must result in reduction or cessation of the drug used irrespective of the magnitude of the reduction in blood pressure, especially in those with pre-existing hypertension.

Centrally acting drugs that can affect mental status, such as clonidine, are not used. The preferred agent is sodium nitroprusside (SNP). Possible alternatives are intravenous labetalol and glyceryl trinitrate.The dose range for SNP is 0.3–0.5 mcg/kg/min, increasing in increments of 0.5 mcg/kg/min to achieve BP target (maximum dose 10 mcg/kg/min). SNP requires normal hepatic and renal function for its metabolism and excretion and hence cannot be used in patients with renal or hepatic impairment. Labetalol can be started at an initial dose of 0.3–1.0 mg/kg (maximum 20 mg) slow IV injection every 10 mins. Alternatively an IV infusion can be started at 0.4 -1.0 mg/kg/hr up to 3 mg/kg/hr. The rate should be adjusted to a total dose of 300 mg which can be repeated every 4-6 hours.

Cardiovascular emergencies

Myocardial ischaemia (see Chapter 5.2)

The aim is to reduce myocardial work and promote coronary blood flow and thus reduce ischaemia. The agent of choice is glyceryl trinitrate given intravenously as a venodilator to reduce the preload and decrease cardiac oxygen demand. β-Blockers, including metoprolol and labetalol, are used to reduce systemic vascular resistance.

Acute pulmonary oedema (see Chapter 5.3)

An easily titratable vasodilator such as glyceryl trinitrate is preferred because of its effect on coronary arteries as well as the reduction of preload and afterload. If acute left ventricular dysfunction is present with pulmonary oedema, loop diuretics are traditionally used; however, they may exacerbate pressure-induced natriuresis and increase stimulation of the renin-angiotensin system.

Aortic dissection (see Chapter 5.10)

Treatment aims to lessen pulsatile load or aortic stress by lowering the blood pressure in order to retard the propagation of the dissection and prevent aortic rupture. Blood pressure should be reduced within minutes to 1 hour by 20% to 25% and then gradually over 2 to 6 hours, aiming for 160/110 mm Hg. Parenteral β-blockers are the agents of choice.

Renal emergencies

In patients with chronic renal failure and acute renal insufficiency, an acute elevation in blood pressure with subsequent worsening of renal function may require a combination of treatments targeting volume imbalance (e.g. by dialysis) as well as blood pressure (e.g. with SNP). It is vitally important to pay attention to the patient's volume status, as diuretic use may be beneficial or deleterious. In patients with de novo acute renal insufficiency, the management is complex and best done in consultation with a physician specializing in kidney disease. Emergency ultrafiltration may be required in cases refractory to medical treatment.

Pre-eclampsia See Chapter 19.6

Hypertensive urgency

Evaluation and treatment

The appropriate management in the ED of markedly elevated blood pressure without signs or symptoms of end-organ dysfunction is less clear. Initial assessment is much the same as in cases of hypertensive emergency and relies on ruling out end-organ dysfunction with a thorough history and examination. Whether or not to initiate routine investigations remains a controversial area due to a lack of large randomized clinical trials. Of the available evidence, ED screening for creatinine level may identify a small group of patients with renal dysfunction. However, it is unclear how this frequency compares with that of patients who present with normal or near normal blood pressures. No other diagnostic tests appear to be useful.

The decision to initiate therapy in the ED for asymptomatic patients is also difficult owing to a lack of high-quality evidence. There are a number of consensus-based opinions that recommend lowering of the blood pressure over time (i.e. within hours to days) with an aim of achieving a blood pressure of <160/<100 mm Hg or a level no more than 25% to 30% lower than baseline (owing to a risk of stroke or myocardial infarction if lowered below the level of autoregulation in patients with pre-existing hypertension).

Treatment strategies include a 'wait, then treat' approach in a quiet room where rest for 30 minutes or more may produce a fall in blood pressure of more than 20/10 mm Hg in up to one-third of these patients. Failing and/or following this it is appropriate to commence oral antihypertensive treatment. Note that the majority of patients are hypertensive due to poor or non-compliance with medications; therefore, if this is known, re-starting regular medications is recommended. Angiotensin-converting enzyme inhibitors (ACEIs) are also reasonable first-line selections in most patients. In general, the disposition of the patient depends on the presence of significant co-morbidities, response to treatment and the availability and accessibility of outpatient follow-up within 24 to 48 hours of discharge.

Prognosis and disposition

Prognosis depends on the success of treatment to halt end-organ damage.

All patients with hypertensive emergencies should be admitted to a suitable high-dependency area with invasive blood pressure monitoring. Patients with hypertensive urgency suitable for discharge must have planned follow-up within 48 hours. Those with high-risk features/co-morbidities should be admitted for observation.

Developments in the next 5 to 10 years

- Better understanding of the precipitants of hypertensive emergencies; in particular, the emerging evidence that intensive comprehensive lifelong treatment to a target blood pressure of 120/80 mm Hg or less could substantially lower cardiovascular disease risk
- More knowledge and guidance on the use of home automated blood-pressure monitoring, which now appears to have sufficient evidence to be incorporated into clinical practice

CONTROVERSIES

- Reduction of the elevated blood pressure in the acute phase of a stroke remains controversial. There is no consensus on the indication to treat or the timing of intervention. Each case should be evaluated individually, with careful consideration given to the risks and benefits of lowering the blood pressure.
- There remains a considerable lack of robust evidence on the overall benefit of antihypertensive drugs as well as choice of first-line therapy in hypertensive emergencies. This mainly relates to the small size of trials, lack of long-term follow-up and failure to report outcomes.

5.10 Aortic dissection

Eoin Fogarty

ESSENTIALS

1 **Untreated aortic dissection has a mortality rate of approximately 1% per hour for the first 48 hours and 90% at 3 months. Early diagnosis and aggressive management improve mortality rates to 20% to 40%.**

2 **Aortic dissection is a rare clinical diagnosis confirmed through focused investigation. A high index of suspicion is required.**

3 **Both false-negative and false-positive diagnoses of aortic dissection result in increased morbidity and mortality.**

4 **If available, transoesophageal echocardiography in the unstable patient and computed tomography aortography in the stable patient are the preferred imaging modalities for patients suspected of suffering aortic dissection.**

5 **Therapy aimed at reducing blood pressure and the force of ventricular contraction should commence as soon as the diagnosis is suspected.**

6 **Proximal dissections require emergency surgery. Uncomplicated distal dissections are generally treated medically, whereas complicated distal dissections are usually managed with endoluminal stenting or surgery.**

Introduction

Aortic dissection is an uncommon yet potentially lethal condition. Owing to the broad range of presenting signs and symptoms, a high index of suspicion is required to diagnose it. Investigations must be carefully chosen and rapidly performed to confirm the diagnosis. Treatment should be commenced as soon as the diagnosis is suspected, because when AD is untreated, the mortality rate is approximately 1% per hour for the first 48 hours.

Aortic dissection is one of a group of similar conditions that constitute the acute aortic syndrome, which comprises several related life-threatening aortic pathologies including aortic dissection, intramural haematoma, penetrating aortic ulcer and traumatic aortic transection with incomplete rupture. These conditions all progress to the same pathophysiological end point: separation of the aortic intima from the outer aortic layers, with predictable and often devastating consequences. There is considerable overlap in the signs, symptoms and principles of management of the conditions that constitute acute aortic syndrome.

Epidemiology, pathophysiology and classification

The incidence of aortic dissection is 3 patients per 100,000 population per year. One-third to one-half of all cases are diagnosed at autopsy. Although the overall incidence is low, aortic dissection is the most common catastrophe of the aorta, being two to three times more common than rupture of the abdominal aorta.

Most cases occur in males, particularly those between the ages of 50 and 70. Proximal dissections involving the aortic arch have a peak incidence 10 years earlier than distal dissections. Risk factors—among which hypertension is the single most important—are shown in Box 5.10.1. The diagnosis of aortic dissection must be considered in any patient with a history of hypertension who presents with sudden severe chest, back or abdominal pain. Approximately 5% of all cases involve patients with a history of Marfan syndrome.

Arterial hypertension and degeneration of the aortic media are the two key elements of aortic dissection. Dissection occurs when blood is forced along a low-resistance tissue plane within the wall of the aorta created by a diseased and weakened media. Two pathophysiological processes have been proposed to initiate the dissection. The traditional explanation requires a breach in the intima (an intimal tear) to initiate the dissection process. The tear occurs at sites where hydrodynamic and torsional forces on the aorta are greatest, most commonly a few centimetres above the aortic valve (60%to 65%) or just beyond the insertion of the ligamentum arteriosum (30% to 35%). A column of high-pressure aortic blood gains access to the media and dissects through the weakened tissue plane, creating a false lumen. The dissection can extend in an antegrade or retrograde direction. The alternative mechanism suggests that diseased or unsupported vasa vasorum within the media rupture, creating an intramural haematoma. The haematoma dissects through the media as it expands, subjecting the unsupported media to increased shearing forces during diastolic recoil of the aorta. Eventually—but not necessarily—this may lead to a tear in the intima. In this mechanism, the intimal tear is a consequence of the dissection, not an initiating factor. An intimal tear is not identified in 12% of autopsies, suggesting that it is not a mandatory precursor of aortic dissection.

Regardless of the primary process producing dissection, the sequelae are identical. As the dissection extends, any structures caught in its path may be affected. Branch vessels of the aorta may be distorted or occluded, resulting in signs and symptoms of ischaemia to the organs they supply. Proximal dissection may produce acute aortic valve incompetence, and continued proximal extension may enter the pericardial sac, tamponading the heart. The false lumen created by the dissection may also partially or completely obstruct the true lumen. It may end in a blind sac or rupture back into the true lumen at any point. The false lumen may also rupture outwards through the adventitia. If this

occurs and the haematoma is not contained, rapid exsanguination will occur. Common sites of external rupture are into the left pleural cavity or mediastinum.

Once dissection begins, propagation is dependent on the blood pressure and the gradient of the arterial blood pressure wave, which is a function of the velocity of left ventricular contraction. This explains why urgent pharmacological treatment is aimed at lowering arterial blood pressure and reducing the ventricular contractile force.

Classification

The Stanford and De Bakey systems are two commonly used, anatomically based classification systems. Both describe the site of the dissection, providing information that assists management.

The Stanford system divides aortic dissection into two types (Fig. 5.10.1). Type A (65% to 70% of cases) involves the ascending aorta, with or without the descending aorta. The presence or absence of an intimal tear, the site of the tear and the extent of distal extension are not considered in this classification. Type B dissections (30% to 35%) involve the descending aorta only, which, by definition, begins distal to the origin of the left subclavian artery. The Stanford system is simple, easy to remember and has become the primary classification system referred to in the literature.

The De Bakey classification system divides aortic dissection into three types (see Fig. 5.10.1). Type I involves both the ascending and the descending aorta. Type II involves the ascending aorta only. Type III involves the descending aorta only and is subdivided into type IIIa, which is confined to the thoracic aorta, and type IIIb, which extends into the abdominal aorta.

Aortic dissection is classified as acute if symptoms are present for fewer than 14 days or chronic if are present for longer than 14 days.

Clinical features

History

Pain is the most common presenting symptom, occurring in 74% to 95% of patients. It is classically described as severe, unremitting, tearing or ripping in nature and maximal at onset. It may be migratory, reflecting proximal or distal extension of the tear. The site of the pain may reflect the site of the dissection, with involvement of the ascending aorta typically producing anterior chest pain. Inter-scapular pain can occur with involvement of the descending aorta; as distal dissection continues, the pain may migrate to the lower back or abdomen.

Other symptoms of aortic dissection are related to the effects of major aortic side branch occlusion. Almost 20% of dissections present with coma, confusion or stroke. This may signify carotid artery involvement or reflect end-organ hypo-perfusion due to hypovolaemic shock from external rupture of the aorta or cardiogenic shock caused by pericardial tamponade. Neurological symptoms often fluctuate. Lower limb paraplegia or paraesthesia (2% to 8%) may occur as spinal arteries are separated from the aortic lumen. Syncope (18% type A and 3% type B) may suggest rupture into the pericardial sac.

Symptoms may also be due to local compression from a contained rupture. These are uncommon but may include superior vena cava syndrome, dysphonia, dyspnoea, dysphagia, upper airway obstruction and Horner syndrome.

A history of risk factors for aortic dissection should also be obtained (see Box 5.10.1).

Examination

There is no single examination finding that will confirm the diagnosis. It is common for patients to be acutely distressed and apprehensive and for their pain to be resistant to narcotic analgesia.

Patients usually present with a tachycardia owing to a combination of pain, anxiety and possibly shock. Hypertension is seen in 50% to 78% of patients, especially those suffering type B dissection. This may reflect an underlying history of hypertension or an acute response to pain and anxiety. Hypotension is an ominous sign, suggesting free rupture of the aorta or pericardial tamponade. Evidence of side branch occlusion may include stroke, limb ischaemia or neurological dysfunction, pulse deficits or a difference of 15 mm Hg or more in manually taken blood pressures between the upper limbs.

Evidence of proximal extension to involve the aortic valve or pericardium may produce acute aortic incompetence, possibly with signs of acute left ventricular failure. A diastolic murmur indicative of acute aortic incompetence is a common finding in proximal dissection (50% to 68%). Pericardial tamponade may manifest with the Beck triad: hypotension, muffled heart sounds and raised jugular venous pressure. Pulsus paradoxus may be present or a pericardial friction rub may be heard. Involvement of the renal arteries may result in oliguria or anuria.

Aortic rupture may present with shock or clinical signs of a haemothorax, usually left-sided.

Serial examination is important, as signs may change as the dissection progresses.

Clinical investigations

Specific investigations are required to confirm or exclude aortic dissection. There are, however, a number of initial investigations that may identify an alternative diagnosis or serve to increase the clinical suspicion of aortic dissection. Routine haematological or biochemical investigations are of little value in the immediate diagnosis of aortic dissection and at best provide baseline renal function and haemoglobin level.

Electrocardiography

An electrocardiogram (ECG) should be performed on all patients with suspected aortic dissection, as acute myocardial infarction (AMI) is a major differential diagnosis. Ten percent to 40% of patients with aortic dissection will have ECG evidence suggestive of acute ischaemia, whereas 7% of dissections involve the coronary arteries. Yet only

Box 5.10.2 Radiographic features suggesting dissection

- Widening of the superior mediastinum (52%–75%)
- Dilatation of the aortic arch (31%–47%)
- Change in the configuration of the aorta on successive chest x-rays (47%)
- Obliteration of the aortic knob
- Double density of the aorta (suggesting true and false lumina)
- Localized prominence along the aortic contour (38%)
- Disparity of calibre between the descending and the ascending aorta (34%–67%)
- Displacement of the trachea or nasogastric tube to the right
- Distortion of the left main stem bronchus
- Calcium sign (>6 mm between the intimal calcium and the shadow of the outer aortic wall: 7%–17%)
- Pleural effusion, more common on the left (15%–20%)
- Cardiomegaly (21%)
- Normal (12%–20%)

0.9% to 2.4% of patients will have ECG changes in keeping with AMI. Total coronary artery occlusion is less common than partial occlusion and the right coronary artery is more commonly involved than the left. The ECG may display voltage criteria for left ventricular hypertrophy, reflecting a long-standing history of hypertension.

Chest x-ray

A number of chest x-ray (CXR) abnormalities have been described in patients with aortic dissection (Box 5.10.2). The sensitivity and specificity of each individual finding is poor; for this reason, no single finding should be used for predictive purposes. Many findings are subtle and are best seen on a good-quality erect posteroanterior (PA) film. In reality, the clinical condition of the patient may allow only a supine, mobile AP film. Retrospective audits of plain radiographs of patients known to have aortic dissection reveal abnormalities suggesting the diagnosis in 72% to 90% of cases; however, attempts to prospectively identify aortic dissection in blinded studies yield less reliable results (sensitivity of 81% and specificity of 82% to 89%).

It has been reported that between 12% and up to 20% of radiographs are normal in patients suffering dissection. At best, the CXR may increase the clinical suspicion of aortic dissection or identify alternative pathology. A normal-appearing CXR must never be used to exclude aortic dissection.

Specific investigations

All patients in whom aortic dissection is suspected must have a diagnostic test performed without delay. Options include computed tomography (CT), echocardiography, aortography and magnetic resonance imaging (MRI). The aim is to determine safely and rapidly whether a dissection is present, its site, the structures involved and the presence of complications. The most appropriate investigation will depend on patient and institutional factors, including patient stability, test availability and access. Each emergency department (ED) should have a prearranged imaging strategy for the diagnosis of suspected aortic dissection.

Computed tomography

Assuming that the patient is suitable for transfer to the scanner, CT is usually the imaging modality of choice to confirm the diagnosis of acute aortic dissection. Arterial phase scanning with intravenous (IV) contrast creates a CT aortogram. Images are rapidly obtained and can be reconstructed in multiple planes. Motion artefact is reduced through the rapid data acquisition capabilities of modern scanners. Increased availability, after-hours reporting via teleradiology and the trend to position scanners in close proximity to EDs has increased the utility of CT.

CT is the preferred study in stable patients with a low-to-moderate index of suspicion for aortic dissection as it is effective in identifying alternative pathologies. Diagnosis is based on the demonstration of an intimal flap, shown as a low-attenuation linear structure within the aortic lumen. Secondary findings of aortic dissection include internal displacement of luminal calcification and delayed contrast enhancement of the false lumen. Sensitivity and specificity for diagnosing arch vessel involvement is high (93% and 98%, respectively). CT can also identify complications of aortic dissection including pericardial, mediastinal and pleural blood. Disadvantages include the requirement for IV contrast and patient transport.

Recent advances in multi-slice CT, including CT coronary angiography, raise the possibility of diagnostic testing for both aortic dissection and coronary artery disease in one test, albeit with higher contrast and radiation loads. There are currently insufficient data to determine the safety or utility of this approach.

Echocardiography

Transoesophageal echocardiography (TOE) has emerged as an excellent diagnostic investigation for aortic dissection in centres where it is available. Ideal for critically ill patients, TOE can be rapidly and safely performed at the bedside and is highly sensitive and specific (Table 5.10.1). In addition, TOE can give a functional assessment of the aortic valve and the left ventricle and can identify other complications of aortic dissection, including the involvement of coronary arteries and the presence of pericardial blood.

Table 5.10.1 Sensitivity and specificity of diagnostic investigations

Investigation	*Sensitivity (%)*	*Specificity (%)*
CT	83–100	90–100
TTE	78–100: type A 31–55: type B 59–85: all	63–96
TOE	97–99	97–100
Aortography	81–91	94
MRI	95–100	95–100

CT, Computed tomography; *MRI*, magnetic resonance imaging; *TOE*, transoesophageal echocardiography; *TTE*, transthoracic echocardiography

Disadvantages of TOE include limited availability outside major centres and the requirement for a skilled and available operator. TOE is invasive and patients may require sedation and airway protection to perform the test. It is contraindicated in patients with known oesophageal pathology, including varices, strictures and/or tumours.

The diagnosis is confirmed by demonstrating the intimal flap separating the true and false lumina. The true lumen can be distinguished from the false lumen as it is usually smaller, expands during systole (compared with compression of the false lumen during systole) and is less commonly thrombosed. Central displacement of luminal calcium may confirm the presence of aortic dissection in situations where the false lumen has thrombosed.

Transthoracic echocardiography (TTE) is no longer considered a useful screening test in view of its low sensitivity and specificity (see Table 5.10.1). TTE is particularly poor at imaging the transverse arch and the descending aorta owing to interference from the airway.

Aortography

Formerly the gold standard investigation for aortic dissection, aortography is now rarely performed owing to the development and refinement of less invasive, more sensitive and rapid alternatives.

Magnetic resonance imaging

MRI is highly sensitive and specific, providing excellent visualization of the site and extent of dissection and complications including side branch involvement. The major disadvantages relate to patient safety and ease of access. Studies are lengthy, patient accessibility is poor during the study and remote monitoring is required. MRI equipment is frequently located at a distance

Box 5.10.3 Differential diagnosis of aortic dissection

- Cardiovascular

  - Renal colic

from resuscitation facilities. For these reasons, MRI is not suitable for unstable or potentially unstable patients despite the comprehensive information it can provide; it is best reserved for surveillance or for ongoing evaluation of aortic dissection.

Biomarkers

The use of biomarkers, particularly the D-dimer, for early detection of aortic dissection and as part of a 'rule out' algorithm is attracting interest. A 2010 meta-analysis of the usefulness of D-dimer to diagnose acute aortic dissection concluded that it could not be used as a 'rule-out' test and that prospective trials are required to further assess the utility of D-dimer in the diagnosis of aortic dissection. There remains no widely accepted strategy for biomarker-assisted diagnosis of acute aortic dissection as no single biomarker has been validated and combination biomarker arrays are yet to be investigated.

Differential diagnosis

The diagnosis of aortic dissection is rarely straightforward, and the list of differential diagnoses (Box 5.10.3) is long owing to the wide range of presenting symptoms and signs. With the advent of thrombolysis for acute embolic stroke, care must be taken to consider aortic dissection as a stroke mimic prior to the administration of thrombolytic agents. This is one reason for CT perfusion protocols for acute stroke imaging from the aortic arch, allowing aortic dissection to be identified.

Treatment

Initial management for all types of aortic dissection focuses on resuscitation, stabilization, prevention of ongoing dissection by management of haemodynamic parameters and facilitation of definitive care if required.

Treatment must be started as soon as the diagnosis is suspected. Unstable patients require immediate resuscitation. Diagnostic investigations and the management of life-threatening complications may need to take place simultaneously. Measures to minimize progression of the dissection must be instituted rapidly, and early surgical referral is mandatory. Early diagnosis, control of blood pressure and heart rate, and early surgical repair are all associated with improved survival.

Patients with aortic dissection are usually in severe pain and require large doses of titrated IV narcotic analgesia, which should not be delayed or withheld. A secondary benefit from the relief of pain is a reduction in blood pressure and heart rate.

Pharmacological control of pulsatile load

Pharmacological treatment is aimed at decreasing the pulsatile load ($\Delta p/\Delta t$) delivered by the left ventricle to the column of blood within the false lumen. This minimizes the likelihood of ongoing dissection. The pulsatile load is determined by the systolic blood pressure and the velocity of blood ejected from the heart. Importantly, blood pressure must be lowered without increasing the velocity of ventricular contraction, which can occur if afterload is reduced prior to blocking the reflex tachycardia and increased contractile velocity of the heart that afterload reduction produces.

If there is no contraindication, β-blockade is the ideal first-line agent owing to its negative inotropic and chronotropic effects on the heart. Esmolol—a short-acting β-blocker (half-life 9 minutes) that can be given by peripheral IV infusion and titrated to heart rate and blood pressure—is effective. A loading infusion of 0.5 mg/kg may be given by handheld syringe over 1 minute. Following this, a maintenance infusion ranging from 50 to 200 μg/kg/min is commenced.

If esmolol is unavailable or experience in its use is limited, titrated IV boluses of metoprolol are equally effective. A heart rate of 60 to 80 beats/min and a systolic blood pressure of 100 to 120 mm Hg are commonly quoted target ranges, but these figures are not defined by controlled trials. Intra-arterial monitoring is necessary for optimal blood pressure management.

If further blood pressure reduction is required following β-blockade, a vasodilator may be added. Sodium nitroprusside reduces afterload via systemic vasodilation. Delivered by IV infusion, it is effective, has a rapid onset and short duration of action and can be readily titrated to effect. The usual infusion range is 0.5 to 10 mg/kg/min. Owing to the possibility of cyanide toxicity, the infusion should not continue for more than 24 hours.

Box 5.10.4 Indications for surgical repair/endoluminal stenting of type B aortic dissection

- Leaking or ruptured aorta
- End-organ ischaemia
- Extension of dissection despite appropriate medical therapy
- Refractory pain
- Severe uncontrollable hypertension

An alternative agent to reduce blood pressure is glyceryl trinitrate (GTN), a drug more commonly and confidently used by most clinicians. Delivered by peripheral IV infusion, GTN reduces both preload and afterload by relaxing vascular smooth muscle. Reflex tachycardia is a common side effect and must be prevented by prior β-blockade. The infusion range is 5 to 50 μg/min and it can be rapidly titrated to clinical effect.

Treatment of type A aortic dissection

Open surgical repair of the aorta is the treatment of choice for acute proximal (type A) aortic dissection. The aim is to prevent rupture of the false lumen, re-establish blood flow to regions affected by occluded side branches, correct any associated acute aortic valve incompetence and prevent pericardial tamponade. Usual practice is to excise the section of the aorta containing the intimal tear and replace this with a prosthetic interposition graft. Operative mortality ranges from 5% to 21%. Without surgery, up to 90% of patients with acute type A dissection will die within 3 months. With surgery, there is a 5-year survival of 56% to 87%.

Treatment of type B aortic dissection

Type B aortic dissection is classified as either complicated (30%) or uncomplicated (70%). *Complicated aortic dissection* refers to the presence of events carrying a high risk for death, including compromised lower body perfusion or end-organ ischaemia, aortic rupture or impending rupture, progression of dissection, uncontrollable hypertension and/or refractory pain (Box 5.10.4).

Medical management has been generally accepted as the standard of care for uncomplicated type B aortic dissection. Tight control of blood pressure and heart rate can produce survival rates of 80% over a 1-year period. Endoluminal stenting has not been shown to improve 2-year survival from uncomplicated type B aortic dissection when compared with medical management.

Complicated type B aortic dissection was historically managed by open surgical repair of the aorta, often in the setting of failed medical therapy. The mortality rates of open surgical repair were very high, between 21% and 33.9%. The advent of less invasive endovascular stent deployment across the primary tear site has significantly improved mortality and morbidity from complicated type B aortic dissection. A significant portion of these patients represent (11% at 30 days, 23% at 90 days and 30% at 180 days), mostly with cardiac and/or aortic problems. A small proportion of these patients required an additional endovascular procedure. In-hospital mortality has fallen to 10% and major morbidity (renal failure and stroke) has halved from 40% to 20% when compared with open surgical repair.

All patients are discharged on lifelong β-blockade regardless of initial medical or surgical treatment or whether the patient is hypertensive or normotensive. Serial MRI examinations are necessary for long-term surveillance of the aorta.

Prognosis

A dramatic improvement in survival has been observed over the past 30 years owing to advances in medical and surgical management. One-year survival rates of 52% to 69% for type A and 70% for type B aortic dissection have been reported.

Eighty-six percent of deaths from aortic dissection are due to aortic rupture, 70% of these rupturing into the pericardial sac. Multi-organ failure is a significant cause of death following medical or surgical therapy.

Disposition

Those patients who do not require emergency surgery require admission to an intensive care area for monitoring and aggressive therapy aimed at minimizing propagation of their dissection. Patients in peripheral or regional centres will require transfer to a specialist cardiothoracic unit after their condition has been stabilized.

CONTROVERSIES

- The role of intravascular ultrasound in diagnosis. Sensitivities and specificities of close to 100% have been reported, but its practicality in the ED is unproven.
- Appropriate investigation. Lack of utility of CXR as a screening test. Choice of investigative modalities is governed by availability of testing modalities and the stability of the patient.
- The role of D-dimers as a rule-out test in low-risk patients.
- Preventive therapy in Marfan syndrome. Routine β-blockade is advocated. Elective grafting of the aortic valve and ascending aorta is being advocated in some patients considered at high risk.

5.11 Aneurysms

Adrian Murphy

ESSENTIALS

1 Abdominal aortic aneurysms (AAAs) generally expand slowly and are asymptomatic.

2 Screening programs aim to detect their presence prior to rupture and promote early elective repair once their size is ≥5.5 cm.

3 Abdominal pain/back pain with hypotension should prompt a rapid search for an AAA in the age group of 65 years or above.

4 Aneurysmal rupture is a surgical emergency and requires prompt operative intervention. Bedside ultrasound can assist in the rapid identification of aneurysms.

5 The mortality after rupture is very high—approximately 80% of those who reach hospital and 50% of those undergoing emergency surgery.

6 Emergency endovascular repair of AAA rupture is effective and may be preferable to traditional open repair in selected patients.

7 Symptomatic aneurysms of any size should be considered emergent.

8 Limited fluid resuscitation (hypotensive resuscitation) for AAA rupture has demonstrated improved outcome if the patient can tolerate such measures preoperatively.

9 Patients with femoral/popliteal aneurysms tend to present with complications from thrombosis/embolism rather than rupture. There is an association of lower limb aneurysms with AAA.

10 The primary risk of central arterial aneurysms (aortic/iliac/pulmonary/visceral) is rupture, which has a high risk of sudden death.

Abdominal aortic aneurysm

Introduction

An abdominal aortic aneurysm (AAA) is a permanent pathological dilation of the aorta more than 1.5 times the expected diameter. It involves all three layers of the vessel wall. For the infrarenal aorta in most adults, this is 3 cm, which is the trigger for annual follow-up once an AAA has been identified. AAAs are estimated to expand at 4 to 5 mm per year. Elective surgical repair is offered for AAAs discovered to be 5.5 cm or larger to prevent death from rupture. They may unfortunately rupture without evidence of growth during the previous year, and rupture of an individual aneurysm is therefore unpredictable.

The distal aorta is subject to the greatest changes in arterial pressure and therefore biomechanical stress. Hence the majority of AAAs are found below the renal arteries (90% to 95%). The remainder may involve the proximal renal arteries or even visceral branches of the aorta. They can also descend into the iliac vessels.

Most aneurysms are asymptomatic until a complication arises. These complications can be rupture, symptomatic expansion, thrombosis or embolism. The majority of ruptures are initially into the retroperitoneal space, where they may be temporarily contained. Intraperitoneal rupture can be primary or may follow a retroperitoneal event, and it has a higher mortality rate. Rarely, an AAA will be complicated by chronic rupture, formation of a false or inflammatory aneurysm, an arteriovenous or aortoenteric fistula, atheroembolism, small bowel obstruction or ureteric obstruction.

Epidemiology

Some 5% to 10% of men 65 to 79 years of age have an AAA, and the prevalence in men increases by 6% per decade. AAAs are more common in men, with a three- to four-fold higher prevalence than in women. The risk of aneurysmal rupture has been shown to be proportional to aneurysmal size, with aneurysms measuring less than 5.4 cm in diameter having an annual rupture rate of approximately 1% to 2%, whereas those greater than 7.0 cm have an annual rupture rate of 32.5%.

Risk factors for AAA are age over 55 years, male gender, smoking, positive first-degree relative family history, chronic obstructive pulmonary disease, Marfan syndrome and Ehlers-Danlos syndrome.

Aetiology/pathophysiology

Traditionally arterial aneurysms were considered to be a consequence of atherosclerotic disease, and intimal atherosclerosis does accompany AAA. Current thinking is evolving and recent data suggests a causative role for matrix metalloproteinases.

This overall pathophysiology is multifactorial, as follows:

- There is proteolytic degradation of the aortic wall connective tissue. Matrix metalloproteinases along with other proteases derived from macrophages/aortic smooth muscle cells are secreted into the extracellular matrix. This enhanced enzyme activity may lead to the breakdown of the structural matrix proteins, such as collagen and elastin. There is an autoimmune process, as IgG complexes have been located in the dilated aorta wall.
- Biomechanical wall stress is a component and the elastin-collagen ratio falls in the distal aorta. Diminished elastin is associated with aortic dilatation, and the collagen degradation predisposes to rupture.

Prevention/screening

Screening may reduce the risk in high-risk groups, and current regimens suggest one-time ultrasound (US) screening for all men above 65 years of age and for those 55 years of age with a positive family history. Surveillance imaging at 12-monthly intervals is recommended for AAA 3.5 to 4.4 cm in diameter. For those AAAs 4.5 to 5.4 cm, 6-monthly surveillance imaging is indicated. With regard to women in high-risk groups, one-time US is suggested for those above 65 years of age, although routine screening currently has insufficient evidence to support it.

Clinical features

History

The patient is usually male and over 65 years of age who complains of pain in the abdomen/back that may radiate to the flanks or down to the groin. There may be associated hypotension

causing collapse or dizziness, associated with rupture. Occasionally neurological signs develop due to spinal cord ischaemia (T10–T12).

Examination

An AAA is felt as an expansile, pulsatile mass in the epigastrium, above the level of the umbilicus. Generally, in thin patients, an AAA greater than 5 cm in diameter can be found clinically. Physical examination can be insensitive in detecting aneurysms due to obesity, abdominal bloating, pain and when the aneurysm is less than 5 cm in diameter. Other physical examination findings may relate to consequences of bleeding, tachycardia, hypotension, postural drop in blood pressure, peritonism or pallor. Examination of the lower limb arterial pulses may reveal associated femoral/popliteal aneurysms or arterial insufficiency. Of note, a contained retroperitoneal rupture may provide an unremarkable physical examination. The classical combination of abdominal pain, hypotension and a pulsatile abdominal mass is found in slightly less than 50% of patients with ruptured AAA. A high degree of clinical suspicion is advocated for patients over 65 years of age with unexplained back/flank pain and syncope/hypotension.

Differential diagnosis

Symptomatic expansion or rupture may mimic other conditions, such as perforated viscus, intra-abdominal sepsis, renal colic, musculoskeletal back pain or myocardial infarction. Therefore a high degree of suspicion is needed in patients over 65 years old.

Clinical investigations

This is directed by the initial index of clinical suspicion and the need to minimize delay in confirming the diagnosis. A patient with a known AAA who presents with abdominal pain and hypotension suggestive of rupture should not have surgery delayed by further investigations. A patient with a suspected AAA from history along with hypotension in whom a tender pulsatile abdominal mass consistent with an aneurysm is found should be considered for immediate surgical repair.

Imaging

Bedside US is the test of first choice in those presenting with a history suggestive of aneurysmal rupture in whom no prior aneurysm was known. US can detect an AAA with sensitivity and specificity greater than 95%, but it can be limited by obesity, intraluminal gas and inadequate operator experience. A leak may not be identified on US and, in stable asymptomatic patients, the exact anatomic mapping of the aneurysm may require further imaging. Other imaging modalities, (e.g. computed tomography [CT], magnetic resonance imaging [MRI] and MR angiography [MRA]) are mainly used for operative planning in stable patients. These modalities can also identify proximal aortic dilatation and renal artery involvement. Most aneurysms are fusiform in shape and appear as symmetrical bulges around the circumference of the aorta. In contrast, saccular aneurysms are asymmetrical, appear on one side of the aorta and are typically caused by trauma or a severe aortic ulcer.

Other Investigations

A full blood count may reveal leucocytosis and pre-existing relative anaemia. Clinical biochemistry, especially for renal function and glucose, is indicated. Cross-match of blood anticipating major transfusion (6 to 10 units) is essential. A coagulation screen may assist in identifying the risk of intraoperative disseminated intravascular coagulation (DIC). C-reactive protein and erythrocyte sedimentation rate (CRP/ESR) may be helpful if infective AAA is suspected. Electrocardiography (ECG) should also be performed to rule out myocardial infarction.

Treatment

Rapid surgical intervention is the definitive treatment of ruptured AAA, so early notification of the vascular surgery team is essential. A judicious approach to fluid resuscitation should be undertaken, as large-volume resuscitation (>3.5 L fluid) has reportedly worsened outcome. Currently minimal fluid resuscitation aiming for a systolic blood pressure of 70 to 80 mm Hg is the suggested approach in the preoperative phase. This approach should be tempered by maintaining vital organ perfusion. Lower limits have been suggested (50 to 70 mm Hg), but this may not be practical in a majority of centres and there are significant institutional variations on the acceptance of such lower limits. Timely intra-arterial pressure and urine output monitoring also assist in optimizing resuscitation end points.

Surgery

Emergency endovascular abdominal aortic aneurysm repair versus open repair Endovascular AAA repair (EVAR) is the least invasive option for repair, aortoiliac anatomy permitting; otherwise traditional open repair is performed. Emergency endovascular abdominal aortic aneurysm repair (eEVAR) reduces surgical stress and can be facilitated using locoregional anaesthesia. Intraoperative calibration angiography can be used to assess the anatomical suitability of aneurysms for eEVAR and reduce the preoperative delay. Approximately 50% of AAAs are suitable for EVAR. A Cochrane review (2017) of endovascular repair for ruptured AAA versus the standard open technique concluded that no benefit has yet been definitively established. Moderate-quality evidence suggests that there is no difference in 30-day mortality for open repair versus eEVAR. It is possible that eEVAR may be associated with a reduction in bowel ischaemia. This is a delicate time-critical decision process that involves the vascular surgeon/anaesthetist/interventional radiologist and patient/family representatives. Repair of a symptomatic unruptured AAA is generally directed towards EVAR, anatomy permitting.

Prognosis

Rupture of an AAA leads to early death in over 80% of those affected. This includes 20% to 65% of those who undergo surgical repair. Severe hypotension (systolic blood pressure <65 mm Hg), use of perioperative vasopressors and blood transfusion are significant predictors of 30-day mortality in this population. There are emerging data to suggest that long-term survival (>4 years) is similar between repair methods. The conventional open surgical approach carries the significant risks of major open surgery and anaesthesia, haemorrhage, aortic clamping and lower torso ischaemic-perfusion injury. After eVAR, long-term surveillance is essential to monitor for endoleaks and stent integrity in order to reduce the small but significant incidence of late aneurysm rupture.

Thoracic aortic aneurysm (see Section 5.10)

Cerebral aneurysms (see Sections 8.2 and 8.3)

Visceral aneurysms

Introduction

The increased utilization of diagnostic imaging studies has led to increased incidental identification of visceral aneurysms, which may involve the splenic, hepatic, coeliac, superior mesenteric, renal, gastroduodenal and other arteries. Visceral aneurysms often result from abnormal haemodynamics or from atherosclerosis or infectious causes and most are asymptomatic. However, they should be considered in any patient with abdominal pain, intra-abdominal bleeding or gastrointestinal bleeding. The diagnosis can be confirmed with CT, US, MRI or angiography. Up to 25% visceral aneurysms may be complicated by rupture, and the mortality rate after rupture is between 25% and 70%.Treatment should be considered in all patients with symptoms related to the aneurysm if the aneurysm is greater than 2 cm in diameter, if the patient is pregnant or if there is demonstrated growth of the aneurysm. The type of treatment depends on the clinical condition, the artery involved and the surgeon's preference. Options include open surgical ligation, prosthetic or venous graft reconstruction, percutaneous transcatheter metal coil

embolization, endovascular stent-graft placement or even organ removal.

Splenic artery aneurysm

Splenic artery aneurysms (SAAs) account for approximately 60% of all visceral arterial aneurysms. They are the only aneurysms that are more common in women, with a female-to-male ratio of 4:1. Multiple aneurysms are present in about 20% to 30% of patients. The more common causes are atherosclerosis and portal hypertension. Splenic artery aneurysms are usually an incidental discovery on abdominal x-rays as signet ring calcifications in the left upper quadrant, especially in elderly patients. Most are less than 2 cm in diameter. Symptoms include left-upper-quadrant or epigastric pain radiating to the left shoulder or subscapular area. Only 2% of splenic artery aneurysms result in rupture. Of those that rupture, more than 95% occur in young women during the third trimester of pregnancy, with reported 35% to 75% maternal and 95% fetal mortality rates. Symptomatic SAAs require immediate operative intervention, particularly in pregnant women or women of childbearing age. In asymptomatic patients, treatment is controversial but should be considered if the diameter of the aneurysm is larger than 2 cm. Ruptured SAA is usually treated by splenectomy.

Hepatic artery aneurysm

Hepatic artery aneurysm constitutes 20% of visceral artery aneurysms and most commonly occurs in elderly males. More than 50% present with right-upper-quadrant/epigastric abdominal pain that radiates to the back. Rupture into the biliary tract may result in the classic triad of acute biliary pain, haemobilia and jaundice. Erosion of the aneurysm into the stomach or duodenum may lead to haematemesis or melaena. Extrinsic compression of the biliary duct may cause obstructive jaundice. Because of the high mortality rate associated with rupture, surgical resection or transarterial catheter occlusion is warranted.

Superior mesenteric aneurysm

Superior mesenteric artery aneurysms are the third most common visceral aneurysm (8%). More than 90% are symptomatic, presenting with upper abdominal pain, gastrointestinal bleeding or acute mesenteric ischaemia from thromboembolism. Around 50% have a pulsatile mass on physical examination.

Peripheral aneurysms

Peripheral aneurysms can occur in isolation, or they may be found in association with other large vessel aneurysms (i.e. aorta). The most common site is the popliteal artery and, when symptoms are present, they generally reflect claudication, ischaemia or chronic embolization rather than rupture.

Popliteal artery aneurysm

True popliteal aneurysms involve all layers of the vessel wall. They can be fusiform or saccular. An aneurysm is present once the size has exceeded 1.5 times the upper limit of normal (usually >1.7 cm in an adult). The pathogenesis is very similar to that described for aortic aneurysm. Growth is not quite as predictable, as some popliteal aneurysms remain stagnant rather than expanding. Clinical presentation may range from a pulsatile mass found in the popliteal fossa with no symptoms to acute limb-threatening ischaemia. Bilateral popliteal aneurysms may be apparent. Duplex ultrasonography is the first-line imaging modality when diagnosis is suspected clinically. This can be supplemented by CT or MRA. Limb-threatening ischaemia is time-critical and investigations should be under the direction of the vascular surgeon, who may opt for surgery over further emergent imaging. Heparin infusion is utilized in patients with evidence of acute thrombosis, distal embolization or acute ischaemia. Elective repair of popliteal aneurysms is generally indicated once the size is equal to or greater than 2 cm.

Femoral artery aneurysm

Femoral artery aneurysms are less common than popliteal aneurysms. They are, however, more prone to rupture. An aneurysm is present once the size is equal to or greater than 2.5 cm.

Upper limb aneurysms

Upper limb aneurysms are rare, are usually the result of trauma and may involve the subclavian, axillary, brachial, radial and ulnar arteries. The risks are of limb ischaemia and thromboembolic complications (including retrograde thromboembolism in the vertebral/carotid circulation). Brachial plexus compression may also occur due to the growth of subclavian aneurysms.

Future developments

- Annual comprehensive screening programs for AAAs do not currently exist; however, one-time screening in men at or above 65 years of age is advocated for the initial detection of an aneurysm.
- Based on animal study data, there may be potential benefit for the administration of macrolide antibiotics as disease modification agents after the identification of an AAA.
- The nomination of the optimal blood pressure target for minimal fluid resuscitation in the ruptured AAA remains controversial; however, limited evidence suggests that a normotensive target is associated with worse outcomes.
- Extension of endovascular repair techniques and the efficiency of delivery is vitally important in time-critical emergency presentations.
- Resuscitative Endovascular balloon of the aorta (REBOA) may provide a temporizing measure in severely hypotensive patients with ruptured AAA awaiting emergency repair; however, further studies are required to confirm long-term benefit.

CONTROVERSIES

- The clinical decision not to proceed to emergency surgery with very high-risk cases of ruptured AAAs (refractory hypotension/cardiac arrest/age >80/requirement for massive blood transfusion)
- The long-term outcomes with EVAR and subsequent risk of re-intervention/complications
- The safe disposition of the stable patient with a symptomatic but non-ruptured small AAA after imaging has been completed

SECTION 6

RESPIRATORY EMERGENCIES

Edited by *Biswadev Mitra*

6.1 Upper respiratory tract

Kenneth Ooi

ESSENTIALS

1 **Management of the airway, breathing and circulation (ABCs) takes precedence over the history, examination and specific treatment of upper airway obstruction.**

2 **Direct laryngoscopy can be an important technique for both the investigation and management of upper airway obstruction.**

3 **Chest thrusts and back blows can be useful first aid techniques in foreign-body upper airway obstruction.**

4 **Acute viral respiratory infections are a frequent reason for seeking medical attention. Over-prescribing of antibiotics continues to be a major problem.**

5 **Bacterial infections and collections are uncommon but may compromise the upper airway.**

6 **A high index of suspicion is needed to diagnose blunt trauma injuries to the larynx and trachea and potential associated injuries of the cervical spine.**

7 **The rates of adult supraglottitis are increasing and the clinical presentation may be nonspecific. Airway interventions are not usually needed.**

Introduction

The upper respiratory tract extends from the mouth and nose to the carina. It comprises a small area anatomically but is of vital importance. The majority of presentations are not life threatening; however, those that are require immediate evaluation and treatment.

Emergent conditions are those likely to compromise the airway. Protection and maintenance of the ABCs take precedence over history taking, detailed examination or investigations. Non-urgent presentations include rash or facial swelling not involving the airway, sore throat in a non-toxic patient and complaints that have been present for days or weeks with no recent deterioration. Pharyngitis and tonsillitis are common causes for presentation in both paediatric and adult emergency practice.

Triage and initial evaluation

Initial evaluation is aimed at differentiating those patients needing urgent management to prevent significant morbidity and mortality from those needing less urgent treatment. Triage must be based on the chief complaint and on vital signs, since the same clinical presentation may result from a range of pathologies. For example, stridor can be due to trauma, infection, drug reactions or anatomical abnormalities such as tracheomalacia.

Symptoms and signs of airway obstruction include dyspnoea, stridor, altered voice, dysphonia and dysphagia. Evidence of increased work of breathing includes subcostal, intercostal and suprasternal retraction; flaring of the nasal alae, as well as exhaustion and altered mental state. Cyanosis is a late sign. The spectrum of signs varies with age and accompanying conditions.

Further examination will be directed by the presenting complaint and initial findings and includes the following:

- General appearance—facial symmetry, demeanour
- Vital signs—temperature, heart rate, respiratory rate, blood pressure and pulse oximetry
- Head and face—rash, swelling, mucous membranes, lymphadenopathy
- Oropharynx—mucous membranes, dental hygiene, tongue, tonsils, uvula

Upper airway obstruction

Upper airway obstruction may be acute and life threatening or may have a more gradual onset. It is essential that the adequacy of the airway be assessed first. Any emergency interventions required to maintain the airway should be instituted before obtaining a detailed history and examination. This may range from relieving the obstruction to providing an alternative airway.

Box 6.1.1 Causes of upper airway obstruction

Altered conscious state
Head injury
Cerebrovascular accident
Drugs and toxins
Metabolic—hypoglycaemia, hyponatraemia, etc.

Foreign bodies
Infections
Tonsillitis
Peritonsillar abscess (quinsy)
Epiglottitis
Ludwig angina
Other abscesses and infections

Trauma
Blunt or penetrating trauma resulting in oedema or haematoma formation
Uncontrolled haemorrhage
Thermal injuries
Inhalation burns

Neoplasms
Larynx, trachea, thyroid

Allergic reactions
Anaphylaxis
Angioedema

Anatomical
Tracheomalacia—congenital or acquired (secondary to prolonged intubation)
Other congenital malformations

Functional upper airway obstruction syndrome
Acute-on-chronic causes
Patients with chronic narrowing of the airway (e.g. due to tracheomalacia) may present with worsening obstruction from an acute upper respiratory tract illness or injury.

Pathology

Obstruction may be physiological, with the patient unable to maintain and protect an adequate airway due to a decreased conscious state. Despite the plethora of possible causes, the initial treatment of securing the airway is the same regardless of the cause. Mechanical obstruction may be due to pathology within the lumen (aspirated foreign body), in the wall (angio-oedema, tracheomalacia) or by extrinsic compression (Ludwig angina, haematoma, external burns). Obstruction may be due to a combination of physiological and mechanical causes. Possible causes of airway obstruction are listed in Box 6.1.1.

Clinical investigations

Investigations are secondary to the assessment and/or the provision of an adequate airway. Once the airway has been assessed as secure, the choice of investigations is directed by the history and examination.

Endoscopy

Direct laryngoscopy by an experienced operator is the single most important manoeuvre in patients with acute upper airway obstruction. It may concurrently form part of the assessment, investigation or treatment. By visualizing the laryngopharynx and upper larynx, the cause of the obstruction can be seen. Any foreign bodies may be removed or, if necessary, a definitive airway, such as an endotracheal tube, may be introduced. In the case of the stable patient with an incomplete obstruction, this should be attempted only when full facilities are available for intubation and the provision of a surgical airway. It may be more appropriately deferred until expert airway assistance is available.

Bronchoscopy may be required to assess the trachea and distal upper airway but it is not part of the initial resuscitation. If the patient is stable, it is more appropriate to transfer him or her to the operating suite or intensive care unit (ICU) for this procedure.

Blood tests

Some blood tests may be useful in guiding further management. These include a full blood count, blood gases and blood cultures. The tests required will be guided by the clinical presentation. Initial treatment in the emergency department should not await their results.

Imaging

Neck x-rays A lateral soft tissue x-ray of the neck is sometimes helpful once the patient has been stabilized. Metallic or bony foreign bodies, food boluses or soft tissue masses may be seen. A number of subtle radiological signs have been described for supraglottitis (Table 6.1.2).

Computed tomography In the patient with a mechanical obstruction, a computed tomography (CT) scan of the neck and upper thorax may be helpful in diagnosing the cause and extent of the obstruction. It may aid in planning further management, especially if surgical intervention is indicated, for example, for a retrothyroid goitre or head and neck neoplasm. However, care should be taken to secure the airway in cases of impending obstruction prior to CT.

Treatment

Management initially consists of securing the airway. This is described in more detail elsewhere in this book, but simple interventions include chin lift or jaw thrust and an oropharyngeal airway. More sophisticated procedures—such as the laryngeal mask, endotracheal intubation (nasal or oral) or surgical airway—may be required.

A surgical airway is rarely necessary in the emergency department, although it is important that equipment be available and that the techniques are understood and have been practised. These include needle insufflation (oxygenation, not ventilation) and cricothyrotomy. A number of commercial kits are available; however, recent emphasis favours simple techniques such as 'knife-finger-bougie'. Whatever technique is chosen, the key remains planning and practice. Further management will depend on the underlying pathology.

Foreign-body airway obstruction

Foreign-body aspiration is often associated with an altered conscious state – for example, in alcohol or drug intoxication, cerebrovascular accident (CVA) or dementia. Elderly patients with dentures are at increased risk.

Laryngeal foreign bodies are almost always symptomatic and are more likely to cause complete obstruction than foreign bodies below the epiglottis. Foreign bodies in the oesophagus are an uncommon cause of airway obstruction but, if lodged in the area of the cricoid cartilage or the tracheal bifurcation, can compress the airway, causing partial airway obstruction. Oesophageal foreign bodies may also become dislodged into the upper airway.

Treatment

In the management of incomplete airway obstruction with adequate gas exchange, care should be taken not to convert partial obstruction into complete obstruction by overzealous intervention.

Awake laryngoscopy can be performed to visualize the foreign body and remove it. The management of complete airway obstruction depends on the patient's level of consciousness.

In conscious patients, chest thrusts and back blows may be effective. The Heimlich manoeuvre/abdominal thrust is no longer recommended following reports of life-threatening complications. Patients who are asymptomatic after uncomplicated removal of a foreign body should be observed for a time in the emergency department and, if they remain well, may be discharged home.

In the unconscious patient, direct laryngoscopy should be performed before bag/valve/mask ventilation. This prevents the foreign body from being moved from a supraglottic to an intraglottic position. If no foreign body is visualized, the patient should be intubated and ventilated. If the patient cannot be ventilated due to airway resistance, the endotracheal tube should be advanced maximally. This aims to convert a complete tracheal obstruction to a main stem bronchus obstruction. The foreign body can then be removed in the operating theatre.

Blunt trauma

Laryngotracheal trauma is rare, comprising 0.3% of all traumas presenting to emergency departments. Increasing rates may be due in part to increased recognition. The upper airway is relatively protected against trauma, since the larynx is mobile, the trachea is compressible and the head and mandible act as shields. Blunt trauma may be difficult to diagnose as external examination may be normal and there may be distracting head or chest injuries.

Mechanisms of injury

'Clothes-line injuries' involve cyclists or other riders hitting fences or cables. Direct trauma from assaults, sporting equipment or industrial accidents also occurs. Suicide attempts by hanging may cause traumatic injuries to the neck as well as airway obstruction due to the ligature. 'Dashboard injuries' occur when seatbelts are not worn, with sudden deceleration resulting in hyperextension of the neck and compression of the larynx between the dashboard and cervical spine.

Pathology

The most common laryngeal injury is a vertical fracture through the thyroid cartilage. Fractures of the hyoid bone and cricoid cartilage also occur and may be found in cases of manual or ligature strangulation. The cricothyroid ligament and the vocal cords may be ruptured and the arytenoids dislocated. Complete cricotracheal transection may occur. Up to 50% of patients sustaining significant blunt airway trauma have a concurrent cervical spine injury.

Clinical features

Tracheal or laryngeal injury should be suspected if aphonia, hoarseness, stridor, dysphagia or dyspnoea occur. Patients may present with complete obstruction or may deteriorate rapidly after arrival. There may be minimal external evidence of injury or the larynx may be deformed or tender and there may be subcutaneous emphysema. It is important to check for associated head, chest and cervical spine injuries.

Clinical investigations

Endoscopy

Both laryngoscopy and bronchoscopy may be required. This should be performed in the operating theatre, as urgent surgical intervention may be indicated.

Imaging

Plain x-ray X-rays should only be considered if the patient is stable with adequate ventilation. Lateral soft tissue x-rays of the neck may provide information about airway patency, subcutaneous or soft tissue emphysema and fractures of the hyoid and larynx. Elevation of the hyoid bone indicates cricotracheal separation. Plain x-rays may also confirm the presence of a foreign body. Cervical spine imaging should be considered owing to the association between upper airway injuries and cervical spine injuries. Chest x-rays may show signs of trauma and subcutaneous or mediastinal emphysema.

Computed tomography CT of the neck is useful in assessing the extent of injuries to the larynx, oesophagus, cervical spine and adjacent structures but should be considered only once the patient has been stabilized.

A classification system for the severity of blunt upper airway injury based on endoscopic and radiological findings has been developed (Table 6.1.1).

Table 6.1.1 Grading of blunt laryngeal injury

Grade	*Endoscopic and radiological findings*
I	Minor laryngeal haematoma without detectable fracture
II	Oedema, haematoma or minor mucosal disruption without exposed cartilage, or non-displaced fractures on computed tomography
III	Massive oedema, tears, exposed cartilage, immobile cords

Treatment

Airway management with protection of the cervical spine is essential. Fibreoptic bronchoscopic intubation is preferable to minimize complications, such as laryngeal disruption, laryngotracheal separation or creating a false tracheal lumen. Cricothyrotomy is relatively contraindicated due to the altered anatomy. Emergency tracheostomy may even be required, ideally performed in the operating theatre. Early ear-nose-throat (ENT) involvement is important and indications for surgical exploration include airway obstruction requiring tracheostomy, uncontrolled subcutaneous emphysema, extensive mucosal lacerations with exposed cartilage as identified on bronchoscopic or laryngoscopic examination, vocal cord paralysis and grossly deformed, multiple or displaced fractures of the larynx, thyroid cartilage or cricoid cartilage.

Prognosis

Mortality rates depend on the location of the injury, ranging from 11% for isolated fractures of the thyroid cartilage to 50% for injuries involving the cricoid cartilage, bronchi or intrathoracic trachea. Asphyxiation is the most common cause of death in blunt laryngeal trauma. Long-term complications include dysphonia and dysphagia.

Penetrating trauma

Mechanism

Penetrating injuries may be secondary to assault or to sporting or industrial accidents. Other causes include eroding head and neck malignancies or post-radiotherapy. A focused history is mandatory.

Clinical features

Penetration of the airway should be suspected if there is difficulty breathing, hoarseness or change in voice, stridor, odynophonia, subcutaneous emphysema, haemoptysis or bubbling from the wound. Penetrating airway injury is often associated with great vessel or pulmonary injuries. Uncontrolled haemorrhage may lead to exsanguination as well as compromising the airway and requires prompt surgical intervention.

Clinical investigation

As for blunt trauma (see earlier).

Treatment

Airway management with protection of the cervical spine is essential. Airway management is as for blunt trauma (see earlier). Early involvement of relevant surgical specialties is a priority.

Burns

Pathology and pathophysiology

Thermal burns may affect the airway by way of facial and perioral swelling, laryngeal oedema or constricting circumferential neck burns. Smoke inhalation occurs in about 25% of burn victims and may cause bronchospasm, retrosternal pain and impaired gas exchange. Chemical burns may result from ingested or inhaled caustic substances.

Clinical features

External examination may show evidence of burns. Carbonaceous material in the mouth, nares or pharynx suggests the possibility of upper airway thermal injury. If the patient presents with stridor or hoarseness, early intubation is essential because of the danger of increasing airway oedema and rapid progression to airway obstruction. Management of the airway in the setting of burns is further discussed in Chapter 3.11.

Clinical investigations

Endoscopy

Endoscopy includes both laryngoscopy and bronchoscopy performed in the operating theatre, as urgent surgical intervention may be required.

Imaging

Chest x-ray may show evidence of burn-associated acute respiratory distress syndrome (ARDS).

Infections

Introduction

Infections may involve the upper respiratory tract directly or adjacent structures. They range from the common and trivial to the rare and potentially life threatening (supraglottitis, parapharyngeal abscesses). Acute respiratory infections are the most frequent reason for seeking medical attention in the United States and are associated with up to 75% of total antibiotic prescriptions there each year. Unnecessary antibiotic use can cause a number of adverse effects including allergic reactions, gastrointestinal upset, yeast infections, drug interactions, an increased risk of subsequent infection with drug-resistant microbes and added costs of over-treatment.

Non-specific upper airway infections

Upper airway infections are generally diagnosed clinically. Symptom complexes where the predominant complaint is of sore throat are labelled pharyngitis or tonsillitis and, where the predominant symptom is cough, bronchitis. Acute respiratory symptoms in the absence of a predominant sign are typically diagnosed as 'upper respiratory tract infections'.

Each of these syndromes may be caused by a multitude of different viruses and only occasionally by bacteria. Most cases resolve spontaneously within 1 to 2 weeks. Bacterial rhinosinusitis complicates about 2% of cases and may be suspected when symptoms have lasted at least 7 days; it include purulent nasal discharge and other localizing features. Patients at high risk for developing bacterial rhinosinusitis or bacterial pneumonia include infants, the elderly and the chronically ill. Treatment should be symptomatic only. Antibiotic treatment neither enhances illness resolution nor alters rates of complications.

Pharyngitis/tonsillitis

Sore throat is among the top 10 presenting complaints to emergency departments. The differential diagnosis is large and includes a number of important conditions (Box 6.1.2).

Pharyngitis has a wide range of causative viral and bacterial agents, most of which produce a self-limited infection with no significant sequelae. Group A β-haemolytic *Streptococcus* (*S. pyogenes*) (GABHS) is responsible for 5% to 15% of cases of pharyngitis in adults and, rarely, can trigger post-infectious syndromes of post-streptococcal glomerulonephritis and acute rheumatic fever.

Clinical investigations

Clinical diagnosis of streptococcal pharyngitis is unreliable. Clinical prediction rules have been developed to help identify patients in whom evaluation with a throat culture or rapid antigen-detection test (RADT) is warranted. The most reliable clinical predictors for GABHS are the Centor criteria. One point each is allocated for the features of tonsillar exudate, tender anterior cervical lymphadenitis, absence of cough and history of fever above 38°C. One point is deducted for age above 45 years. For a score of 0 to 1, no further testing or antibiotic treatment is recommended. For scores of 2 to 3, further testing is recommended with antibiotics given only to patients with positive RADT or cultures. For a score of 4, empirical antibiotic treatment and/or further testing are advised.

RADTs have sensitivities ranging between 65% and 97%. Throat cultures take 2 to 3 days and may give false-positive results from asymptomatic carriers with concurrent non-GABHS pharyngitis. Serological testing is not useful in the acute treatment of pharyngitis but is useful in the diagnosis of rheumatic fever. In populations with a high incidence of acute rheumatic fever, such as in the Northern Territory and North West Queensland, testing for GABHS should be considered in all patients presenting with a sore throat.

The Infectious Diseases Society of America recommends throat cultures for children and adolescents with appropriate clinical criteria (fever, tonsillar exudates, tender cervical lymphadenopathy, absence of cough) but negative rapid antigen test. Patients can be treated up to 9 days after onset of symptoms to prevent acute rheumatic fever. Delaying empirical antibiotic therapy is therefore reasonable if follow-up is practicable.[1]

Adults with a negative RADT will not require cultures owing to their lower incidence of GABHS pharyngitis and lower risk of rheumatic fever. Testing is not recommended for patients with clinical features suggestive of a viral aetiology (e.g. cough, oral ulcers, rhinorrhoea and hoarseness).

Box 6.1.2 Differential diagnosis of sore throat in the adult

- Infective pharyngitis
  - Bacterial: Group A β-haemolytic *Streptococcus* most common pathogen. Diphtheria should be considered in patients with membranous pharyngitis
  - Viral: including Epstein-Barr virus and herpes simplex virus
- Traumatic pharyngitis (exposure to irritant gases)
- Non-specific upper respiratory tract infection
- Quinsy (peritonsillar abscess)
- Epiglottitis
- Ludwig's angina
- Parapharyngeal and retropharyngeal abscesses
- Gastro-oesophageal reflux
- Oropharyngeal or laryngeal tumours

Neisseria gonorrhoeae is an uncommon cause of pharyngitis and may be asymptomatic or cause unilateral or bilateral exudative pharyngitis. *N. gonorrhoeae* pharyngitis is important to diagnose correctly both for appropriate treatment and because of the need to trace and treat contacts.

Human immunodeficiency virus (HIV) is an unusual cause of pharyngitis but should be considered in high-risk populations. The acute retroviral syndrome may present with an Epstein-Barr virus (EBV) mononucleosis-like syndrome. Other causes include primary or secondary syphilis, diphtheria (particularly in overseas travellers) and viral infections such as EBV, enterovirus and herpes simplex virus (HSV) types 1 and 2.

Treatment

Timely use of appropriate antibiotics prevents the development of acute rheumatic fever, decreases the duration of symptoms and decreases the incidence of suppurative complications, such as otitis media and peritonsillar abscesses. However, empirical antibiotic treatment on the basis of symptoms alone results in the overuse of antibiotics, increased costs and an increased rate of side effects from antibiotics. Antibiotics have not been shown to decrease the incidence of post-streptococcal glomerulonephritis, which is related to the subtype of *Streptococcus*.

First-line antibiotics include oral penicillin V, amoxycillin, cephalexin, clindamycin or clarithromycin for 10 days or a single dose of intramuscular penicillin G.

The recommended treatment for gonococcal pharyngitis is ceftriaxone 500 mg IM or IV as a single dose. Consideration should be given to concomitant treatment for *Chlamydia* if this has not been ruled out.

Most patients with pharyngitis are managed as outpatients. Airway compromise is rare, as the nasal passages provide an adequate airway. Some patients who are toxic or dehydrated may need admission for intravenous hydration and antibiotics. Penicillin or amoxicillin remain the drugs of choice for streptococcal pharyngitis. Adjuvant corticosteroid therapy has been shown to reduce pain and shorten the time to symptom resolution. Studies show no difference in adverse events, relapse rates or recurrence rates for corticosteroid compared with placebo groups.

Quinsy/peritonsillar abscess

Epidemiology and pathology

Peritonsillar infections occur between the palatine tonsil, its capsule and the pharyngeal muscles. Peritonsillar cellulitis may progress to abscess formation. Cellulitis responds to antibiotics alone, but differentiating between the cellulitis and abscess and identifying those who require drainage may be difficult. Peritonsillar abscesses

occur most commonly in males between 20 and 40 years of age.

Clinical features, investigations and complications

Symptoms include progressively worsening sore throat (usually unilateral), fever and dysphagia. On examination, the patient may have a muffled 'hot potato' voice, trismus, drooling, a swollen red tonsil with or without purulent exudate and contralateral deviation of the uvula.

Clinical features do not always differentiate between quinsy and peritonsillar cellulitis. In such situations, imaging (e.g. CT), needle aspiration or a trial of intravenous antibiotics can help to differentiate between them.

Complications include airway obstruction and lateral extension into the parapharyngeal space.

Treatment

Antibiotic therapy should include cover for GABHS, *Staphylococcus aureus*, *Haemophilus influenzae* and respiratory anaerobic species (*Fusobacterium*, *Peptostreptococcus* and *Bacteroides*). Appropriate antibiotics include penicillin V or clindamycin for patients allergic to penicillin.

Needle aspiration in experienced hands can be useful but has a 12% false-negative rate and carries the risk of damaging the carotid artery. Formal surgical drainage or tonsillectomy may be necessary.

Ludwig's angina

Infections of the parapharyngeal 'space' have become rare in the post-antibiotic era but, of these, Ludwig's angina or cellulitis of the submandibular space remains the most common. It was first described by Wilhelm Fredrick von Ludwig in 1836; at that time, it was usually fatal because of rapid compromise to the airway. With prompt treatment, including intravenous antibiotics, the mortality rate has declined to less than 5%.

Pathogenesis and pathology

Ludwig's angina is classically bilateral. Infection may spread rapidly into adjacent spaces including the pharyngomaxillary and retropharyngeal areas and the mediastinum. Ludwig's angina is related to dental caries involving the mandibular molars, or it may be associated with peritonsillar abscess, trauma to the floor of the mouth or mandible or recent dental work.

Cultures are usually polymicrobial and include viridans group streptococci (40.9%), *S. aureus* (27.3%), *S. epidermidis* (22.7%) and anaerobes (40%) such as *Bacteroides* species.

Clinical features

Clinical features include toothache, halitosis, neck pain, swelling, fever, dysphagia, elevation of the tongue and trismus.

Treatment and disposition

Treatment necessitates admission and careful airway management. This may include endotracheal intubation, as abrupt obstruction can occur. Surgical drainage is indicated if the infection is suppurative or fluctuant.

The antibiotics of choice are metronidazole plus high-dose penicillin or metronidazole plus intravenous clindamycin if the patient is sensitive to penicillins.

Other abscesses

Parapharyngeal abscesses

Parapharyngeal abscess involves the lateral or pharyngomaxillary space. Presentation and treatment are similar to those described for Ludwig angina, from which they may develop. As well as the complications of Ludwig's angina, including airway obstruction and spread to contiguous areas, there is the added risk of internal jugular vein thrombosis and erosion of the carotid artery, which has a mortality of 20% to 40%.

Retropharyngeal abscess

Retropharyngeal abscesses are more common in children below 5 years of age. In adults, they often result from foreign bodies or trauma. Presenting symptoms and signs include fever, odynophagia, neck swelling, drooling, torticollis, cervical lymphadenopathy, dyspnoea and stridor.

Lateral neck x-rays show widening of the prevertebral soft tissues; sometimes a fluid level. CT of the neck may help in determining the extent and in differentiating an abscess from cellulitis. Magnetic resonance imaging (MRI), if available, is more sensitive than CT in assessing soft tissue infections of the head and neck but demonstrates cortical bone poorly. Treatment requires admission, airway management, intravenous antibiotics and may include surgical drainage.

Acute supraglottitis

Epidemiology and pathology

Acute supraglottitis (AS) is becoming an adult disease; however, in adults there is significantly less risk to the airway than in children. Although commonly referred to as epiglottitis, *supraglottitis* is a more accurate term in adults, as the pathology involves other structures including the pharynx, uvula, base of tongue, arytenoids, aryepiglottic folds, glottis and vocal cords.[2] The incidence of adult supraglottitis has increased over the last decade (4.13 to 5.41/100,000 patients per year) compared with falling paediatric rates in the post Hib vaccine era (0.3 to 0.7/100,000 per year).[3] This may be due in part to increased awareness and increased access to flexible laryngoscopy, allowing more accurate diagnosis. The rate of interventional airway procedures is low (6.6 to 16%)[4,5] compared with the paediatric population, reflecting the changing relationship of anatomical structures with age. Supraglottitis is more common in men (56%), is associated with smoking (42%) and occurs predominantly in winter. The adult mortality rate varies according to case mix and reporting from zero to approximately 8%.[6,7]

A definitive microbiological diagnosis is often not made in adult AS, possibly due to prior antibiotic treatment, the difficulty in obtaining site-specific swabs in the unintubated patient, low rates of bacteraemia and presumed viral aetiologies. *H. influenzae* has been isolated in 12% to 17% of cases, but this is falling as the prevalence of *Haemophilus influenza B* (Hib)–vaccinated adults increases. *S. pneumoniae*, *S. pyogenes*, *H. parainfluenzae* and herpes simplex have also been isolated. Epiglottitis may also occur following mechanical injury, such as ingestion of caustic material, smoke inhalation and following illicit drug use (smoking heroin).

Clinical features

Adult AS patients are more likely to present with nonspecific symptoms, most commonly sore throat and odynophagia. Other symptoms include fever, dysphagia and muffled voice. Drooling and stridor are infrequent. Factors shown to be associated with an increased risk of airway obstruction include stridor, dyspnoea, preferred upright posture and short duration of symptoms.

Clinical investigations

Direct visualization of the epiglottis is the diagnostic gold standard. CT of the neck has a greater sensitivity than lateral soft tissue radiographs but may be less easy to access in a clinical setting. An 'alphabet P sign' formed by the thickened epiglottis adjacent to the shadow of the hyoid bone on a longitudinal ultrasonographic view through the thyrohyoid membrane has been described.[8] Further studies are needed to validate this technique. Lateral neck radiographs are still used frequently, as they are readily obtained; however, they are of only moderate sensitivity. A number of x-ray changes have been described and are listed in Table 6.1.2.

Treatment

Patients should be admitted for observation, which may include surveillance in an ICU. Antimicrobial therapy should provide cover

Table 6.1.2 Radiological findings in adult epiglottitis

The 'thumb' sign	Oedema of the normally leaf-like epiglottis, resulting in a round shadow resembling an adult thumb. The width of the epiglottis should be less than one-third the anteroposterior width of C4. In adults with epiglottitis, the width of the epiglottis is usually >9 mm.
The vallecula sign	Progressive epiglottic oedema resulting in narrowing of the vallecula. This normally well-defined air pocket between the base of the tongue and the epiglottis may be partially or completely obliterated.
Swelling of the aryepiglottic folds	
Swelling of the arytenoids	
Loss of the vallecular air space	
Prevertebral soft tissue swelling	The width of the prevertebral soft tissue should be less than half the anteroposterior width of C4.
Hypopharyngeal airway widening	The ratio of the width of the hypopharyngeal airway to the anteroposterior width of C4 should be less than 1.5.
Straightening of the normal cervical lordosis	

against Hib, *S. pneumoniae*, β-haemolytic streptococci and *S. aureus*. Third-generation cephalosporins (ceftriaxone or cefotaxime) or other antistaphylococcal agents active against methicillin-resistant *S. aureus* (MRSA) (e.g. clindamycin) should be used.

The role of steroids and nebulized or parenteral adrenaline (epinephrine) in airway management is controversial. Most adults can be treated conservatively without the need for an artificial airway.

CONTROVERSIES

- Finding a standardized approach for the use of antibiotics in adult pharyngitis
- The role of intubation, steroids and nebulized or parenteral adrenaline (epinephrine) in adult supraglottitis
- The role of ultrasound in diagnosing supraglottitis

6.2 Asthma

Anne-Maree Kelly

ESSENTIALS

1 Asthma is a major health problem worldwide, resulting in significant morbidity and mortality.

2 Asthma is characterized by episodic bronchoconstriction and wheeze in response to a variety of stimuli.

3 Features suggesting an increased risk of life-threatening asthma include a previous life-threatening attack, previous admission to an intensive care unit (ICU) with ventilation, requiring three or more classes of asthma medication, heavy use of β-agonists, repeated emergency department attendances in the last year and having required a course of oral corticosteroids within the previous 6 months. Behavioural and psychosocial factors have also been implicated in life-threatening asthma, including non-compliance with treatment or follow-up, obesity and psychiatric illness.

4 Attacks vary in severity from mild to life threatening and may develop over minutes.

5 Clinical features supported by bedside pulmonary function tests and pulse oximetry are reliable guides to the severity of attacks.

6 Oxygen, β_2-adrenergic agents and corticosteroids are the mainstays of therapy.

7 Hospital admission is essential if pretreatment peak expiratory flow rate (PEFR) or forced expiratory volume in 1 minute (FEV_1) is less than 25% of predicted or post-treatment levels are less than 60% of predicted.

8 'Thunderstorm' asthma is a rare environmental event that may affect people with no history of asthma.

Introduction

Asthma is a major health problem worldwide, resulting in significant morbidity and mortality. The prevalence of asthma varies significantly between regions across the world. In Australasia, New Zealand and the United Kingdom (UK), it is thought to affect about 20% of children and 10% of adults. Sufferers tend to present to emergency departments (EDs) when their usual treatment plan fails to control symptoms adequately. The respiratory compromise caused can range from mild to severe and life threatening. For these patients, the main role of the emergency care is therapeutic. Other reasons for patients with asthma to attend an ED include having run out of medication, having symptoms after a period of being symptom- and medication-free and a desire for a 'second opinion' about the management of their asthma. For this smaller group, the primary role is one of educating them about the disease, planning an approach to the current level of asthma symptoms and referring them to appropriate health professionals for long-term care.

Epidemiology

Data from the Global Initiative for Asthma suggest that more than 300 million people in the world are currently affected by this disease. Australasia, the UK and North America have a greater prevalence of asthma than the Middle East and some Asian countries. There is also considerable geographical variation in severity, with Australasia reporting the highest proportion of severe disease. The reason for this geographical variation is unclear but may relate in part to ethnicity, rural versus metropolitan environment and air pollution. A number of epidemiological studies suggest that the prevalence and severity of asthma is slowly increasing worldwide.

Aetiology, pathophysiology and pathology[1,2]

Asthma is characterized by hyper-reactive airways and inflammation leading to episodic, reversible bronchoconstriction in response to a variety of stimuli. It is a complex immunologically mediated disease. There is strong evidence that it is inherited, although no single gene is directly implicated. A polygenic basis is likely to account for asthma's wide clinical spectrum.

Triggers of the immunological response (e.g. an extrinsic allergen, viral respiratory tract infection, pollutants, occupational exposures, emotion, exercise and drugs such as aspirin and β-blockers) cause an exaggerated inflammatory response with activation of various cell types including mast cells, eosinophils, basophils, Th-2 cells and natural killer cells. This leads to the release of primary mediators, including histamine and eosinophilic and neutrophilic chemotactic factors as well as secondary mediators, including leukotrienes, prostaglandins, platelet-activating factor, interleukins and cytokines. These result in bronchoconstriction via direct and cholinergic reflex actions, increased vascular permeability (resulting in oedema) and increased mucous secretions.

Pathophysiologically, the effects of acute asthma are

- increased physiological dead space
- respiratory muscle fatigue
- intrinsic positive end-expiratory pressure secondary to hyperventilation with air trapping

Thunderstorm asthma

Thunderstorm asthma is rare. Research suggests that it is usually triggered by an uncommon type of thunderstorm that causes grass pollen to be swept up into the clouds as the storm forms. The pollen then absorbs moisture, bursts open and releases large amounts of smaller allergen particles that are blown down to ground level. These particles are very small and, unlike the pollen itself, can be breathed deeply into the lungs, in some people causing irritation and asthma symptoms. Such events usually occur in late spring and early summer when the pollen load is highest.

People at increased risk of thunderstorm asthma may have a history of asthma, unrecognized asthma, hay fever and particularly seasonal hay fever; or they may be allergic to grass pollen. That said, people without these risk factors can also suffer severe symptoms.

Clinical assessment

The aims of clinical assessment are confirmation of the diagnosis, assessment of severity and identification of complications.

History

Asthma is characterized by episodic shortness of breath, often accompanied by wheeze, chest tightness and cough. Symptoms may be worse at night. Attacks may progress slowly over days or rapidly over minutes. Atypical presentation includes cough and decreased exercise tolerance.

Features suggesting an increased risk of life-threatening asthma include a previous life-threatening attack, previous admission to an ICU with ventilation, requiring three or more classes of asthma medication, heavy use of β-agonists, repeated ED attendances in the last year and having required a course of oral corticosteroids within the previous 6 months. Behavioural and psychosocial factors have also been implicated in life-threatening asthma, including non-compliance with medications, monitoring or follow-up; self-discharge from hospital; frequent general practitioner contact; psychiatric illness; denial; drug or alcohol abuse; obesity; learning difficulties; employment or income problems and domestic, marital or legal stressors.

Examination

Physical findings vary with the severity of the attack and may range from mild wheeze and dyspnoea to respiratory failure. Findings indicative of more severe disease include an inability to speak normally, use of the accessory muscles of respiration, a quiet or silent chest on auscultation, restlessness or altered level of consciousness, oxygen saturation on room air of less than 92% and cyanosis. Clinical features are a good guide to the severity of attacks. Features of the major severity categories are summarized in Table 6.2.1. Pulsus paradoxus has been abandoned as an indicator of severity.

Clinical investigations

Mild to moderate asthma

For mild and moderate asthma, investigations should be limited to pulmonary function tests (PEFR or FEV_1 if available). A chest x-ray is indicated only if clinical features suggest pneumothorax or pneumonia. Arterial blood gases and other blood tests are rarely useful in this group of patients.

Severe or life-threatening asthma

Assessment should include an assessment of PEFR or FEV_1 if possible. A chest x-ray is necessary as localizing signs in the chest may be hard to detect. Blood gas analysis may be useful if the oxygen saturation is less than 92% on room air at presentation, if improvement is not occurring as expected and if the patient appears to be tiring. For those with severe asthma, arterial blood gases may show

- respiratory alkalosis and mild-to-moderate hypoxia (reflecting an increase in respiratory rate in an attempt to maintain oxygenation) or
- hypoxia and respiratory acidosis as the $PaCO_2$ rises with fatigue and air trapping

Blood gas analysis may also be helpful if intubation is being considered because of worsening respiratory failure. That said, the impact of blood gas analysis early in management is minimal and these tests should not be considered 'routine'. There is increasing evidence that venous blood gases can accurately screen for arterial hypercarbia and acidosis. Given the accuracy of pulse oximetry, venous blood gas analysis may be adequate for detecting acidosis and hypercarbia, thus avoiding significant discomfort for patients.[3]

Table 6.2.1 Categorization of asthma severity based on clinical features

Severity category	*Features*	*Respiratory function*
Life threatening	Exhaustion, confusion, coma, cyanosis Silent chest Inability to speak Poor respiratory effort Dysrhythmia, bradycardia Hypotension	FEV_1/PEFR inappropriate; SpO_2 <90% despite supplemental oxygen
Severe	Laboured respiration Tachycardia, heart rate ≥110 Tachypnoea, respiratory rate ≥25/min Unable to complete a sentence in one breath (i.e. words, short phrases only)	FEV_1/PEFR unable or <40% predicted SpO_2 <90% on air PEFR <200 L/min
Moderate	Dyspnoeic at rest Able to speak in short sentences Chest tightness Wheeze Partial or short-term relief with usual therapy Nocturnal symptoms No features of severe asthma	FEV_1/PEFR 40%–60% predicted; PEFR 200–300 L/min
Mild	Exertional symptoms Able to speak normally Good response to usual therapy	FEV1/PEFR >60% predicted PEFR >300 L/min

FEV_1/PEFR, Forced expiratory volume in 1 minute/peak expiratory flow rate; *SpO_2,* oxygen saturation via pulse oximetry.
(Modified with permission from Guidelines for Emergency Management of Adult Asthma, Canadian Association of Emergency Physicians, British Guideline on the Management of Asthma (SIGN) and Asthma Management Handbook (NAC)).

Table 6.2.2 Categorization of asthma severity and initial management

Severity category	*Features*	*Respiratory function*	*Initial management*
Mild	Exertional symptoms Able to speak normally Good response to usual therapy	FEV_1/PEFR >60% predicted PEFR > 300 L/min	**Salbutamol** 4–12 puffs (100 mcg per actuation) via MDI plus spacer OR **Salbutamol** 5 mg by nebulizer Consider **prednisolone** 37.5–50 mg
Moderate	Dyspnoeic at rest Able to speak in short sentences Chest tightness Wheeze Partial or short-term relief with usual therapy Nocturnal symptoms No features of severe asthma	FEV_1/PEFR 40%–60% predicted PEFR 200–300 L/min	Repeat **salbutamol** dose every 20–30 minutes for first hour or sooner if needed. If poor response, add **ipratropium bromide** 8 puffs (21 mcg per actuation) via MDI OR 500 mcg by nebulizer added to nebulized salbutamol. Repeat every 20 minutes for first hour, then q 4–6 h. **Prednisolone** 37.5–50 mg daily for 5–10 days orally OR **hydrocortisone** 100 mg IV q 6 h.

FEV_1/PEFR, Forced expiratory volume in 1 minute/peak expiratory flow rate; *MDI,* metered-dose inhaler.
(Modified from Guidelines for Emergency Management of Adult Asthma, Canadian Association of Emergency Physicians, British Guideline on the Management of Asthma (SIGN) and Australian Asthma Handbook (NAC).)

Full blood examination is usually not useful, as a mild-to-moderate leucocytosis may be present in the absence of infection. Electrolyte measurements may show a mild hypokalaemia, particularly if frequent doses of β-agonists have been taken.

Treatment

The emergency management of acute asthma varies according to severity as defined by the clinical parameters described earlier. The principles are to ensure adequate oxygenation, reverse bronchospasm and minimize the inflammatory response. Initial management based on severity classification are shown in Table 6.2.2 and Fig. 6.2.1. It is important to remember that managing asthma is a dynamic process—patients can both improve and deteriorate quickly. Frequent review and reconsideration of management is essential.

Patients with PEFR above 70% best or predicted 1 hour after initial treatment may be discharged from the ED unless there are concerns about compliance or social circumstances, the patient has a history of brittle or near fatal asthma, discharge would occur overnight or the patient is pregnant. This group is likely to benefit from a longer period of observation and treatment (e.g. in an emergency observation or short-stay unit).

For patients who are discharged, oral corticosteroids at a dose of 0.5 to 1 mg/kg/day, in addition to inhaled steroids at standard doses, should be continued for at least 5 days or until recovery. Oral steroids may then be withdrawn; tapering of dose is unnecessary.

Life-threatening asthma

For life-threatening asthma (defined as exhibiting drowsiness, collapse, exhaustion, cyanosis, poor respiratory effort, soft/absent breath sounds or O_2 saturation <90%), immediate management includes care in a resuscitation area with close physiological monitoring, delivery of adequate oxygen (see below) and administration of 10 mg of nebulized salbutamol by oxygen-driven nebulizer. If this results in marked improvement, the patient can be changed to intermittent salbutamol dosing by metered-dose inhaler (MDI) or nebulizer and care as per the severe asthma pathway, including administration of systemic corticosteroids. If there is no improvement, early consideration of ventilatory support by non-invasive ventilation (NIV) (see below) or endotracheal intubation and mechanical ventilation is recommended. For patients without marked improvement, it is also recommended to administer ipratropium bromide 500 mcg by nebulizer every 20 minutes for 1 hour (in addition to salbutamol) as well as systemic corticosteroids.[4] If there continues to be no improvement or worsening, administration of intravenous magnesium sulphate 10 mmol (diluted according to local institution policies) should be given.[5] If life-threatening asthma persists, continuous nebulized salbutamol can be administered and/or salbutamol by infusion (bolus of 250 µg followed by an infusion at 5–10 µg/kg/h according to local institution policies). Note that monitoring of electrolytes, acid-base status and lactate is important to detect deterioration and the advent of salbutamol toxicity, which can occur with both nebulized and intravenous delivery. The requirement for ventilatory support should be re-considered at regular intervals, especially if there is failure to improve or deterioration. These patients frequently require ICU admission.

If severe/life-threatening asthma does not respond to recommended treatment, consider the possibility of unrecognized anaphylaxis and treat accordingly.

Specific treatments

Oxygen

The objective is to ensure oxygen saturation in excess of 92%. Because these patients often have high respiratory rates, it is important to

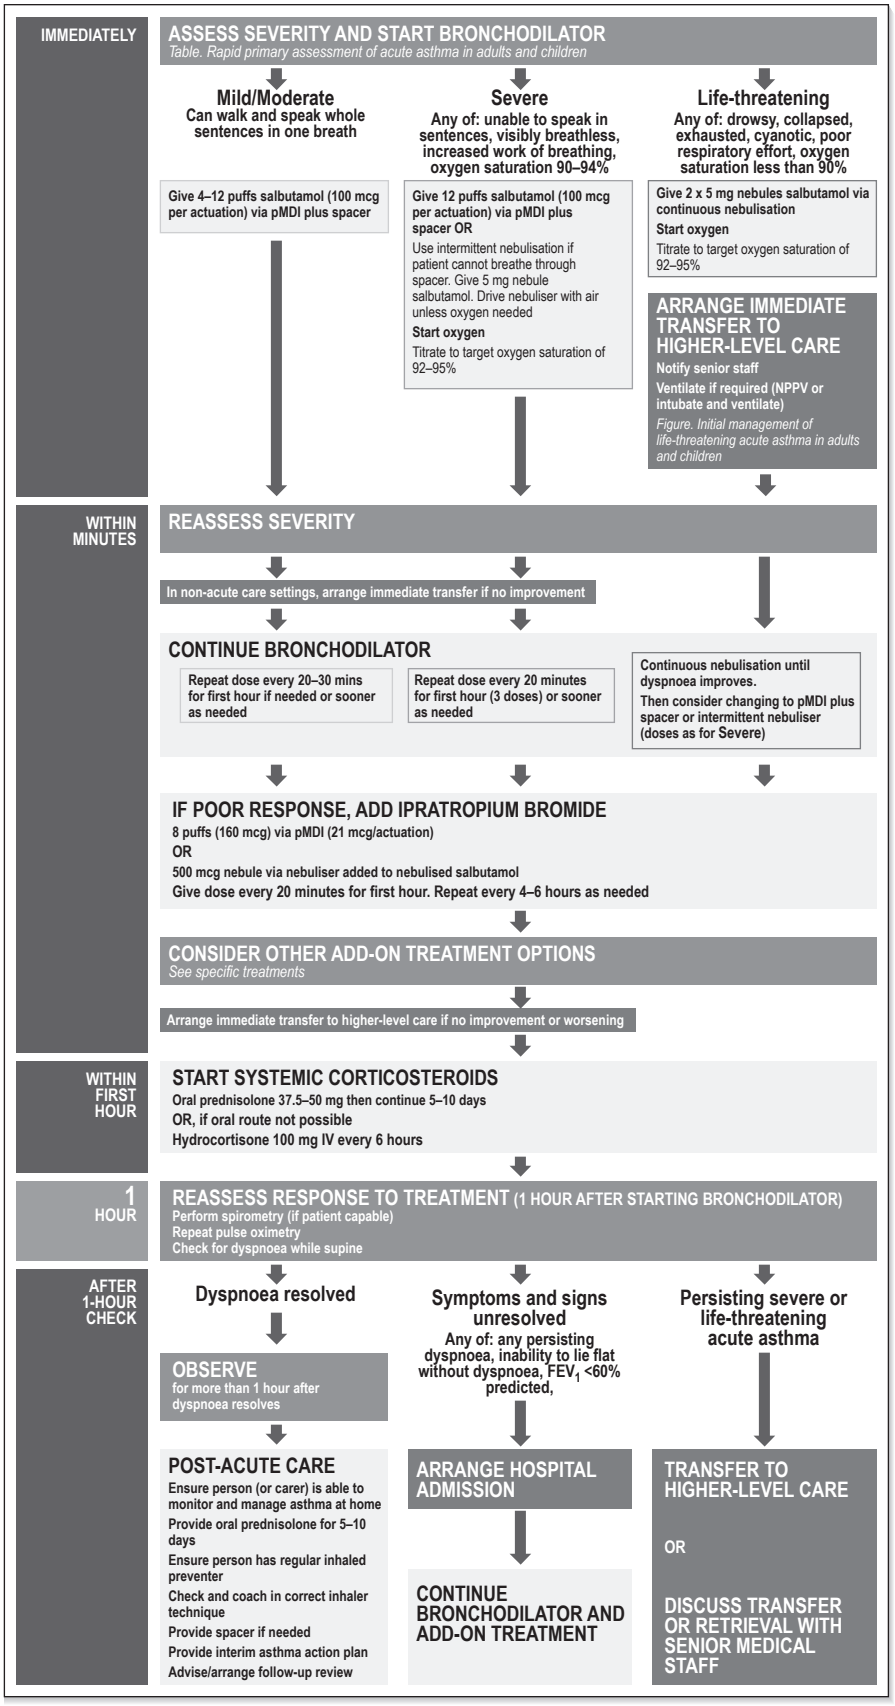

FIG. 6.2.1 Initial management. Modified from the National Asthma Handbook (NAC) with permission.

ensure adequate gas flow—for example, by the use of either a reservoir-type mask or a Venturi delivery system. High oxygen concentrations may be necessary.

Magnesium

Magnesium is postulated to have both bronchodilatory and anti-inflammatory effects. With respect to intravenous magnesium, a Cochrane review[6] suggests that a single dose of intravenous magnesium sulphate reduces hospital admissions and improves lung function in adults with acute asthma who have not responded sufficiently to oxygen, nebulised short-acting β_2-agonists and intravenous corticosteroids. There was insufficient data to determine whether the effect was greater in different severity sub-groups.

The current recommendation is that a single dose of intravenous magnesium sulphate (10 mmol over 20–30 minutes) be considered in patients with

- acute severe asthma who do not have a good response to inhaled therapy or
- life-threatening asthma

Ventilatory support

If ventilatory support is required for patients with an acceptable conscious state and airway protective mechanisms, NIV may be suitable and avoid endotracheal intubation and mechanical ventilation. NIV has been shown to reduce airways resistance and to bronchodilate as well as to counter atelectasis, reduce the work of respiration and reduce the cardiovascular impact of changes in intrapleural and intrathoracic pressures caused by asthma. When used alone, it does not improve gas exchange. A recent case series of patients admitted to a critical care unit with severe asthma found rapid correction of pCO_2 and significant short-term improvement with a median duration of NIV of 5 hours.[7] Compared with endotracheal intubation, NIV also appears to be associated with a lower risk of adverse events. There are currently no guidelines governing the use of NIV in asthma; however, in suitable patients, a trial of NIV under closely supervised conditions would seem reasonable.

If the patient is unsuitable for or does not improve with NIV, endotracheal intubation and mechanical ventilation will be needed. Ketamine, which has been shown to be an effective bronchodilator, is the induction agent of choice. Care must be taken with ventilation, as severe air trapping can result in markedly raised intrathoracic pressure with cardiovascular compromise. A slow ventilation rate of 6 to 8 breaths/min with low-volume ventilation and prolonged expiratory periods is recommended. To reduce the risk of barotrauma, permissive hypercapnia is allowed as long as adequate equate oxygenation is achieved.

Aminophylline

Although pooled studies and meta-analyses fail to show benefit in adults, there is anecdotal evidence that selected rare patients who fail to respond to the standard treatment combinations may benefit from intravenous aminophylline (5 mg/kg loading dose over 20 minutes, followed by 0.3–0.6 mg/kg/h).[8] It should not be used without specialist input and should be used with particular care in patients already taking oral xanthines at admission.

Antibiotics

Routine prescription of antibiotics is not indicated.

Ketamine

A potential benefit from cautious sub-induction doses of ketamine in severe asthma has been suggested. The postulated mechanisms of action of ketamine in asthma are sympathomimetic effects, direct relaxant effects on bronchial smooth muscle, antagonism of histamine and acetylcholine and a membrane-stabilizing effect. There is only one randomized trial investigating the role of ketamine in acute asthma. It showed that, in doses with an acceptable incidence of dysphoria, ketamine did not confer benefit. For intubated patients, there is some evidence that ketamine infusion (bolus 1 mg/kg, followed by 1 mg/kg/h) may reduce peak inspiratory pressures and improve gas exchange, dynamic compliance and minute ventilation.[9]

Disposition

Patients with mild disease can usually be discharged after treatment and the formulation of a treatment plan. For patients with moderate and severe asthma, bedside pulmonary function tests can be a useful guide to disposition decisions. Those with a post-treatment PEFR below 70% predicted after initial treatment can be discharged on appropriate therapy (see earlier). Those with PEFR 40% to 70% predicted require an extended period of observation and treatment (e.g. in an ED observation unit) after which many will be suitable for discharge. Patients with life-threatening asthma or post-treatment PEFR less than 40% predicted require hospital admission. In addition, other factors should be considered in assessing the safety of discharge. These include history of a previous near-death episode, recent ED visits, frequent admissions to hospital, current or recent steroid use, sudden attacks, poor understanding or compliance, poor home circumstances and limited access to transport back to hospital in case of deterioration.

Indications for admission to an ICU or high-dependency unit include the following:

- Deteriorating PEFR
- Persisting or worsening hypoxia
- Hypercapnia
- Acidosis
- Exhaustion/deteriorating respiratory effort
- Drowsiness, confusion, altered conscious state
- Requirement for ventilatory assistance
- Respiratory arrest

All discharged patients should have an asthma action plan to cover the following 24 to 48 hours, with particular emphasis on what to do if their condition worsens. They should also have a scheduled review, either in the hospital or with a general practitioner within that time. Discharge medications are as described earlier.

6.3 Community-acquired pneumonia

Mark Putland • Karen Robins-Browne

ESSENTIALS

1 **The term *community-acquired pneumonia* refers to a syndrome of acute lower respiratory tract infection with a new infiltrate on chest x-ray (CXR) in a patient who has not been hospitalized in the preceding 14 days.**

2 **Recent studies have demonstrated that CXR is less reliable than previously thought for the diagnosis of pneumonia, particularly in the elderly and those with comorbidities such as congestive cardiac failure (CCF) or chronic obstructive pulmonary disease (COPD); however, computed tomography (CT) is still too resource- and radiation-intense to replace CXR for routine diagnosis.**

3 **Severity assessment is used to guide investigations, site of care and antibiotic therapy. Scoring systems such as SMART-COP and CORB enable the identification of patients at high risk of need for intensive care, while the previously established Pneumonia Severity Index (PSI) and CURB-65 were predominantly able to identify low-risk cases that could be treated at home.**

4 ***Streptococcus pneumoniae* is the most common bacterial causative agent; decreases in the proportion of cases attributed to it may be due to the use of pneumococcal vaccine. Other causative agents vary with demographics, severity and epidemics. Antibiotic susceptibilities vary widely around the world. Knowledge of local organisms, susceptibilities and outbreaks will facilitate better empiric prescribing.**

5 **Beta-lactams and macrolides or tetracyclines are the mainstays of antibiotic treatment. Respiratory fluoroquinolones also have a role. Cost, emerging resistance and complications with *Clostridium difficile* infection may limit their use.**

6 **Use of locally adapted structured guidelines for the management of community-acquired pneumonia is associated with improvement in mortality.**

Introduction

Community-acquired pneumonia (CAP) represents a spectrum of disease from mild and self-limiting to severe and life threatening. Most cases, many without radiological confirmation, are treated in the community with oral antibiotics. In the emergency department, CAP is generally not a great diagnostic challenge but rather a matter of separating the serious cases that require inpatient treatment and supportive care from the mild cases that can be managed more efficiently at home. Infrequently, CAP presents with the need for urgent lifesaving interventions and critical care.

The chest x-ray (CXR) has long been the gold standard diagnostic test for pneumonia; however, increased use of advanced imaging and studies of interrater reliability for CXR findings have led to concern regarding misdiagnosis. This is compounded by the increasing elderly population with multiple comorbidities in whom CXR interpretation is more subjective. Currently CXR remains the first-line investigation in most patients because of the cost and radiation exposure of the available alternatives. Ancillary tests including the urinary antigen test (UAT), sputum and blood cultures, inflammatory markers, renal and liver function tests and blood counts have roles in selected cases. A rational approach to pathology testing will reduce excess health care cost and inappropriate decisions based on spurious or misleading results.

The antibiotic management of CAP has changed little for decades, although respiratory fluoroquinolones such as moxifloxacin and levofloxacin have found a role. In some patients, drug-resistant *Streptococcus pneumoniae* (DRSP) and community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) present new challenges in management.

The last two decades have seen the publication of comprehensive evidence-based guidelines from the British Thoracic Society (BTS) and the Infectious Diseases Society of America and American Thoracic Society (IDSA/ATS), The Australian Therapeutic Guidelines Group and similar documents from Japan, Sweden, Canada, India and other countries. There is evidence that the use of a structured, guideline-based approach to CAP management improves mortality and that such guidelines should be adapted to local conditions.

Epidemiology

Rates of pneumonia are difficult to estimate owing to issues of case definition and the fact that most cases occur unstudied in the community. International data suggest that the incidence is around 5 to 11/1000 per year in 16- to 59-year-olds and over 30/1000 per year in those above 75 years of age. The incidence of CAP requiring hospitalization in the United Kingdom is less than 5/1000 per year and represents probably less than 50% of CAP cases. On the other hand, CAP accounts for 8% to 10% of intensive care unit (ICU) medical admissions.

Rates of admission to ICUs vary enormously around the world and probably represent resource availability and usage more than differences in disease severity. New Zealand studies report that 1% to 3% of cases need ICU care, whereas in the United Kingdom the figure is around 5% and in Australia 10%. Much higher percentages are reported from the United States.

The mortality rate of CAP treated in the community is thought to be very low: probably less than 1%. Mortality among hospitalized patients varies depending on the health service but is around 5% to 10%. Mortality among patients admitted to an ICU with CAP is much higher, but the statistics are much more varied, again depending on ICU admission criteria. Mortality obviously varies with severity of disease (see the section later on severity assessment) but also with the type of organism. *S. aureus*, gram negative bacilli (especially *Pseudomonas*), *Burkholderia pseudomallei* and *Legionella* spp. all carry a higher-than-baseline mortality, whereas *Mycoplasma* and the *Chlamydophila* spp. have lower mortality.

Influenza and pneumonia (ICD codes J10–J18) account for 2.3% of all deaths in Australia and are a contributing cause of illness in 13.3% of cases.

Clinical features

Pneumonia should be suspected in patients with

- fever
- new cough
- rigors
- change in sputum colour
- pleuritic chest pain
- dyspnoea

Many patients with these features, however, will not have pneumonia, and certain groups of patients (particularly the elderly) may have pneumonia with few or none of these features.

A normal chest examination makes pneumonia less likely but does not rule it out. The classically described progression of chest examination findings is from crackles and reduced air entry in the first days to dull percussion note and bronchial breathing, which persists until resolution begins at around day 7 to 10, when crackles return. Fever is said to be persistent until a 'crisis' followed by resolution. The actual clinical reality may bear little resemblance to this. The presence of classical findings in the chest may precede radiological abnormality by several hours, particularly in pneumococcal pneumonia.

Much has been made of the role of the clinical syndrome as a predictor of aetiology, but the evidence shows this to be unreliable. Previously 'typical' and 'atypical' pneumonia have been differentiated clinically, but there is now consensus that these terms should be abandoned, as they are misleading. The term 'atypical organism', however, has persisted as an umbrella term for the *Chlamydophila* spp., the *Legionella* spp. and *Mycoplasma*. With these caveats in mind, there are certain associations that should be considered (Box 6.3.1).

The term 'community-acquired pneumonia' means pneumonia occurring in a patient who has not been an inpatient in hospital for more than 48 hours in the preceding 14 days. Definitions vary in how recent a hospital admission should be to influence treatment choice, but a 48-hour admission in the last 10 to 14 days should prompt consideration of treatment for hospital-acquired pneumonia instead of CAP. Patients with advanced Acquired Immunodeficiency Syndrome (AIDS), cystic fibrosis, current chemotherapy or active haematological malignancy presenting with pneumonia are treated as presenting with a complication of their underlying condition rather than with CAP. Nursing home status carries an increased mortality risk and an increased risk of both aspiration pneumonitis and of infection with *S. aureus* and aerobic gram negative bacilli; however, multiresistant organisms are much less likely to be seen than in hospital-acquired pneumonia, and use of the classification 'health care–associated pneumonia' has led to the overprescribing of broad-complex antibiotics to this group. Australian prescribing guidelines have been changed to reflect that pneumococcus remains the most common bacterial organism in these patients, whereas the atypical organisms are rare.

Box 6.3.1 Clinical features associated with specific organisms

Streptococcus pneumoniae
Increasing age
High fever
High acuity
Pleurisy

Bacteraemic pneumococcal pneumonia
Female
Diabetic
Alcoholic
COPD
Dry cough

Legionella
Young and previously healthy patient
Smoker
Multisystem illness (LFT abnormality, elevated CK, GIT upset, neurological disturbance)
More severe illness

Mycoplasma
Young and previously healthy patient
Antibiotic use prior to presenting to hospital
Isolated respiratory illness

Staphylococcus aureus
IVDU
Severe illness
History of influenza

Gram-negative rods
Alcoholic
Nursing home resident

COPD, Chronic obstructive pulmonary disease; *GIT*, gastrointestinal; *IVDU*, intravenous drug use; *LFT*, liver function test.

Pathogenesis and aetiology

Most cases of CAP result from aspiration of flora from the upper respiratory tract, although *Legionella* spp. and *Mycobacterium tuberculosis* may be aspirated directly in aerosolized droplets suspended in the atmosphere. Haematogenous spread to the lung also occurs, for example, from right-sided endocarditis.

Large-volume aspiration of gastrointestinal and upper respiratory tract contents is normally prevented by a coordinated swallow and intact gag and cough reflexes; however, microaspiration occurs routinely in normal individuals during sleep. Aspirated matter is generally quickly cleared by the mucocilliary escalator and by periodic coughing.

Pathogens lodging on the lower respiratory mucosa meet with a fine layer of mucus, rich in secreted Immunoglobulin A (IgA), that acts to prevent their adhesion and to activate other arms of the immune system. These defences may still be breached by the common organisms. Derangement of the defences allows 'opportunistic' organisms to cause infection, such as the gram negative rods, anaerobes, *Staphylococcus* and fungi.

Estimates of the rates of occurrence of various organisms implicated in CAP are difficult to make for several reasons. Isolation of a potentially causative organism occurs in only around 40% of cases in hospital-based studies, less so in community-based ones and much less commonly in actual clinical practice (particularly in CAP treated in the community). A Centers for Disease Control (CDC) survey of aetiological agents in CAP requiring hospitalization in two cities found only viral agents in 24% of cases and bacteria in 14%.[1] There is a great deal of heterogeneity in pneumonia studies regarding underlying patient characteristics, setting, case definition, degree of diagnostic investigation and timing with relation to epidemics, which further complicates interpretation of the data.

Streptococcus pneumoniae

This encapsulated bacterium (*S. pneumoniae*, or pneumococcus) has previously been isolated from around 30% of cases of CAP in the community, hospital wards and ICUs (50%–60% of cases where a cause is found) and more commonly when highly sensitive methods were used for its detection. Recent studies have found declining rates, although it remains the predominant bacterial agent, which was present in 5% of the CDC study cohort.[1–3] The decrease in the relative proportion of cases attributed to pneumococcus may relate to the use of pneumococcal vaccines, thus changing relative ease of identification of different agents (pneumococcus is easily cultured using traditional techniques, whereas the identification of viruses has become much easier with modern genetic techniques) or a changing population and improved living conditions. *Chlamydophila pneumoniae* and *psitacii* (formerly *Chlamydia pneumoniae* and *psittaci*) and the *Legionella* spp. present much greater diagnostic difficulty, potentially skewing the data in favour of pneumococcus. In about 25% of cases of pneumococcal pneumonia, bacteraemia is identified; in a few of these, there are other foci of invasive disease (such as meningitis).

Traditionally this organism has been extremely sensitive to penicillin; however, DRSP is emerging around the world. In Australia, approximately 12% to 20% of isolates express intermediate sensitivity to penicillin, but only around 1% have high-level resistance. Moreover, there is considerable local variation in the resistance pattern. Invasive strains (isolated from blood or cerebrospinal fluid [CSF]) tend to be more susceptible; 5%

are intermediate or highly resistant in Australia. Rates in the United Kingdom are lower; there, less than 3% of pneumococcal bacteraemias show intermediate or high penicillin resistance. In Asia, resistance is much more common, with 23% of isolates exhibiting intermediate sensitivity and 29% high-level resistance, again with marked local variation. Blood levels achieved by giving 1 g of amoxicillin orally every 8 hours or 1.2 g of benzyl penicillin intravenously every 6 hours are sufficient to treat the sensitive and intermediate-sensitivity strains. In fact, it is only strains with very high-level resistance that present a significant likelihood of treatment failure at these doses.

Macrolide resistance ranges from 15% in the United Kingdom to 92% in Vietnam. Again, invasive strains are less commonly resistant than non-invasive ones.

Multiple drug resistance is a problem, with around 17% of Australian isolates demonstrating diminished sensitivity to two or more classes of antibiotic. Respiratory fluoroquinolone resistance remains rare in Australia and the United Kingdom; however, in countries where levofloxacin or moxifloxacin have been more extensively used, resistance is already becoming a problem.

Mycoplasma pneumoniae

These organisms are not strictly bacteria. They lack a cell wall and so are innately insensitive to beta-lactams but are treated with macrolides, tetracyclines and fluoroquinolones. They are fastidious in vitro; hence diagnosis is generally by serological or complement-fixation testing. Pneumonia due to *Mycoplasma* is most common in 5- to 20-year-olds and is rare in the elderly and in the tropical north of Australia. A 4- to 6-yearly cycle of winter epidemics (with the number of reports varying by a factor of 6–7) is well demonstrated around the world. *Mycoplasma* accounts for perhaps 10% to 15% of cases of CAP. The disease is usually mild and probably self-limiting in adults, although patients with sickle cell disease or cold agglutinin disease are at risk of severe complications.

Legionella species

These aerobic gram negative bacilli are fastidious in culture. They occur in sources of lukewarm water, probably hosted by freshwater amoebae, and are killed by temperatures above 60°C. *Legionella pneumophila* serogroup 1, *L. pneumophila* indeterminate serogroup and *L. longbeachiae* account for approximately equal shares of legionellosis in Australia. The genus causes a small percentage of cases of mild and moderate CAP (<5%) but is overrepresented among severe cases, causing 17.8% of cases in UK ICUs. Outbreaks occur due to contaminated water in air conditioning cooling towers, and water supplies and are a significant public health issue. The disease tends to be severe and is often multisystemic. Patients on long-term oral steroids are more susceptible, but the disease is less common among the elderly.

Staphylococcus aureus

S. aureus, a gram positive coccus, is a commensal on the skin and in the oro- and nasopharynx; it may reach the lung by aspiration or by haematogenous spread. It is overrepresented in severe disease, accounting for 25% of ICU pneumonia in the United Kingdom and being associated with a high mortality. It is universally resistant to penicillin, but most cases are sensitive to flucloxacillin and dicloxacillin. CA-MRSA is an emerging problem. Staphylococcal pneumonia classically occurs following influenza and complicates two-thirds of cases of influenza pneumonia in ICU patients. Association between genes encoding drug resistance and the Panton-Valentine Leukocidin gene is concerning, as the latter is a virulence factor leading to destructive necrotic pneumonia.

Mycobacterium tuberculosis

A comprehensive review of the pathogenesis and treatment of tuberculosis is beyond the scope of this chapter. The classical pattern of disease is for inhalation of the bacillus to lead to a chronic inflammatory reaction, usually in the right lower lobe, producing a walled-off granuloma containing surviving organisms and giant macrophages that gradually becomes calcified. At some time after the initial infection—often in the context of immunosuppression due to steroids, malignancy, Human Immunodeficiency Virus (HIV), malnutrition or old age—the disease reactivates and lobar pneumonia develops (typically in the right upper lobe). The disease is usually subacute in onset and, without treatment, relentless. The patient often suffers chronic cough, weight loss, fevers and fatigue. That said, tuberculosis (TB) presents in many and varied ways and a high index of suspicion should be maintained. The patient with pulmonary TB and a productive cough presents a significant infection control and public health risk; respiratory isolation must be initiated while the diagnosis is confirmed.

Other important organisms

Non-typable *Haemophilus influenzae* is a rare cause of mild CAP and is uncommon in young patients. Although it is associated with exacerbations of chronic obstructive pulmonary disease (COPD), it is no more common as a cause of CAP in COPD patients than in the general population. It does, however, become more common with increasing severity of pneumonia and increasing age. Less than 25% of isolates produce beta-lactamase; others are susceptible to aminopenicillins (less so to benzyl-penicillin). *Moraxella catarrhalis* has similar antibiotic susceptibilities and is less common than *Haemophilus*. Tetracyclines are effective, as are second-generation cephalosporins or amoxycillin-clavulanate.

Chlamydophila (formerly *Chlamydia*) *pneumoniae* causes a mild illness, and there is some doubt about its role as a pathogen at all. It is sensitive to macrolides and tetracyclines.

Burkholderia pseudomallei occurs in the soil in the tropical north of Australia and in Southeast Asia. Infection with *B. pseudomallei* (melioidosis) typically causes a severe pneumonia, although any organ may be affected. Fifty percent of cases involve bacteraemia, which is associated with 50% mortality and comprises 25% of cases of bacteraemic pneumonia in tropical Australia (4% of all pneumonia presentations to hospital and 18% of cases where a cause is found). It occurs mainly during the monsoon season, and risk factors include diabetes mellitus, renal failure, chronic lung disease, alcoholism, long-term steroid use and excess kava intake. It is somewhat sensitive to third-generation cephalosporins although better treated with ceftazidime or carbapenems. It is intrinsically resistant to aminoglycosides. The gram negative rod *Acinetobacter baumanii* occurs in a similar area, time of year and group of people and also causes severe pneumonia. It is much less common, but the case fatality rate is similar. It is generally treated with aminoglycosides. Expert consultation should be sought.

Influenza A and B are common causes of pneumonia in adults. Disease may be mild, moderate or severe. Coinfection with *S. aureus* is a well-described complication. Clinical and radiological differentiation from bacterial pneumonia is unreliable and diagnosis is usually made with viral studies on nasopharyngeal or bronchial aspirates or on serological testing after convalescence. Other viruses are being found more often as testing becomes more available; however, their role as causative agents is not always clear.

Anaerobic organisms are generally aspirated in patients with poor dentition. Edentulous patients are thus protected, and these organisms are actually rare in aspiration pneumonia among nursing home patients.

The gram negative rods are a diverse group of opportunistic agents all carrying a high risk of severe pneumonia and mortality. They are more common in Hospital Acquired Pneumonia (HAP) than in CAP and include *Pseudomonas aeruginosa*, *Serratia* spp. and *Klebsiella pneumoniae*. Emergence of antibiotic resistance during treatment occurs with *Pseudomonas*; therefore antibiotics from two classes should be used concurrently if infection is proven or highly likely.

Associations between risk factors and organisms in CAP are weak, and routine questioning about risk factors is likely to be misleading. For

example, despite the well-known association between *C. psittaci* and sick parrots, 80% of patients with psittacosis have no history of bird contact. Stronger associations are those between *S. aureus* and influenza, between *S. aureus* and intravenous drug use (IVDU) and between *Legionella* and travel. Workers in the animal handling and slaughtering industries are at risk of infection with *Coxiella burnetii* (Q fever). Awareness of any local epidemics is important, particularly outbreaks of *Mycoplasma* or legionellosis.

Prevention

Prevention of pneumonia in the 'first world' centres on vaccination for influenza and pneumococcus. In developing regions, the provision of adequate nutrition and housing is more important. Legionellosis is avoided by appropriate design and maintenance of air-conditioning and water supply systems in large buildings.

Note that aspiration pneumonia is not prevented by the use of nasogastric or percutaneous endoscopic gastrostomy (PEG) feeding tubes.

Differential diagnosis

The clinical syndrome of pneumonia is non-specific and the differential diagnosis is broad. CXR findings of lobar infiltrate, however, narrow the possibilities significantly. Underlying malignancy should always be considered, especially in older patients or those with a history of smoking. Pulmonary embolus (PE) is less likely in the presence of a lobar infiltrate, but this should be differentiated from the wedge-shaped opacification of a pulmonary infarction due to PE. Bi-basal pneumonia can be very difficult to distinguish from left ventricular failure, especially in the elderly patient, in whom clinical signs and the white cell count can be unreliable. CXR changes may be pre-existing, such as in localized fibrosis from radiotherapy or when there has been a recent pneumonia with opacification yet to resolve. Aspiration pneumonitis should be differentiated from pneumonia, as antibiotic therapy is less likely to be of benefit. The main indicators are on history (neurological deficit, loss of consciousness, choking while eating or vomiting in the patient with diminished airway reflexes), although most episodes go unwitnessed.

Complications

Pleural effusion and empyema

Para-pneumonic effusions (PPEs) develop in about half of the patients hospitalized with pneumonia; their presence causes a fourfold increase in mortality. Clinically, PPEs are classified as simple PPE, complicated PPE, and frank empyema. Simple PPEs are transudates with a pH greater than 7.20, whereas complicated PPEs are exudates with a glucose level less than 2.2 mmol/L and pH less than 7.20. Persistent fever with effusion or a non-resolving effusion should be aspirated. Aspiration may also provide a specimen for aetiological diagnosis.

Abscess

Lung abscess is a rare complication, most common in the alcoholic, debilitated or aspiration pneumonia patient. Some will respond to antibiotics, but drainage is often required. *S. aureus*, anaerobes and gram negatives are more likely culprits, and polymicrobial infection is common. Tuberculosis should be considered in any patient with a cavitating lesion.

Severe sepsis syndromes

Severe sepsis syndromes are a relatively common occurrence in CAP. Approximately 40% of hospitalized patients develop non-pulmonary organ dysfunction, with 28% having evidence of it at presentation. Septic shock develops in 4% to 5% of cases and is manifest at presentation in just under half of these. The PSI (see later) correlates with the likelihood of severe sepsis; however, the SMART-COP and CORB scores (see further on) better predict the need for inotropic and respiratory support.

Respiratory failure

Respiratory failure is a common reason for ICU admission in CAP. In patients with moderate to severe disease, a widened A–a gradient can be detected, with PCO_2 falling with increases in minute volume to compensate for failure of gas exchange. As severity increases, the PCO_2 will return to normal as the patient tires and PO_2 will fall. Type II respiratory failure occurs late and is an ominous sign.

Renal failure

Renal failure may occur in any case of severe CAP but is particularly associated with legionellosis. Multiorgan failure may follow severe sepsis.

Clinical investigations

Imaging

Chest x-ray

Presence of a new infiltrate on CXR remains central to the diagnosis of pneumonia. Diagnosis without CXR has been shown to be unreliable, although a normal chest examination makes the diagnosis unlikely. In elderly patients and patients with other pulmonary pathology (COPD, CCF), CXR has poor interrater reliability for pneumonia; however, practical alternatives are still lacking.

CXR has proven to be an unreliable indicator of aetiology; however, some clues may be found. *Mycoplasma* is less likely in the presence of homogeneous shadowing but is suggested by lymphadenopathy. Multilobar infiltrates and pleural effusions make bacteraemic streptococcal pneumonia more likely, whereas a multilobar infiltrate with pneumatocoeles, cavitation and pneumothorax is suggestive of *S. aureus*. *Klebsiella* tends towards the right upper lobe, but the described association between this agent and a bulging horizontal fissure is unsupported by evidence.

Tuberculosis should always be considered in cases of upper lobe infiltrate, especially in the presence of a Ghon focus or calcified nodule, usually found in the right middle or lower lobe.

Clues to severity may be found on the CXR (see later).

The role of the repeat CXR is unclear. The rate of improvement is quite variable. It is slower with increasing age, presence of comorbidity, multilobar infiltrates and *Strep.* (especially bacteraemic) or *Legionella* as pathogens. *Legionella*, in fact, is characterized by worsening radiological appearance after admission. The role of a convalescent film is likewise unclear. Rates of underlying lung cancer vary, and most cases are diagnosed on the acute film. Smokers over 50 years of age are particularly at risk; routine convalescent imaging should be considered in this group.

Computed tomography

With the increasing use of computed tomography (CT), it is more and more common for pneumonia to be diagnosed on CT scans of the chest when looking for other pathology; however. this remains an impractical test for routine diagnosis owing to radiation, cost and time involved.

Ultrasound

Point-of-care ultrasound is a rapidly developing field, and lung ultrasound is acquiring advocates; however, sensitivity and specificity remain around 85%, depending on diagnostic criteria. Studies demonstrating a higher sensitivity have a lower specificity, and vice versa. When there are long delays to x-ray imaging, this may become a useful test in the right hands.

General pathology

The roles of non-microbiological pathological testing in CAP are to help confirm the diagnosis, to assess severity, to identify complications and to screen for underlying or comorbid conditions. Previously well young people with non-severe pneumonia will not benefit from routine tests.

Full blood count

The full blood count is routine in the patient requiring hospitalization with pneumonia. Anaemia, thrombocytopaenia, severe leucocytosis and leucopaenia are all markers of severity (see later). Polycythaemia may indicate dehydration

or underlying chronic hypoxia. A white cell count over 15,000/mm^3 suggests a bacterial aetiology (especially *S. pneumoniae*) but is insensitive and non-specific.

Urea and electrolytes

Urea, electrolytes and creatinine are also routinely measured in the hospitalized patient. Hyponatraemia (Na <130 mmol/L) and elevated urea (≥11 mmol/L) are proven markers of severe pneumonia. Acute renal impairment is a complication of chronic renal failure a risk factor for severe disease.

Liver function tests

Liver function tests frequently demonstrate some abnormality, although this may not change management. Chronic liver disease is a risk factor for severe pneumonia. Hypoalbuminaemia is a marker of severity.

Blood gas testing

Measurement of arterial blood gases has been common practice in patients hospitalized with pneumonia. There is evidence that a venous blood gas is acceptable for the assessment of acid–base status and may be a valid screening tool for hypercapnia. Transcutaneous oxygen saturation measurement (SpO_2) is, likewise, an acceptable screening tool for hypoxia, although it becomes inaccurate when SpO_2 is less than 90%.

Inflammatory markers

Measurement of C-reactive protein (CRP) remains contentious. CRP offers no indication of severity. It may have a role in differentiating pneumonia from exacerbation of COPD or non-infective diseases and pneumonia in uncertain cases. Where point-of-care tests are available, a negative CRP may help to limit antibiotic use in ambulatory care.

Serum procalcitonin, D-dimer, serum cortisol and other novel biomarkers have been found to correlate with the severity of pneumonia, but their discriminatory value and role, if any, remain undefined.

Testing for aetiology/microbiology

As discussed earlier, achieving an aetiological diagnosis in CAP is difficult, even in the research setting in tertiary referral centres.

Advantages of doing so include the opportunity to tailor therapy, to detect outbreaks or bioterrorism events and to identify resistant organisms. Current aetiological knowledge depends heavily upon laboratory reports to surveillance authorities and 'accumulated knowledge' rather than prospective research.

Disadvantages of an aggressive diagnostic approach are its high cost and low yield, the risk of inappropriate changes to therapy based on false-positive results from contaminants, the long delay between testing and results (particularly from culture and paired serology), the potential to delay treatment while specimens are obtained and exposure of the patient to added unpleasant and invasive procedures. Moreover, it is uncommon for therapy to be streamlined even with microbiological diagnosis, and directed therapy has not been shown to be beneficial compared with empiric therapy (although small mortality benefits are suggested in the ICU subgroups).

Sputum

Sputum can be collected for microscopy and for culture. The two should be considered separately, although the value of sputum collection in general is unclear. Many patients are unable to produce sputum, and waiting for them to do so may cause significant delays to antibiotic treatment.

Microscopy (generally with Gram stain, although Zeil-Neilsen stain for acid-fast bacilli should be requested if tuberculosis is suspected) can provide useful guidance for empiric prescribing as well as an indication of whether the specimen is of sufficient quality for culture to be useful.

Sputum culture has a higher sensitivity than Gram stain and provides more definite identification, typing and sensitivity data; however, results are not available when treatment is started and colonization may be hard to distinguish from infection, particularly if Gram stain was negative or not performed. Special culture is indicated if *Legionella* or *M. tuberculosis* is to be identified.

Sensitivity of both microscopy and culture decline if antibiotic therapy has already started; moreover, even under ideal conditions, neither is highly sensitive or specific.

Likewise, tuberculosis requires both special stains and culture media as well as prolonged culture time. Provision of good clinical details to the lab including suspected organism, timing of specimen and use of antibiotics is essential.

Blood culture

Blood cultures have traditionally been recommended for all patients admitted to hospital with suspected pneumonia. More recently, the performance of blood cultures in admitted pneumonia patients has been linked to hospital accreditation in the United States. The most common non-contaminant organism isolated is pneumococcus, which is generally covered by empiric treatment and yields are generally low (around 7% overall and 25% at most in pneumococcal pneumonia). Contaminants are found with similar frequency. Pneumococcal pneumonia with and without bacteraemia has been shown to have a similar prognosis. A positive non-contaminant result, however, is highly specific for microbiological aetiology.

A rational approach is to limit blood culture use to cases where yield is higher, the likelihood of a resistant or non-pneumococcal organism is higher, the consequences of inappropriate prescription are greatest or where there is concern about a significant outbreak or epidemic.

Independent predictors of a positive blood culture in CAP include coexistent liver disease, systolic blood pressure below 90 mmHg, temperature below 35°C or ≥40°C, pulse or ≥125/min, urea or ≥11 mmol/L, Na less than 130 mmol/L, WBCs less than 5000/mm^3 or greater than 20,000/mm^3 and lack of prior antibiotic therapy. A prediction rule has been developed based on these variables, with presence of two or more predictors associated with a 16% rate of positive blood culture. These indicators are also markers of severity and it is patients with severe pneumonia who are most at risk of adverse outcome if initial antibiotics are not sufficient. A positive pneumococcal UAT (see later) is associated with a higher yield from blood culture; this may be an indication for performing blood culture to monitor community resistance rates.

Guideline recommendations vary; however, blood cultures offer little in non-severe pneumonia and are best reserved for ICU cases or patients with risk factors for non-pneumococcal organisms.

Urinary antigen testing

The two commonly available UATs are the *Legionella* and pneumococcal UAT. Both are fast and simple to perform and minimally affected by antibiotics. The pneumococcal UAT is 50% to 80% sensitive and more than 90% specific. False positives occur in children with chronic respiratory illness and colonization with pneumococcus and in adults who have had CAP in the preceding 3 months. The *Legionella* UAT is probably highly sensitive and specific for *L. pneumophila* serogroup 1, is positive from day 1 and remains so for up to 3 weeks.

The precise role of these tests remains uncertain, however. CAP is assumed to be pneumococcal by default; therefore a positive test provides little helpful information whereas a negative test is of little predictive value. The *Legionella* UAT identifies only *L. pneumophila* serogroup 1, which is the predominant member of this genus in the northern hemisphere but accounts for less than half of *Legionella* cases in Australia. It is unclear whether a positive *Legionella* UAT justifies streamlining to macrolide monotherapy in sick inpatients or whether it obligates upgrading from oral to intravenous macrolide. A positive *Legionella* UAT is associated with ICU admission, perhaps because the higher antigen load present in cases with a positive test represents a greater infective burden. A negative *Legionella*

UAT, however, does not rule out legionellosis, as other species and serogroups are not detected.

Other tests

Serology has little to offer in the emergency management of CAP but has a public health role if an outbreak of viral or 'atypical' pneumonia is suspected. If symptoms have been ongoing for more than 7 days, then a high titre of *Mycoplasma* or *Legionella* IgM is diagnostic. Otherwise, however, paired serology tests weeks apart are required, with the diagnosis coming only after treatment is completed.

Influenza rapid point-of-care testing has a low sensitivity (50%–70%) and cross-reacts with adenovirus. A positive test is highly specific and may be an indication for treatment with antivirals, where available, or for respiratory isolation, and may be useful in outbreak detection, although it is unlikely to be superior to physician judgement in this role. Influenza direct fluorescent antibody testing is more reliable but takes 2 hours and requires special laboratory skills. It is used for identification of specific strains of influenza (e.g. avian influenza/H5N1 and 'swine flu' H1N1).

Severity assessment

A key clinical problem in the assessment of a patient with suspected CAP is determining severity. The great majority of CAP cases are mild and would be self-limiting, although antibiotic treatment shortens the illness. A significant minority of cases cause an acutely debilitating illness and a small minority are life threatening. Formalizing the process of severity assessment with severity scoring systems has focused on two aims: identifying those who can safely be managed at home, thus reducing unnecessary admissions and unplanned readmissions, and identifying those who are likely to need ICU care, with the aim of reducing mortality and complications from delayed recognition of severe disease while avoiding overuse of the ICU. Many systems have been developed and validated, including the PSI, the British Thoracic Society's BTS, modified BTS, CRB, CURB and CURB-65 scores, the American Thoracic Society(ATS), modified ATS (m-ATS) and revised ATS (r-ATS) scores, the Spanish Society of Pulmonology and Thoracic Surgery's SEPAR score and the Australian scores SMART-COP and CORB.

Proven markers of severity

The following have all been defined as markers of severity:

- Demographic factors
  - Increasing age
  - Residence in a nursing home or being bedridden
  - Male sex
- Comorbidity
  - CCF, diabetes mellitus, coronary artery disease, chronic lung disease, liver disease, cerebrovascular disease, chronic renal failure and neoplastic disease
- Examination findings
  - Respiratory rate greater than 30/min or less than 6/min
  - Confusion (Abbreviated Mental Test Score (AMTS) <8 or new disorientation to time, place or person)
  - Systolic BP below 90 mmHg, diastolic BP below 60 mmHg or septic shock requiring aggressive fluid resuscitation or vasopressors
  - Temperature below 35°C or ≥40°C
  - Heart rate ≥125/min
- Haematology
  - Haematocrit below 30%
  - White cell count less than 4000/mm^3 or greater than 20,000/mm^3
  - Platelets less than 100,000/mm^3
- Biochemistry
  - Urea elevated (cut-offs vary)
  - Sodium less than 130 mmol/L
  - Glucose greater than 14 mmol/L
  - Arterial pH less than 7.35
  - Hypoxia (PaO_2 less than 60 mmHg, SpO_2 less than 92%, PaO_2:FiO_2 less than 250 mmHg)
  - Albumin less than 3.5 g/dL
- Radiology
  - Bilateral or multilobar involvement
  - Effusions, especially bilateral
  - Worsening radiological changes after admission in the ICU patient
- Microbiology
  - Positive blood culture (retrospective)
  - *S. pneumoniae*, gram negative bacilli, *S. aureus* and *P. aeruginosa*.

Table 6.3.1 Calculating the SMART-COP score

S	Systolic BP <90 mmHg		2 points
M	Multilobar CXR involvement		1 point
A	Albumin <3.5 g/dL		1 point
R	Respiratory rate (age-adjusted)	1 point	
		≤50 years	≥25 breaths/min
		>50 years	≥30 breaths/min
T	Tachycardia ≥125 beats/min		1 point
C	Confusion (new)		1 point
O	Oxygen low (age-adjusted)		2 points
		≤50 years	PaO_2 <70 mmHg; SpO_2 ≤93% on air; PaO_2/FiO_2 <333 mmHg
		≥50 years	PaO_2 <60 mmHg; SpO_2 ≤90% on air; PaO_2/FiO_2 <250 mmHg
P	Arterial pH <7.35		2 points

CXR, Chest x-ray.

SMART-COP

The SMART-COP score was derived and validated in temperate Australia as part of the Australian Community Acquired Pneumonia Study (ACAPS) study and has since been validated in tropical Australia. It has been shown to predict the need for intensive respiratory or vasopressor support (IRVS) during the initial assessment in the emergency department with high sensitivity and negative predictive value (NPV). The score has eight components, which have different weightings, and some of the criteria are age-adjusted (Table 6.3.1). Patients are then risk-stratified into four risk groups ranging from very low risk to very high risk of requiring IRVS (Table 6.3.2). The score can be modified for primary care physicians without access to blood tests and is then called SMRT-CO as it excludes measurement of albumin and pH.

Importantly, immunosuppressed patients were excluded from all derivation and validation studies of SMART-COP, so the score should be used with caution in this patient population. A modification of the SMART-COP score, developed in the Northern Territory for use in tropical regions of Australia and known as the SMARTACOP score, doubles the relative weight of the serum albumin score and adds Indigenous ethnicity as a risk factor. Although no significant advantage of the SMARTACOP over the SMART-COP score for the prediction of IRVS has been demonstrated, both scores significantly outperformed PSI.

CORB

CORB is another Australian-derived and validated study that predicts the need for intensive care in patients with CAP. It has four equally weighted components, scoring one point each:

Table 6.3.2 Interpreting the SMART-COP score

0–2 points	Low risk of needing IRVS
2–4 points	Moderate (1 in 8) risk of needing IRVS
5–6 points	High (1 in 3) risk of needing IRVS
≥7 points	Very high (2 in 3) risk of needing IRVS
In primary care, albumin, arterial pH and PaO_2 may be omitted and the results interpreted as follows:	
0 points	Very low risk
1 point	Low (1 in 20) risk
2 points	Moderate (1 in 10) risk
3 points	High (1 in 6) risk
≥4 points	High (1 in 3) risk

IRVS, Intensive respiratory or vasopressor support.

- Confusion: new onset or worsening impairment
- Oxygenation: O_2 saturation less than 90% or PaO_2 less than 60 mmHg
- Respiratory rate: ≥30/min
- Blood pressure: SBP less than 90 mmHg or DBP less than 60 mmHg

A score of ≥2 equates with severe pneumonia. CORB has the advantage of being easy to remember and all variables being available at the patient's bedside. However, it was a single centre derivation and validation study potentially limiting its external validity. It is less sensitive and has a lower NPV than SMART-COP.

Pneumonia Severity Index

The PSI was derived by retrospectively and validated both retrospectively and prospectively in separate groups of patients in the late 1980s and early 1990s. Over 54,000 patients and 275 hospitals from across the North America were involved in the study. The rule is a two-step process with low-risk patients identified on clinical grounds alone in the first step and all other patients further differentiated—on the basis of age and 19 dichotomized and weighted clinical and investigation features—into four further groups (Tables 6.3.3 and 6.3.4).

Despite rigorous derivation and validation, the PSI is unwieldy and is heavily weighted toward elderly patients. Importantly, the PSI was derived and validated for the prediction of mortality, not for predicting ICU care or antibiotic choice.

Studies have found that the PSI is poorly adhered to by clinicians, likely due to its complexity. In its favour, the variables used by the PSI are all available at the end of a typical workup, particularly as there are data supporting the substitution of venous pH for arterial pH.

Finally, the PSI was derived and validated in adult patients with no recent hospitalization who did not have HIV. Use of the PSI in immunocompromised patients has been investigated in one study and was found to perform well in patients with HIV, solid organ transplant or treatment with immunosuppressive drugs and poorly in patients with haematological malignancy, on chemotherapy or after chest radiotherapy or bone marrow transplantation.

The CURB-65 score

The BTS currently recommends use of this score for stratification of CAP patients. The system stratifies patients on the basis of a 0-to-5 scale with one point scored for each of the following:

- Confusion of new onset (AMTS below 8 or new disorientation to time, place or person)
- Urea greater than 7 mmol/L
- Respiratory rate ≥30/min
- Blood pressure below 90 mmHg (systolic) or up to or less than 60 mmHg (diastolic)
- Age 65 years or above.

Scores are correlated with risk of death, and site of care is suggested (Table 6.3.5).

The CURB-65 score has been validated in thousands of patients from the United Kingdom and other countries and is the result of a process of refinement of a series of other validated scoring systems. It has the significant advantage of simplicity and has been shown to perform as well as a previous two-stage BTS score. It is easy to remember and quick to calculate. It is worth noting for community practitioners, that the CRB-65 score (CURB-65 without the urea measurement) performs similarly and that patients with a CRB-65 score of 0 are generally safely managed in the community, whereas those with a score of 1 or more should be assessed at hospital.

The CURB-65 score has been compared with the PSI as well as the various ATS scores: all perform similarly well. All are strong at identifying well patients who can be safely treated at home provided that social factors and oxygen requirements are considered. Neither PSI nor CURB-65 reliably predicts risk of death or need for ICU care.

All scoring systems should be used in conjunction with clinical judgement. Scoring systems using age as a predictor should be applied with caution in young patients. Patients requiring supplemental oxygen cannot be discharged regardless of their score. A patient who is vomiting, homeless or unreliable should not be discharged on oral antibiotics from the emergency department (ED) and some underlying conditions such as advanced neuromuscular disease and general frailty may warrant admission for relatively mild pneumonia.

No scoring system is a substitute for regular review by an experienced clinician.

Treatment

Site of care

As discussed earlier, the PSI and CURB-65 score are both useful for identifying patients who are well enough to be discharged home provided that oxygenation, psychosocial factors and the overall clinical picture are considered. Typically cases with a PSI class I or CURB-65 score of 0 can confidently be treated at home and cases with a PSI class II or CURB-65 score of 1 are probably safe to discharge as well.

Cases of intermediate severity (PSI ≥III or CURB-65 score ≥2) are likely to benefit from a short period of supervised hospital treatment to ensure that antibiotics are given effectively and to monitor for any deterioration. Emergency observation units, short-stay units or medical assessment units are ideal for this purpose. Alternatively, a 'hospital in the home' service may be appropriate, particularly if it incorporates early medical review.

The decision to admit to an ICU can be aided by SMART-COP (≥3) or CORB (≥2) scores.

General supportive care

For the patient being discharged to the community, general advice regarding rest, analgesia for chest wall pain and maintenance of adequate hydration and nutrition is appropriate. Physiotherapy is of no proven benefit. All discharged patients should undergo scheduled medical review within 24 to 48 hours to check for deterioration.

For the admitted patient, similar measures will be required. Hydration may need to be supplemented with intravenous fluids; in severe or prolonged illness, nutritional support will be required. Oxygen should be provided to maintain SpO_2 above 95% (PaO_2 >60 mmHg). A lower SpO_2/PaO_2 may be desirable in patients with severe COPD.

The role of non-invasive ventilatory support (NIV) in respiratory failure due to pneumonia is controversial. In patients with underlying COPD, it is almost certainly of benefit. In other patients, it has been shown to raise SpO_2 and decrease

Table 6.3.3 Calculating the Pneumonia Severity Index

Step 1	
The patient is **Class I** and needs no further investigation if he or she is ≤50 years old and has none of the following:	
History:	
Neoplastic disease	
Liver disease	
Renal disease	
Congestive cardiac failure	
Cerebrovascular disease	
Examination:	
Acutely altered mental state	
Respiratory rate ≥30/min	
Systolic BP <90 mmHg	
Temperature <35°C or ≥40°C	
Pulse rate ≥125/min	
Step 2	
If the preceding is not satisfied, then the PSI score must be calculated as follows:	
Factor	***Score***
Demographic	
Age	Age in years
Sex	−10 if female
Nursing home (not hostel) resident	+10
Coexisting illness	
Neoplastic disease	+30
Liver disease	+20
Congestive cardiac failure	+10
Cerebrovascular disease	+10
Chronic renal disease	+10
Signs on examination	
Acutely altered mental state	+20
Respiratory rate ≥30/min	+20
Systolic blood pressure <90 mmHg	+20
Temperature <35°C or ≥40°C	+15
Pulse rate ≥125/min	+10
Investigations	
Arterial pH <7.35	+30
Serum urea ≥11 mmol/L	+20
Serum sodium <130 mmol/L	+20
Serum glucose ≥14 mmol/L	+10
Haematocrit <30%	+10
PaO_2 <60 mmHg or SpO_2 <90%	+10
Pleural effusion on CXR	+10

Table 6.3.4 Mortality and Pneumonia Severity Index class

Score	*Class*	*30-Day mortality (%)*
no score	I	0.1
1–70	II	0.6
71–90	III	0.9
91–130	IV	9.3
>130	V	27

Table 6.3.5 Mortality and the CURB-65 score

Score	*Risk of death or ICU admission (%)*	*Comments*
0	0.7	Low risk. Nonsevere pneumonia. May be suitable for treatment at home.
1	3.2	
2	13	Increased risk of death. Consider for short inpatient or hospital-supervised outpatient treatment.
3 4 5	17 41.5 57	High risk of death. Treat as inpatients with severe pneumonia. Consider use of ICU.

ICU, Intensive care unit.

heart rate, but deterioration requiring intubation is the rule and patients intubated after a failure of a prolonged trial of NIV fare worse than those intubated early. At best, it is a temporizing measure if intubation is not immediately possible or if it is not immediately clear that intubation is appropriate.

Invasive ventilation should be low volume (6 mL/kg of ideal body weight) even if hypercapnia results. Severe sepsis syndrome and septic shock should be recognized and treated early and aggressively.

The use of structured guidelines for CAP management, covering a range of interventions, has been shown to reduce hospital mortality. It is important that the guidelines be locally appropriate (considering local patient demographics, comorbidity spectrum, social issues, organism prevalence and antibiotic resistance patterns). Wide local variation in antibiotic resistance rates is noted, both between countries and within them.

Antibiotic treatment

Initial therapy in CAP is almost always empiric, with antibiotics selected to cover the likely

organisms. *S. pneumoniae* is treated generally with a beta-lactam. The 'atypical' organisms are covered with a macrolide, although a tetracycline is acceptable if oral therapy is being used. These also provide cover against *Legionella* spp. Doxycycline and macrolides also provide some cover against *S. pneumoniae*; but, due to high levels of resistance, they should be used only as monotherapy in patients with mild pneumonia, and a beta-lactam should be added if treatment fails. Addition of specific coverage for gram negative coliforms, *S. aureus*, *P. aeruginosa*, *B. pseudomallei* and *A. baumanii* is added when severity or the clinical or epidemiological picture warrants. Monotherapy with a fluoroquinolone is an alternative to the combination of beta-lactam and macrolide in mild pneumonia or in patients with immediate hypersensitivity to beta-lactams, but emerging resistance is a problem.

Drug resistant *S. pneumoniae* is a growing problem around the world, particularly in Asia, but it remains an uncommon cause of pneumonia in Australia and the United Kingdom. Macrolide resistance is common in vitro but the significance of this has been questioned. Modern macrolides are concentrated at the site of infection and, until recently, few cases of treatment failure with macrolide monotherapy had been reported. Macrolide resistance among pneumococci has recently been recognized as a significant clinical problem.

Community-acquired MRSA is another looming problem, although it is more commonly reported from skin and soft tissue infections than CAP. It is less broadly resistant than hospital-acquired MRSA. Ominously, the genes for drug resistance in CA-MRSA are associated with the gene for the Panton-Valentine Leucocidin virulence factor, which is associated with necrotizing pneumonia, respiratory failure and shock.

As discussed earlier, the clinical and radiological pictures are often unhelpful in assessing the microbiological aetiology of CAP. In the absence of a positive UAT or sputum Gram stain, it is unlikely that initial treatment decisions will be made on data other than the clinical picture and knowledge of local pathogens. With increasing severity of pneumonia, antibiotic coverage is generally broadened for two reasons: organisms other than *S. pneumoniae* become more likely and there is more to be lost by failure to cover the causative agent in the first instance.

Despite widespread dissemination of antibiotic guidelines, overprescribing of broad-spectrum antibiotics remains a problem. Pneumonia guidelines are often generalized to non-pneumonic lower respiratory tract infections, such as bronchitis and exacerbations of COPD, and severe pneumonia tends to be overdiagnosed. Overprescription of broad-spectrum antibiotics contributes to many adverse outcomes, including increases in antibiotic-associated enteropathy and *C. difficile* infection; increases in other side effects such as anaphylaxis; increased health care costs; and increased spread of resistant organisms.

SMART-COP and CORB have been recommended by the Australian Therapeutic Guidelines: Antibiotic as tools for selection of antibiotic coverage. It is to be noted that this is not directly supported by the available evidence, although it is in line with the principles discussed previously.

Mild pneumonia

Oral therapy is preferred in patients well enough to be treated at home who can tolerate oral medications and are likely to be adherent to a treatment regimen. Given the known spectrum of pathogens as described earlier, whether to use a beta-lactam alone or in combination with dedicated 'atypical cover' is debated. A Cochrane review has found no benefit in addition of 'atypical cover', although most of the studies examined compared fluoroquinolone monotherapy to beta-lactam monotherapy. In the United Kingdom, where the 4-yearly cycle of *Mycoplasma* epidemics is well described, amoxicillin as a single agent is recommended, with erythromycin as an alternative, if tolerated, unless a *Mycoplasma* outbreak is known to be occurring. In the United States, the practice of using macrolide monotherapy stemmed from the previously well-established failure against DRSP, which means that dual therapy is now recommended. Australian guidelines recommend monotherapy with amoxicillin unless there is specific concern about atypical organisms.

The combination of a macrolide with amoxicillin has always been shown to be effective against DRSP, and the combination increases the likelihood of covering *H. influenzae* adequately. Cefuroxime is an alternative to amoxicillin as it has a similar spectrum including moderate activity against *Haemophilus*. Monotherapy with a fluoroquinolone, such as moxifloxacin, is an alternative for mild pneumonia and is useful if immediate hypersensitivity to penicillins is suspected. There is concern that the use of these agents will increase resistance to important reserve agents, such as ciprofloxacin.

In cases where a single intravenous dose of an antibiotic is to be given before discharge from the ED, benzyl penicillin is preferred to amoxicillin for its narrower spectrum of activity, although patients well enough for discharge are generally well enough to forgo the single dose. Amoxicillin is preferred for oral treatment, as oral phenoxymethyl-penicillin is too poorly absorbed to reach adequate levels to cover intermediately resistant DRSP and is of no value against *H. influenzae*.

Patients who prefer to be treated at home but who are unlikely to be adherent to oral therapy, can be treated with intramuscular (IM) procaine penicillin 1.5 g daily for 5 days, which can be supplemented with a supervised daily dose of oral azithromycin.

Moderate pneumonia

For patients requiring hospitalization, the combination of benzyl penicillin or amoxicillin and a tetracycline (e.g. Doxycycline) remains most appropriate. The beta-lactam should be given intravenously to guarantee sufficient blood levels to treat intermediate-sensitivity *S. pneumoniae*. If non-immediate penicillin hypersensitivity is thought to be a problem, a third-generation cephalosporin should be used intravenously instead; in cases of immediate hypersensitivity to penicillin, a fluoroquinolone is indicated.

Sputum specimen may be sent for Gram stain if this service is available and, if gram negative bacilli are seen, gentamicin can be added or a third-generation cephalosporin substituted for penicillin/amoxicillin.

Severe pneumonia

Although *S. pneumoniae* remains the most common pathogen, there is an overrepresentation of *S. aureus*, *Legionella* spp. and gram negative organisms in severe cases. Moreover, it is of greater importance in this group that initial therapy be adequate. Therefore empiric cover must be broader than for the less severe cases. The most commonly recommended approach is to use a combination of a third-generation cephalosporin with an intravenous macrolide. Alternatively, the combination of benzyl penicillin, an aminoglycoside and an intravenous macrolide has also been recommended, although head-to-head studies demonstrating equivalence of this to the former, more established regimen are lacking. Staphylococcal pneumonia should always be considered in this group (see later).

Staphylococcal pneumonia

In all severe cases of pneumonia, a sputum specimen should be examined if possible, but this should not delay therapy. If gram positive cocci in clusters are seen or if the clinical or radiological picture is suggestive of staphylococcal pneumonia, treatment should be instituted with flucloxacillin/dicloxacillin. It is important to be aware of local rates of CA-MRSA. In most settings, this remains a rare cause of CAP and it is not necessary to treat with vancomycin in the first instance in cases of moderate illness. In severely ill patients, CA-MRSA cover with vancomycin, co-trimoxazole or clindamycin should be used until susceptibilities are known.

Pneumonia in tropical areas

Patients in certain tropical areas are prone to infection with *B. pseudomallei* and *A. baumanii*,

while 'atypicals', such as *Mycoplasma* and *Legionella*, are rare. Mild pneumonia can generally be treated safely with a beta-lactam alone. In moderate cases, if risk factors for these infections are present (see earlier), a third-generation cephalosporin (for *Burkholderia*) and gentamicin (for *Acinetobacter*) should be used. In severe pneumonia in these regions, especially during the monsoon, all patients should be treated with a carbapenem and a macrolide.

Aspiration pneumonia

Most cases of aspiration do not result in any significant respiratory compromise; of those that do, the majority are not infective pneumonia but non-infective chemical pneumonitis. Unfortunately the two are very difficult to distinguish. Treatment recommendations vary and hard evidence is limited. If antibiotic therapy is to be used, a beta-lactam and metronidazole is an appropriate combination in most cases. In patients without teeth, anaerobic cover is probably not required. In certain patients (nursing home residents and alcoholics), gram negative cover with a third-generation cephalosporin should be considered.

Likely developments over the next 5 to 10 years

- Novel biomarkers will continue to be proposed as diagnostic or severity predicting agents. Critical appraisal of evidence for their use will be required to avoid increasing cost of treatment without increasing benefit.
- With CXR increasingly recognized as unreliable in the diagnosis of pneumonia, there may be a role for another imaging modality such as low-dose CT if the cost and radiation can be minimized.
- Clinician-performed bedside ultrasound has an emerging role for the diagnosis and assessment of complications; however, expertise in its use it not yet widespread.
- Drug-resistant organisms will become an increasing problem, particularly multidrug-resistant pneumococcus.
- Increasing rates of HIV, increasing numbers of patients on long-term immunosuppression after organ transplant and on long-term chemotherapy and an ageing population are likely to alter the spectrum of CAP, with an increasing frequency of opportunistic infection.
- Better transportation systems and increased movement of people around the world, coupled with an increasing population of immunocompromised patients, is likely to contribute to resurgence in tuberculosis in the developed world, with multidrug-resistant strains becoming a particular problem.
- Increasing uptake of the pneumococcal vaccine may lead to even fewer cases of pneumonia caused by this organism.

CONTROVERSIES

- Optimal antibiotic therapy for mild pneumonia is not defined, particularly with regard to the need to treat for atypical organisms such as *Mycoplasma* and *Chlamydophila* spp.
- The value of an aggressive approach to aetiological investigation is unclear, given the expense. Pathogen-directed therapy has not been shown to have a mortality benefit over empiric treatment.
- The use of SMART-COP, CORB and other risk-stratification tools versus clinician judgement to guide empiric antibiotic therapy and site of care remains a matter of debate.
- Antibiotics are commonly prescribed for aspiration episodes even though most cases are non-infectious A reliable way of predicting cases that require antibiotics is not available.
- Systemic corticosteroids continue to be investigated for pneumonia; however, good-quality patient-oriented outcome data have never supported their use.

6.4 Influenza and emerging respiratory infections

Michelle van den Driesen • Nicola Walsham

ESSENTIALS

1 Influenza is infectious before symptoms appear.

2 Pneumonia and exacerbation of underlying chronic disease are the most common complications of influenza.

3 The sensitivity and specificity of clinical signs is poor. Testing by polymerase chain reaction (PCR) is essential for diagnosis.

4 The use of antiviral therapy is controversial; however, it has a role in the treatment of specific patient groups.

5 Nosocomial spread is a threat to patient and staff safety and to emergency department (ED) business continuity; the identification and application of personal protective equipment (PPE) at triage is the optimum method of protecting patients and staff.

6 Influenza vaccination in high-risk groups and in health care workers is the most effective way to prevent disease.

7 Emergency preparedness for seasonal and pandemic influenza should be seen as a continuum, with escalation depending on patient numbers, staff sick leave and patient acuity.

Introduction

Influenza is caused by an RNA virus of the family Orthomyxoviridae. It is a highly contagious common respiratory infection with an attack rate that varies between 5% and 10% of adults and 20% and 30% of children[1] and a mortality that varies between 1.4 and 16.7 deaths per 100,000.[2] Every year, seasonal epidemics of influenza result in 3 to 5 million cases of severe illness and 290,000 to 650,000 deaths worldwide.[3] Mortality from seasonal influenza is highest among the elderly, infants and the immunocompromised, but considerable morbidity and productivity loss also occur in terms of worker and school absenteeism. General practice clinics, emergency departments and hospitals can be overwhelmed during peak seasonal influenza periods.[3] Influenza pandemics occur as a result of a mutation that produces a novel virus. Pandemics have the potential to cause widespread disruption of the health sector and economy.

Microbiological classification

The influenza viruses are classified into three types (A, B, C) based on their core proteins. Influenza A and B cause seasonal winter epidemics in Australia; influenza C causes rare cases of respiratory illness in humans and is not thought to cause epidemics. Influenza A is more virulent than the other two types and causes the most severe disease. Type A viruses are further divided into subtypes or strains based on two surface proteins—haemagglutinin (H) and neuraminidase (N). There are 18 different haemagglutinin subtypes and 11 different neuraminidase subtypes. Haemagglutinin binds to the cell surface receptors and mediates viral attachment and entry into the host cell. The specificity of this binding partly explains the species barrier between animal and human influenza viruses. Neuraminidase is essential for the release of virus from infected cells, which, in turn, facilitates the spread of virus. Both haemagglutinin and neuraminidase are targets for antiviral drugs. Influenza B viruses are not divided into subtypes but can be divided into lineages and strains. Currently circulating influenza B viruses belong to either the B/Yamagata or the B/Victoria lineage.[3]

Influenza viruses are named according to an international convention that recognizes the antigenic type, the host origin, the geographical origin, the strain number and the year of isolation. If the virus is type A, it is further classified by its H and N antigens (e.g. H1N1, H5N1).

Epidemiology

Antigenic drift results from a minor change in the antigenicity of the haemagglutinin or neuraminidase (H or N). It is caused by a point mutation that enables the virus to evade immune recognition and is responsible for most seasonal influenza epidemics.

Antigenic shift is a major change in the antigenicity of H and/or N proteins. It is caused by genetic reassortment between different subtypes of influenza A during coinfection of a single host. Reassortment between animal and human influenza strains can also occur, producing entirely new antigens that are unrecognizable to the human immune system. This, along with efficient human transmissibility and high virulence, may produce a lethal pandemic. The most significant pandemic recorded was the 1918 Spanish flu (H1N1), which led to an estimated 30 to 50 million deaths worldwide; but there have been subsequent pandemics with lower numbers of fatalities, including the 1957 Asian flu (H2N2), the 1968 Hong Kong flu (H3N2) and the 2009 swine flu (H1N1).[3]

Avian and other zoonotic influenzas

The specificity of haemagglutinin binding limits the transmissibility of zoonotic influenza viruses such as the avian influenza subtypes (H5N1, H7N9) and the swine flu subtypes (H1N1, H3N2). Transmission to humans requires close direct or indirect contact with infected live or dead animals. This type of contact is common in wet markets and in slaughtering or the preparation of food. Person-to-person transmission requires close personal contact, as when individuals are being nursed or when procedures are performed that aerosolizes infectious secretions. There is no evidence that zoonotic influenza can infect humans through properly cooked food.[4]

In 1997, human infections with H5N1 were reported during a poultry outbreak in Hong Kong. Since 2003, this virus has spread from Asia to Europe and Africa, becoming endemic in many poultry populations. In 2013, human infections with H7N9 were reported in China, with subsequent cases detected in other parts of Asia. Both viruses possess novel antigens that ensure widespread human susceptibility; however, neither is capable of ready human-to-human transmission. These two viruses, like many, are capable of acquiring pandemic potential, but

they are differentiated from many of the others because of the high human mortality they have caused and their persistence and international spread in poultry stock.[4]

Incubation period and infectivity

The incubation period is typically 2 days (range 1–4 days). Transmission occurs primarily by droplet spread via sneezing and coughing, but it may also occur by direct or indirect contact with surfaces (particularly as touched by the hands). Health care workers are at great risk of acquiring influenza infection, with a subsequent risk of nosocomial spread, particularly to vulnerable individuals.

An infected person can be infectious from the day before until 5 to 7 days after symptoms develop. Children and the immunosuppressed may remain infectious for up to 3 weeks. The amount of virus shed is proportional to the severity of the illness and the degree of temperature elevation. Immunity from previous vaccination or from infection by antigenically similar influenza strains may be partially protective.

Survival of the virus is enhanced under conditions of low humidity and in the cold, hence human influenza epidemics in temperate climates typically occur during the winter months. The virus survives for 24 to 48 hours on hard, non-porous surfaces, 8 to 12 hours on cloth/paper/tissue and up to 5 minutes on hands. Disinfectants and detergents easily inactivate influenza viruses.

Clinical features

Uncomplicated influenza is characterized by the abrupt onset of fever, rigors, myalgia, headache and malaise, followed by the occurrence of respiratory symptoms such as sore throat and a non-productive cough. Rhinitis may occur but it is not common or pronounced. Gastrointestinal symptoms are more commonly seen in children and include nausea, vomiting and diarrhoea as well as otitis media.

Examination findings are non-specific, with fever (37.8°C–40.0°C), tachycardia and non-exudative hyperaemic pharyngitis.

Influenza causes disease in all age groups. The severity of illness ranges from asymptomatic infection to severe disease, including respiratory failure and death. Patients with partial immunity may have milder manifestations. Symptoms typically resolve within 5 to 7 days, although cough and malaise may persist for at least 2 weeks. Complications, hospitalization and death occur predominantly in high-risk groups.[3] This group includes the following:

- The elderly (above 65 years of age)
- Children below 5 years of age (especially below 2 years)
- Pregnant women (especially during the third trimester) and women within 2 weeks of delivery
- Those with chronic medical conditions (chronic cardiac, pulmonary, renal, metabolic neurodevelopmental, liver or hematologic diseases)
- Individuals with immunosuppressive conditions (such as Human Immunodeficiency Virus (HIV)/Acquired Immunodeficiency Syndrome (AIDS), those receiving chemotherapy or steroids, and those with malignancy)
- Indigenous persons
- Individuals with morbid obesity (body mass index (BMI) >40)
- Residents of nursing homes or long-term-care facilities

Complications

Influenza can exacerbate underlying medical problems, in particular congestive cardiac failure. It can also precipitate exacerbations of asthma and of chronic obstructive pulmonary disease (COPD).

Pneumonia is the major complication of influenza. It may be primarily viral, bacterial or a combination of the two. Secondary bacterial pneumonia is heralded by a recurrence of fever and lower respiratory tract symptoms after initial improvement. The characteristic non-productive cough may change, with expectoration of purulent sputum. Pathogens include *Streptococcus pneumoniae, Staphylococcus aureus* and *Haemophilus influenza*. Staphylococcal pneumonia is associated with a high mortality; it may be caused by both methicillin-sensitive and methicillin-resistant strains. Primary viral pneumonia is less common but more severe than secondary bacterial pneumonia. It can progress to acute respiratory distress syndrome (ARDS) and multiorgan failure. Those at greatest risk of primary influenza pneumonia are the elderly (especially nursing home patients), those with cardiovascular disease, and pregnant women in their third trimester. Avian influenza (H_5N_1) is associated with a high rate of primary viral pneumonia. Progression to ARDS and respiratory failure occurs in 60% confirmed cases.[3]

Non-respiratory complications of influenza infection also include myositis, rhabdomyolysis, myocarditis and pericarditis. Encephalitis, aseptic meningitis, transverse myelitis and Guillain-Barre syndrome may also occur. Reye syndrome has been associated with the use of aspirin in children with influenza.

Differential diagnosis

The symptoms of influenza are non-specific. Care must be taken in differentiating influenza from early bacterial sepsis, influenza-like illnesses (ILIs) such as other respiratory viral illnesses (rhinovirus, respiratory syncytial virus [RSV], parainfluenza, adenovirus and human metapneumovirus) and from emerging respiratory infections (ERIs) such as Severe acute respiratory syndrome (SARS) and Middle Eastern respiratory syndrome (MERS-CoV).

The diagnosis of influenza is favoured when the onset is abrupt and is associated with high fever and the presence of constitutional symptoms. Case definitions of influenza include fever (>38.5°C), the presence of one constitutional symptom (headache, myalgia, joint pain, lethargy) and one respiratory symptom (cough, sore throat). Case definitions vary depending on whether they are used in clinical or research settings. The hospital case definition, outlined earlier, has a sensitivity of 77% and specificity of 33% during seasonal influenza outbreaks. However, case definition sensitivity is lower when applied outside the influenza season and in the elderly and immunocompromised patient groups, where fever may be absent.[5] Specificity of the case definition is also affected by the season and the patient group. Hence the definitive diagnosis of influenza requires microbiological testing.

Clinical investigations

Blood tests

The total white blood cell count (WBC) is generally normal, with lymphopaenia a characteristic finding.

A leucocytosis with a WBC greater than 15,000/μL suggests pneumonia, either viral or bacterial.

A moderately elevated C-reactive protein (CRP) may be seen (<100). It is useful when used with other clinical and laboratory signs.

Imaging

A chest x-ray should be performed to exclude pulmonary involvement in patients with severe disease, pulmonary signs and in those with a high WBC or CRP (>100). Primary viral pneumonia appears as bilateral diffuse reticular or reticulonodular infiltrates without superimposed consolidation. Focal consolidation is found in secondary bacterial pneumonia. Multiple cavities are characteristic of pneumonic infection with *S. aureus*.

Microbiology

Patients who are at low risk of complications and who do not require hospitalization do not require investigation and can be managed symptomatically. Testing should be performed if it guides management of the patient.

Patients who require hospitalization for their ILI or deterioration in their chronic medical condition should have influenza testing, as should patients at high risk of developing severe influenza.

A viral throat and/or nasal swab should be taken and sent for influenza PCR testing. An appropriate swab, taken when the patient is symptomatic, has high sensitivity and specificity and can be used for diagnosis and subsequent management. Swabs must be of the type recommended by the manufacturer. Testing should also be performed with appropriate quality standards and governance. Swabs can test for influenza A/B and RSV or for a suite of respiratory viruses. Physicians should be aware of the viruses that are tested for in their local institutions.

Management

Management decisions are based on disease severity, the risk or presence of complications, the identification of high-risk patients, the existence of medical and social supports in the community and the risk of nosocomial and/or residential care spread.

Infection Prevention in the Emergency Department and Hospital

All patients presenting to the emergency department with fever and cough should be masked at triage and placed in droplet precaution isolation while awaiting assessment.

Antiviral agents

Antiviral agents may help to prevent infection and to reduce the duration of influenza illness. They have no proven effect on mortality. Controversy exists because of publication bias and the difficulties encountered in conducting clinical studies where the interplay of virus, vaccination status and patient characteristics affect primary and secondary outcomes.[6] Current recommendations from the World Health Organization, the Centres for Disease Control and Prevention, the National Institute for Health and Care Excellence and the Victorian Department of Human Services support the use of antivirals, on the basis of decreased duration of symptoms, reduced time until return to normal activities and reduced duration of fever. The effect is much greater in healthy children and adults.

There are three classes of antiviral agent: M2 inhibitors (adamantanes), neuraminidase inhibitors and endonuclease inhibitors. Adamantanes are no longer recommended because of a high incidence of drug resistance. They are active against Influenza A only and work by inhibiting the M2 protein involved in viral replication. Neuraminidase inhibitors, (osteltamivir, zanamivir) are active against both Influenza A and B. They act by competitively inhibiting neuraminidase thereby preventing release of newly formed virus from host cells. Baloxavir is a novel influenza drug recently approved by the US Food and drug administration. It is active against both Influenza A and B. It is a viral endonuclease inhibitor that prevents the modification of host mRNA needed for viral synthesis.

At the time of writing, Osteltamivir is considered the drug of choice for the treatment of influenza. If indicated, it should be started within 48 hours of symptom onset at a dose of 75mg bd for 5 days. It can be used in all age groups including infants. The major adverse effect of osteltamivir is nausea, which occurs in 10% of patients.

In the future, Baloxavir may replace osteltamivir as the drug of choice because of its ease of administration. In limited studies it has a similar efficacy to osteltamivir, when commenced within 48 hours of symptom onset. It is approved for children and adults over the age of 12 years. It is prescribed as a single dose of 40mg (for patients under 80kg) or 80mg (for patients over 80kg). Initial data suggests the potential for the development of resistance.

Treatment of high-risk groups

Antiviral treatment is recommended for outpatients presenting within 48 hours of symptom onset with suspected or proven influenza who are at high risk of complications. Those at high risk of complications presenting after 48 hours of symptoms and who are clinically improving do not require antiviral therapy. Conversely, those who are not improving may be considered for treatment.[3]

Severe illness or patients requiring hospital admission for comorbidities

Patients with severe clinical illness associated with suspected or confirmed influenza (i.e. clinical syndromes of pneumonia, sepsis or exacerbation of underlying chronic diseases) should be placed in droplet precaution isolation and treated with antiviral drugs and appropriate antibiotics to cover community-acquired pneumonia.

Patients may be removed from droplet precautions if any of the following applies:

- PCR testing for influenza is negative.
- Following 72 hours of oseltamivir treatment (if they have been afebrile in the preceding 24 hours without antipyretic).
- After 7 days of illness if they have not been treated with oseltamivir and have been afebrile for the previous 24 hours without antipyretic.

Patients developing severe respiratory failure in the setting of influenza require mechanical ventilation and should be considered early for extracorporeal membrane oxygenation (ECMO).

ECMO was used extensively in the 2009 H1N1 swine flu pandemic.[7] A meta-analysis on the outcome of ECMO therapy used as an adjunct or salvage therapy for severe seasonal H1N1 influenza was inconclusive but suggested that its early institution may result in improved survival.[7]

Adjunctive treatment with corticosteroids should not be used for viral pneumonia. They have been associated with prolonged viral clearance, with bacterial and fungal superinfection and with increased mortality.[3] Corticosteroids are indicated for the treatment of asthma and COPD.

Influenza prevention

The duration and severity of seasonal influenza epidemics and of their impact on society cannot be predicted accurately. Annual vaccination remains the most effective method for preventing influenza and reducing the impact of influenza. The quadrivalent seasonal flu vaccine provides protection against the most common circulating influenza viruses: influenza A (H1N1 and H3N2 viruses) and influenza B (Brisbane and Phuket-like viruses).[8] Provided that there is a good antigenic match between the vaccine and the circulating viruses, vaccines can provide protection against clinical disease in 70% to 90% of healthy adults, reduce hospital admissions by 25% to 39% in the elderly and reduce overall mortality by 39% to 75%.[1] Influenza vaccination is essential in reducing both the health care costs and the productivity losses associated with seasonal influenza epidemics. The frequent changes in viral surface antigens make the annual reformulation of vaccines necessary to match the circulating viruses. Annual 'flu' vaccination is highly recommended for children, the elderly, patients with chronic medical illness, nursing home residents, health care workers and pregnant women.[1] Influenza vaccines should not be used in people with allergy to egg proteins.

Influenza preparedness

Emergency departments and hospitals must develop and practice their own guidelines for the management of influenza.[9] Management of seasonal and pandemic influenza should be seen as a continuum, with escalation depending on patient numbers, illness severity and staff sick leave.

At a basic level, the guidelines should mandate adherence to hand hygiene, procedural aseptic non-touch technique, knowledge and use of standard and transmission-based precautions and the use of appropriate personal protective equipment (PPE). High levels of staff vaccination against all vaccine-preventable diseases including influenza should be advocated.[1]

Screening for ILIs should occur at triage. Screening methods will depend on the capacity of the emergency department but should also involve questioning regarding the presence of fever, either alone or in combination with cough. A history of immunosuppression, sick contacts and international travel within the preceding 3 weeks should be sought. Case definitions for influenza or an ILI should be distributed to staff and used to guide management. During the influenza

season in an emergency department setting, the combination of fever and cough has high sensitivity (77%) but only moderate specificity (33%).[5] Patients identified with an ILI at triage should have a surgical mask applied and be directed to hand hygiene equipment in the waiting room. If possible, they should be seated at least 1 m from other patients. Patients triaged to a cubicle should be isolated to a single room with signage denoting the need for droplet isolation precautions. Health care workers should use surgical masks and gloves when they are caring for these patients.

Unsafe practices should be discarded. Aerosolization of virus particles occurs when medications are nebulised. If a nebulized medication is used, the application of airborne transmission–based precautions (rather than droplet precautions) is required. Aerosol transmission precautions include the use of a negative pressure room and PPE with impervious gowns, N95 masks, face shields and gloves. If a negative pressure room is not available, a single room with the door closed and PPE as described should be used. However, if a single room is used, it should not be used by other patients for 1 hour following nebulizer usage. This is the minimum time required to clear aerosolized virus from a normal pressure single room.

Hospital influenza preparedness guidelines should consider the role of flu clinics in supporting business continuity plans. Decisions regarding their establishment should be based on discussion and agreement between adjacent heath care centres, medical administration, the emergency department and inpatient services. Implementation thresholds for clinics can be only approximate, but they should consider the increase in emergency department presentations, patient acuity and staffing levels. Consideration should be given regarding the site of flu clinics, their hours of operation, their staffing and funding. Similar discussions should determine the threshold for decommissioning clinics.

Preparedness guidelines should outline the quantity of PPE and of neuraminidase inhibitors available. State health departments will decide whether antivirals will be prescribed to first responders such as emergency department staff. In the 2009 H1N1 pandemic, neuraminidase inhibitors were not prescribed. Reliance was placed on appropriate infection control practices and the use of PPE.

Ethical concerns should build on the drive for advance care planning. Both value and treatment-based directives should be explored, when appropriate, by emergency department staff. Hospitals involved in nursing home and in-reach services should be made available to provide and support appropriate care options outside acute hospitals.

Emerging respiratory infections

ERIs are defined as infections that are novel and those that have changed. Changes may include altered drug susceptibility, increased virulence, and more efficient human-to-human transmission. This definition encompasses MERS-CoV and pandemic influenza as well as other infections that are yet unknown or that have yet to be seen as a threat. Activation and escalation of each hospital's seasonal influenza plan is the best method of protecting staff and patients from infection. Emergency department staff are likely to be among the first groups of heath care workers exposed to an ERI. Infection control and PPE considerations must be centre stage in all interactions with patients.

CONTROVERSIES

- Mandatory influenza vaccination for health care workers, including opt-out schemes
- The role of neuraminidase inhibitors
- The clinical use and cost-effectiveness of ECMO in severe influenza

6.5 Chronic obstructive pulmonary disease

Katie Walker • Christine Jackman

ESSENTIALS

1 Chronic obstructive pulmonary disease (COPD) is characterized by airflow limitation that is not fully reversible.

2 The majority of exacerbations of COPD are due to infection, but other important precipitants must be excluded.

3 It is prudent to control oxygen flow rate to achieve an arterial oxygen saturation of approximately 88% to 92% to ensure correction of hypoxia while avoiding the complication of hyperoxic hypercapnia.

4 The use of non-invasive ventilation in acute respiratory failure is associated with reduced mortality, reduced rates of intubation and reduction in treatment failure.

5 Bronchodilators and systemic steroids are recommended for acute exacerbations.

Introduction

Chronic obstructive pulmonary disease (COPD) is a major public health problem causing chronic morbidity and mortality throughout the world. It is characterized by airflow limitation that is not fully reversible, is usually progressive and is associated with an abnormal inflammatory response of the lung to noxious particles or gases. An acute exacerbation of COPD is a heterogeneous event believed to be caused by complex interactions between the host, respiratory viruses, airway bacteria and environmental pollution. It is clinically characterized by an increase in the patient's baseline dyspnoea, cough and/or sputum that is beyond normal day-to-day variations, is acute in onset and may warrant a change in regular medication. COPD is a complex chronic systemic inflammatory disorder with multiple extrapulmonary manifestations and acute exacerbations that may include life-threatening respiratory failure.

Aetiology, genetics, pathogenesis and pathology

The most important factor leading to the development of COPD is cigarette smoking. Less common factors include genetic disorders, such as α_1-antitrypsin deficiency, occupational exposures and exposure to air pollution. Only 30% of smokers develop clinically significant COPD.[1,2]

The airflow limitation seen in COPD is due to a combination of luminal obstruction with hypersecretion of mucus, disruption of alveolar attachments and mucosal and peribronchial inflammation and fibrosis (obliterative bronchiolitis).

COPD causes chronic and increasing dyspnoea with a reduction in exercise tolerance. It is characterized by intermittent acute exacerbations (usually due to intercurrent infection). Chronic complications include pulmonary hypertension, cor pulmonale, secondary polycythaemia, bullous lung disease, medication-related complications (e.g. osteoporosis), weight loss and increasingly poor quality of life.

There is a high incidence of comorbid bronchiectasis in COPD patients, which is associated with a poorer prognosis. These patients are more likely to be male, have longer smoking histories, produce greater daily sputum and have more frequent exacerbations. They are more likely to be colonized by potentially pathogenic microorganisms, including *Pseudomonas aeruginosa* (requiring broader antibiotic therapy during exacerbations).

Epidemiology

Projections from the Global Burden of Disease Study suggest that COPD will be the fifth leading cause of disability-adjusted life years lost worldwide by the year 2020. COPD is found in 7.5% of Australians aged 40 years or over and ranks sixth among the causes of death in Australian men and women.[3] In the New Zealand population, it ranks fifth.

Clinical features

History

Most patients with COPD experience a slow, steady deterioration in their respiratory function. Most emergency department (ED) presentations are the result of a superimposed acute exacerbation. As the disease becomes more severe, the frequency of exacerbations also increases. It is important to have a good understanding of the patient's baseline function. Questioning to determine this should include the following[4]:

- Questions to establish diagnosis:
  - Has the patient been diagnosed with COPD, and if so, when?
  - When did symptoms first develop?
  - If pulmonary function tests were undertaken, what were their most recent results?
  - Is the patient a smoker (past or present) and what are the total pack-years?
  - Are there any other risk factors, such as family history of COPD or α_1-antitrypsin deficiency?
  - Who is the physician managing this?
- Questions to establish severity:
  - Current medications: short- and long-acting bronchodilators, antimuscarinic agents, steroids (inhaled or oral), home oxygen and any other medications.
  - When the patient is well, what is his or her usual level of exercise tolerance?
  - Does the patient limit his or her physical activity to avoid breathlessness?
  - What is the patient's baseline peak expiratory flow rate?
  - What is the patient's incidence, frequency and severity of hospital admissions over the last few years (specifically including non-invasive ventilation [NIV] or intubation).
  - What is the patient's current body mass index (BMI)?
  - Has the patient experienced a recent weight loss?
- Nature of acute deterioration (seeking baseline and current features):
  - Fever
  - Cough
  - Sputum quantity and colour
  - Chest pain
  - Ability to walk between rooms
  - Ability to eat and sleep with current dyspnoea
  - Current increase in out-patient therapy and duration of escalation
  - High-risk comorbid conditions making out-patient therapy challenging (ischaemic heart disease, morbid obesity, congestive cardiac failure, diabetes)
  - Inhaler technique and compliance with medications
  - Presence of medications that may exacerbate COPD (e.g. β-blockers, sedatives)
  - Is there an advanced care plan and has the patient considered goals-of-care/end-of-life issues?
- Questions regarding complications should also be asked.

Examination

Exacerbations of COPD can be immediately life-threatening for some individuals and require immediate management of the airway and breathing with concurrent assessment. Clinical features of severe respiratory compromise or failure include the following:

- Work of breathing
  - Tachypnoea
  - Posture (pursed-lip breathing, tripoding)
  - Ability to speak (sentences, phrases, words)
  - Intercostal recession or poor respiratory effort
- Hypercapnia
  - Altered conscious state, somnolence, exhaustion
  - Miosis/smaller pupils
- Auscultation
  - Silent chest
  - Poor air-entry in lower lung zones
- Clinical evidence of tension pneumothorax
  - Tracheal deviation
  - Unilateral absence of breath sounds
  - Distension of neck veins
- Profound hypoxia
  - Central cyanosis
  - Hypoxia confirmed with either blood gas sampling or good trace oximetry

Once critical issues have been managed, assessment focuses on acute and chronic features of COPD. Acute examination findings may include non-specific features (tachypnea, tachycardia, hypotension, atrial fibrillation or multifocal atrial tachycardia), infection (fever, focal crepitations, coloured/blood-stained sputum) and bronchospasm. Chronic examination findings are varied due to the heterogeneity of the disease. Patients may be thin and barrel-chested through to oedematous with cor pulmonale.

Important precipitants and complications to search for include infection, sputum retention, bronchospasm, air pollution, reduction in respiratory drive (e.g. sedatives), chest injuries, reduced respiratory muscle strength (e.g. metabolic or

neuromuscular cause, other unrelated illness that increase metabolic demand). Important differential diagnoses include decompensated left ventricular failure, acute coronary syndromes, pulmonary embolism, pneumothoraces and bullae.

Classification of severity and typical stepwise management for each phase of COPD[5]

Mild

Patients have few symptoms, they are breathless on moderate exertion, are prone to recurrent chest infections and COPD has little to no effect on their daily activities. Their typical lung function is 60% to 80% of predicted forced expiratory volume (FEV_1) and their treatment commences with short-acting medications (short-acting β agonists or short-acting muscarinic antagonists). At each medical encounter, inhaler technique should be checked. Patients should also be assisted with smoking cessation, regular exercise should be encouraged and vaccination status should be checked. It is important that pneumococcal and influenza vaccines be administered to these patients.

Moderate

Patients are breathless walking on level ground and find their daily activities increasingly limited. They have some cough and sputum, and exacerbations tend to require oral steroids and antibiotics. Their typical lung function is 40% to 59% of predicted FEV_1. In addition to the management already described, long-acting bronchodilators (β agonists and antimuscarinics) are commenced. Many will be taking inhaled steroids. Additional management includes reviewing nutrition and managing comorbidities.

Severe

Patients are breathless on minimal exertion, with severe curtailment of their daily activities. They have a chronic cough and regular sputum production and experience an increasing frequency and severity of exacerbations. Their lung function is usually <40% of predicted FEV_1. In addition to the therapy recommended earlier, home oxygen is now considered. They may benefit from bronchoscopy, advanced care planning should be undertaken and palliative care referrals should be considered.

Clinical investigations

The following investigations may be used during the evaluation of an ED patient with COPD, but not all will be necessary in every situation.

Tests performed at the bedside

- Pulse oximetry: required in all patients. Providing adequate oxygenation is a balance between acceptable oxygenation (avoidance of hypoxic complications) and avoidance of hyperoxygenation. Hyperoxygenation can lead to loss of respiratory drive in some due to the dependence on hypoxia for respiratory drive.
- Chest x-ray (CXR): in the acute setting. CXR provides valuable information regarding the presence of coexisting illnesses that may require immediate and specific interventions (e.g. pneumothorax, pneumonia, pleural effusions and heart failure). Up to 23% of admitted patients may have a change in their management related to their CXR findings. Features of chronic airflow limitation may include hyperinflation, flattened diaphragms, bullae, increased retrosternal airspace, reduced vascular markings and a small heart.
- Spirometry: provides confirmation of obstruction—FEV_1 less than 80% of predicted and FEV_1/Forced vital capacity (FVC) below 0.7. In the acute situation, the patient may not be able to perform spirometry and it is often inaccurate. Some experts no longer recommend it. It is a very important diagnostic tool in stable patients outside the ED.
- Electrocardiography (ECG): may detect multifocal atrial tachycardia or atrial fibrillation, or it may demonstrate evidence of intercurrent ischaemic heart disease. ECG evidence of pulmonary hypertension and right ventricular hypertrophy may be present but is often insensitive and nonspecific.

Tests that have results available within minutes include the following:

- Venous blood gases: This should be undertaken in all moderately to severely ill patients. It provides information regarding chronicity (bicarbonate elevation), respiratory failure (HCO_3 elevation), pH (depression reflects acidosis and acute severity). It also rapidly gives information about shock (lactate), polycythaemia (Hb), glucose and electrolytes. pH and HCO_3 readings closely agree with arterial results. The limits of agreement are −0.10–0.08 and −3.5 ± 3.5 mEq/L for pH and HCO_3, respectively.[6] PCO_2 values vary markedly and cannot be adjusted with a simple correction factor. Venous pCO_2 can be used as a screening test for arterial hypercarbia. Venous pCO_2 below 45 mmHg has 100% sensitivity and negative predictive value for the prediction of arterial hypercarbia.
- Arterial blood gases (ABGs): provide more accurate information about oxygenation and hypercarbia. Therapeutic decisions about acute care are made using clinical findings (e.g. drowsiness or failure to respond to therapy) and blood gas results. Oxygenation levels can be determined non-invasively using oximetry. Carbon dioxide level trends can be followed by either ABGs or by venous pH and HCO_3 levels and by clinical findings. Acute hypercarbia can be distinguished from chronic hypercarbia by consideration of HCO_3 levels and pH. Although this information is useful, ABGs play little part in clinical decisions, such as the requirement for assisted ventilation or intubation.
- Point-of-care microbiology tests are available to guide treatment with antibiotics and antiviral agents. These can be used to rapidly diagnose influenza, pneumococcus, *Legionella* and respiratory syncytial virus infections. The current inaccuracy and cost of these tests limits their utility.

Other tests

- Full blood examination: may reveal evidence of secondary polycythaemia or a raised white cell count due to infection, long-term steroid use or the hyperadrenergic stress response of the acutely ill patient.
- Electrolytes: note potassium, sodium and glucose levels.
- Sputum culture: 50% of exacerbations of COPD may be due to bacteria, with *Haemophilus influenzae*, *Streptococcus pneumoniae* and *Moraxella catarrhalis* the predominant pathogens. Exacerbations complicated by pneumonia involve similar pathogens. Patients with more compromised lung function have a higher frequency of infections with *Pseudomonas aeruginosa* and other gram negative bacteria than those less severely affected. Colonization of the respiratory tract can make interpretation of results difficult.
- Viral cultures and detection assays: 20% of acute exacerbations are due to viruses, such as rhinoviruses, the influenza and parainfluenza viruses and the coronaviruses. Viral studies may not be performed in the ED due to their expense, varying sensitivities and specificities and their infrequency of altering management. Because of the highly infectious nature of respiratory viruses, some hospitals require viral studies for newly admitted patients so as to assist with hospital infection control. Influenza virus remains a pathogen associated with considerable morbidity and mortality, especially in high-risk groups such as patients with COPD. However, the specific role of influenza in causing acute exacerbations of COPD remains unknown. Vaccination remains an effective measure to reduce the burden of disease associated with influenza, but they cannot completely prevent disease. Nevertheless they should be encouraged among all patients with COPD presenting to the ED.

- Theophylline level: this is rarely required. Note: a patient may be toxic despite having a measured level within the therapeutic range.
- Plasma brain natriuretic peptide (BNP) level: debate exists regarding the role and utility of BNP in patients with COPD presenting with worsening dyspnoea. A plasma BNP level below 100 pg/mL argues against heart failure as a contributing factor in clinical deterioration. A plasma level above 500 pg/mL points to the decompensation of heart failure but does not exclude concomitant COPD exacerbation. Plasma BNP levels ranging from 100 to 500 pg/mL must be interpreted in conjunction with clinical findings.
- Pulmonary function tests: these are useful once the patient has recovered to determine baseline function and diagnoses.
- Computed tomography (CT) of the chest: CT pulmonary angiograms are useful for investigating possible pulmonary embolism, especially when the CXR is abnormal. High-resolution chest CT may demonstrate the diagnosis and severity of emphysema, concurrent bronchiectasis; it also helps with alternative diagnoses such as lung cancer. It is rarely required in the acute setting.
- Cardiac studies: cardiac biomarkers, echocardiography and cardiac stress studies may be required to determine the presence or severity of cardiac ischaemia and ventricular dysfunction.

Treatment in the emergency department

The overall goals of treatment in COPD are to confirm the diagnosis and assess severity; optimize function (including use of long-acting bronchodilators to provide sustained relief of symptoms in moderate to severe COPD and the use of inhaled glucocorticoids in those who have severe COPD with frequent exacerbations); prevent deterioration; develop a support network and self-management plan; and manage exacerbations.

The following is a summary of the therapeutic modalities used to treat an acute exacerbation of COPD. The timing and level of intervention depend on disease severity. It is important to remember that management decisions for the patient in extremis are solely clinical—no further investigation is necessary to determine whether immediate intubation is required.

Oxygen therapy

Severe hypoxaemia must be corrected. Oxygen therapy for most patients with COPD will not produce clinically significant carbon dioxide retention. Hypercarbia in COPD is a multifactorial condition caused by changes in pulmonary blood flow, worsening ventilation/perfusion mismatch and increasing dead-space ventilation and not simply hypoventilation from loss of hypoxic drive. However, it is recommended that oxygen delivery be controlled, with a target SpO_2 range of 88% to 92%, corresponding to an arterial oxygen tension of 60 to 70 mmHg. There is an increased risk of morbidity and mortality in patients with hypercapnic respiratory failure when the arterial oxygen tension is increased above this level (>93% to 95%). Supplemental oxygen can be used to oxygenate patients, starting with low-dose nasal prong oxygen doses of ½ to 2 L/min and escalating if required to masks and then masks with oxygen reservoirs. Persisting hypoxia (SpO_2 <85%) necessitates a search for complications such as pneumonia, pulmonary oedema, pulmonary embolus and pneumothorax as well as consideration of ventilatory assistance.

Non-invasive ventilation

NIV has become the first-line intervention in the management of acute respiratory failure in patients with COPD. Continuous positive airway pressure (CPAP) and bi-level positive airway pressure (BiPAP) are the two main modes of non-invasive positive pressure ventilation. Multiple devices are available to allow concurrent administration of inhaled medication via the NIV circuit.

This is an underutilized treatment modality for hypercapnic respiratory failure in EDs despite its reduction in patient mortality and intubation rates.[7,8] A Cochrane review of 17 randomized controlled studies of patients admitted to hospital with acute respiratory failure secondary to an acute exacerbation of COPD concluded that non-invasive positive pressure ventilation in addition to usual medical care resulted in reduced mortality risk by 46% (Relative risk (RR) 0.54, 95% CI 0.38 to 0.76), reduced need for intubation (Number Needed to Treat (NNT) 5, 95% CI 5 to 6), reduced length of hospital stay and reduced incidence of complications.

Numerous studies, using either a face mask or nasal mask and varying combinations of the airway pressure manipulations have shown significant reductions in the need for intubation. In addition, NIV was associated with rapid improvement in oxygenation and acidosis and respiratory rate within 1 hour of initiation. Clinical practice guidelines from American College of Physicians-American Society for Internal Medicine/American College of Chest Physicians (ACP-ASIM/ACCP) and the Thoracic Society of Australia and New Zealand/Australian Lung Foundation (COPD-X) and evidence-based management guidelines from the Global Initiative for Chronic Obstructive Lung Disease (GOLD) recommend that NIV should be considered early in the course of respiratory failure, before severe acidosis ensues.

The presence of dynamic hyperinflation and the development of intrinsic positive end-expiratory pressure (PEEPi) during an acute deterioration lead to an increased work of breathing. The application of CPAP or external PEEP at levels to overcome PEEPi, has been shown to reduce respiratory work. This has resulted in patients reporting less dyspnoea and respiratory fatigue as well as laboratory evidence of better gas exchange.

BiPAP involves the use of both inspiratory and expiratory pressure support ventilation and has also proved an effective form of NIV in acute respiratory failure. Initiation of ventilation triggers the inspiratory positive airway pressure, which is limited to a predetermined level, usually 10 to 20 cm H_2O. Expiratory positive airway pressure of approximately 5 cm H_2O is predetermined and persists throughout expiration.

Indications for NIV include moderate to severe dyspnoea with use of accessory muscles and paradoxical abdominal motion, moderate to severe acidosis and/or hypercapnia ($PaCO_2$ >45 mmHg) and respiratory rate greater than 25 breaths/min. Contraindications include respiratory arrest, profound hypotension, an inability to safely maintain an airway (obtunded), an uncooperative patient, frequent vomiting, copious secretions, recent facial or gastro-oesophageal surgery, craniofacial trauma and facial burns. Eighty-five percent of patients will respond to NIV,[1] but there are no definite clinical predictors to identify which patients with respiratory failure will benefit. The chance of COPD patients with acute respiratory failure having a second episode of acute respiratory failure after an initial (first 48 hours) successful response to NIV is about 20%.

Invasive ventilation

Endotracheal intubation with positive pressure ventilation can be used in patients who fail non- invasive ventilatory assistance or who have indications for intubation present at the outset (e.g. unprotected airway or respiratory arrest). The goal of mechanical ventilation is to prevent excessive work of breathing while maintaining a work of breathing that is sufficient to prevent respiratory muscle atrophy. The major problems with positive pressure ventilation in this patient population are the risk of barotrauma and the production of PEEPi. Commonly recommended ventilation strategies include using tidal volumes of approximately 5 to 7 mL/kg, using a reduced respiratory rate and using an inspiratory:expiratory ratio of 1:3. Most patients also usually require a bolus of intravenous fluids to counter the effects of positive pressure ventilation on venous return and cardiac output. Patients who need mechanical ventilation have an inpatient mortality of 17% to 30%.

When the patient is severely symptomatic or has had multiple exacerbations in the last 12 months (ask yourself if you would be surprised

if the patient died in the next 12 months), consider the appropriateness of intubation and intensive care therapy in discussion with the patient. Consider the patient's goals of care, baseline function and the likelihood of the patient being able to be successfully extubated and returned to his or her usual functional status.[5]

Bronchodilators

Bronchodilators are used in the management of acute exacerbation of COPD because of the possibility of a small reversible component to the airflow obstruction. In the ED setting, these drugs are usually given by nebulizer, although there is little evidence to support this route over metered-dose inhalers, particularly when used in conjunction with a spacer device. It is common practice to use β_2-agonists and anticholinergic agents in combination.

β_2-Agonists

Salbutamol is commonly used as a first-line agent in Australasia. The usual dose is 5 mg via nebulizer, repeated as necessary. An equivalent alternative is 8 to 12 puffs of 100 µg salbutamol by metered-dose inhaler and spacer. Nebulized salbutamol is often used continuously in the severely ill patient. Occasionally, in the patient with a severe exacerbation, the intravenous route may be required, though evidence for this practice is lacking. Common side effects include tachycardia, tremor and a reduction in potassium levels.

Long-acting β_2-agonists (e.g. salmeterol, eformoterol) cause prolonged bronchodilatation for at least 12 hours and can thus be administered twice daily. They have been shown to produce statistically significant benefits in lung function, quality of life, use of 'reliever' short-acting bronchodilators and acute exacerbations. Their role in acute exacerbations is unknown.

Anticholinergic agents

A systematic review of randomized controlled trials comparing anticholinergic bronchodilators versus β_2-sympathomimetic agents for acute exacerbations of COPD found no significant difference in the degree of bronchodilatation between the two agents and the combination of the two did not appear to increase the effect on FEV_1 more than either agent used alone. The duration of action of short-acting anticholinergics is greater than that of short-acting β-agonists. They also have a lower adverse effect profile.

The most commonly used agent in Australasia is ipratropium bromide. The usual dose is 500 µg by nebulizer every 4 to 6 hours. Doses as frequent as every 20 minutes are used in clinical practice, albeit with little supporting evidence. Tiotropium bromide is a long-acting anticholinergic agent that is used once daily and has been shown to produce significant improvements in lung function, symptoms and quality of life as well as reducing exacerbations in chronic stable COPD. It is not typically used in acute exacerbations.

Corticosteroids

Systemic corticosteroids have been shown to hasten recovery, reduce hospital stay, reduce risk of relapse and reduce early treatment failure in patients with acute exacerbations of COPD (NNT 9 [95% CI 7 to 14] to avoid one treatment failure).[9] There is no longer any role for long-term low-dose oral steroid therapy.

For acute exacerbations, the optimal initial dose and course duration are yet to be determined, but prednisolone 30 to 50 mg/day for 5 days is currently recommended. Evidence suggests that oral administration is just as effective as parenteral administration of steroids except in conditions that preclude the oral route, such as vomiting. In these cases, 50 to 100 mg hydrocortisone may be administered intravenously. Short courses have been found to cause one extra adverse effect for every five people treated (95% CI 4 to 9), and the complications of long-term use are myriad. The potential role of hypothalamo-pituitary–adrenal axis suppression complicating patient presentations must be remembered. The effects of inhaled corticosteroids (beclomethasone, budesonide, fluticasone, ciclesonide) on the course of an acute exacerbation of COPD are uncertain.

Antibiotics

Bacteria play a role in approximately 50% of exacerbations of COPD. In 30% of patients, no clear cause can be found. Antibiotics have only been shown to have consistently beneficial effects in patients admitted to an intensive care unit (ICU).[10] Antibiotics may be of benefit when a patient presents with increased dyspnoea, sputum purulence and volume. Patients with more severe exacerbations are more likely to benefit from antibiotic treatment than those with less severe exacerbations.

Antibiotics should cover *H. influenzae*, *S. pneumoniae* and *M. catarrhalis*, depending on local sensitivities. A β-lactamase–resistant drug (e.g. ampicillin with clavulanic acid or doxycycline) is often required. The use of fluoroquinolones is increasing. The presence of an altered mental state, inability to swallow safely or a CXR suggesting pneumonia may require the administration of intravenous antibiotics. The antibiotic treatment of pneumonia in COPD patients should follow the recommendations for the initial treatment of community-acquired pneumonia. Cultures may guide ongoing therapy.

Other therapies

- Monitor fluid balance and nutrition
- Correction of electrolyte abnormalities
- Consider subcutaneous heparin for deep vein thrombosis prophylaxis
- Identify and treat associated conditions

Therapies no longer recommended due to lack efficacy and/or complications

- Theophylline
- Heliox
- Chest physiotherapy

Longer-term measures

- Smoking cessation
- Vaccinations (pneumococcus vaccine, *H. influenzae* type B vaccine [Hib])
- COPD action plans
- Exercise training
- Home oxygen therapy
- Other medications—statins, roflumilast, proton pump inhibitors, angiotensin-converting enzyme inhibitors
- Lung volume reduction surgery
- Transplantation.
- Long-term NIV
- Palliative care services and advanced care planning

Prognosis

Patients with acute exacerbations of COPD often require hospital admission for treatment of respiratory failure. Hospital mortality for such patients is about 10%, reaching 40% by 1 year after discharge; it is higher for patients aged over 65. Whether the patient requires admission will depend on the severity of the present exacerbation, how easily correctable the precipitating factor is and how well the patient responds to therapy.

Indications for hospitalization of patients with COPD include inadequate response to community or initial ED management, inability to walk between rooms when previously mobile, inability to eat or sleep because of dyspnoea, inability to manage at home even with homecare resources, presence of high risk co-morbid conditions, altered mental status suggestive of hypercapnia, worsening hypoxaemia or cor pulmonale, newly occurring arrhythmia or diagnostic uncertainty.

Indications for the ICU admission of patients with exacerbation of COPD include severe dyspnoea that responds inadequately to initial emergency therapy, changes in mental status (confusion, lethargy, coma), persistent or worsening hypoxaemia despite supplemental oxygen, worsening hypercapnia ($PaCO_2$ >70 mmHg) or severe or worsening respiratory acidosis, requirement for assisted mechanical ventilation and haemodynamic instability requiring vasopressors. The

appropriateness of ICU admission is often questioned. Variables associated with intermediate-term mortality are those that reflect the underlying severity of the acute illness: post-arrest, low score on the Glasgow Coma Scale, cardiac dysrhythmia, high acute physiological score (Acute Physiology And Chronic Health Evaluation (APCHE II) or CAPS) and low bicarbonate (<20 mmol/L) on ICU admission.

A decision to discharge the patient from the ED requires the presence of good home conditions, social supports and the organization of appropriate follow-up.

CONTROVERSIES

- The duration of non-invasive ventilation prior to deciding that treatment has failed
- Which patients will respond to intensive care therapy
- The role of antibiotic and antiviral therapy
- The dosing, duration and timing of bronchodilators and steroids

6.6 Pneumothorax

Anne-Maree Kelly

ESSENTIALS

1 **Pneumothorax can occur spontaneously, as a result of trauma or iatrogenically. Spontaneous pneumothorax has traditionally been further subdivided into primary and secondary (related to underlying lung pathology). The utility of this distinction is being challenged, as there is increasing evidence of underlying lung abnormalities in patients previously labelled as having primary spontaneous pneumothorax.**

2 **Clinical features are unreliable indicators of pneumothorax size.**

3 **The diagnostic test of choice is a chest x-ray.**

4 **Treatment options include observation, aspiration, thoracostomy and primary or delayed surgery. The evidence base to guide choice of therapy is weak.**

5 **Tension pneumothorax is rarely seen, particularly after spontaneous pneumothorax. It is a life-threatening problem and must be managed immediately. It is a clinical, not a radiological, diagnosis.**

6 **Smoking cessation is associated with a reduction in the risk of recurrent pneumothorax and is strongly advised in all patients.**

Introduction

Pneumothorax is the presence of free air in the interpleural space; it may occur spontaneously, due to trauma or iatrogenically.

The most common form of pneumothorax is spontaneous. Its reported incidence is 18 to 28/100,000 per year for men and 1.2 to 6/100,000 per year for women. Many patients do not seek medical advice for several days. In one study, 46% of patients waited more than 2 days before presentation despite symptoms.

Aetiology, genetics, pathogenesis and pathology

Traditionally spontaneous pneumothorax was classified as primary—occurring in otherwise healthy people without known lung—and secondary—occurring in those with underlying lung disease. Recently improved understanding of the pathophysiology has challenged the validity of this classification.[1] In patients without known lung disease, detectable lung abnormalities are common, including emphysema-like changes, sub-pleural blebs and bullae. Current thinking is that there is probably a continuum between so-called primary and secondary spontaneous pneumothorax.[1]

Spontaneous pneumothorax in patients without known lung disease is more common in tall thin males aged 20 to 40 years. Smoking is the main risk factor. There is no association with exertion.

Spontaneous pneumothorax in patients with underlying lung disease has a peak incidence at 60 to 65 years and is associated with higher

morbidity and mortality. Although chronic obstructive airways disease and asthma are the most common underlying conditions in developed countries, pneumothorax may also be due to bacterial or tuberculous pneumonia, Human Immunodeficiency Virus (HIV) with active *Pneumocystis* pneumonia, cancer, honeycomb lung disorders and cystic fibrosis. There is also an association with amphetamine, cocaine, marijuana and nitrous oxide use as well as anorexia nervosa. Thoracic endometriosis has been associated with spontaneous pneumothorax, and its identification mandates targeted therapy.

Several inherited disorders—such as Marfan syndrome, Birt-Hogg-Dubé syndrome, other mutations of the folliculin gene, α_1-antitrypsin deficiency and homocysteinuria—predispose to pneumothorax.

Iatrogenic pneumothorax may result from central line placement, intercostal blocks, thoracocentesis, lung biopsy, bronchoscopy, high pressures from artificial ventilation and acupuncture. Traumatic pneumothorax occurs in up to 15% to 20% of patients who sustain blunt chest trauma and is usually secondary to fractured ribs. It may also be the result of penetrating wounds or barotrauma.

In most cases of spontaneous pneumothorax, the air leak seals spontaneously. In a subset of those where a leak continues, a ball-valve effect can occur, with the development of tension pneumothorax. The trachea and mediastinal structures are pushed away from the collapsed lung and venous return to the heart may become obstructed. The result is severe respiratory compromise and hypotension. Emergent decompression is required. Tension is rare as a complication of primary spontaneous pneumothorax.

Clinical features

History (MCQ 2)

Symptoms of primary spontaneous pneumothorax often begin suddenly without a precipitant but can be associated with deep inspiration, hyperventilation or coughing. They may also be precipitated by changes in atmospheric pressure that occur with flying and diving. Chest pain on the side of the pneumothorax is the most common presenting symptom (90% of cases). It can be sharp and pleuritic or dull and may radiate to the back or neck. Dyspnoea occurs in up to 80% of patients but is generally not severe. Some patients may be relatively asymptomatic or become asymptomatic after 24 hours.

Clinical symptoms are usually more severe in patients with spontaneous pneumothorax with known underlying lung disease. In particular, there is usually dyspnoea out of proportion to the size of the pneumothorax. These patients are more likely to be hypoxic, in part related to underlying lung pathology. Those with pneumothorax and pneumomediastinum related to drug abuse may also have neck pain, sore throat and dysphagia.

Examination

The physical signs of pneumothorax can be subtle and hard to detect. The classic signs are reduced or absent breath sounds, reduced chest expansion and hyper-resonance to percussion on the affected side. Less common findings include subcutaneous emphysema, unilateral enlargement of the chest, inferior liver displacement and Hamman crunch (a noise heard with each heartbeat due to mediastinal emphysema). Patients who develop tension pneumothorax have evidence of air hunger, cyanosis, distended neck veins, tachycardia, hypotension and, classically, as a late sign, tracheal deviation away from the affected side.

Differential diagnosis

The differential diagnosis is that of chest pain and includes costochondritis, pneumonia, pleurisy, pulmonary embolus, exacerbation of bronchospastic disease and myocardial ischaemia.

Clinical investigation

No investigations are indicated for patients with suspected tension pneumothorax. It is a clinical, not a radiological, diagnosis and requires immediate treatment.

Imaging

X-ray

In stable patients with a suspected pneumothorax, erect postero-anterior (PA) chest x-ray is the primary investigation. The characteristic feature is displacement of the pleural line (i.e. a gap between the line of the visceral and parietal pleura). Other findings may include hyperlucency, lack of pulmonary markings and an air-fluid level in the costophrenic angle. Associated pneumomediastinum is seen in 1.5% of cases. Although traditionally expiratory chest x-rays have been used for the detection of pneumothoraces, they do not increase the detection of clinically relevant pneumothoraces. Large bullae or lung cysts may mimic a pneumothorax. If there is doubt about the presence of a pneumothorax or its differentiation from bullous disease, a computed tomography (CT) scan is recommended.

On a supine chest x-ray (usually used in trauma patients), the only clues to a pneumothorax may be a deep sulcus sign on the affected side, an unusually distinct cardiac apex or increased hyperlucency of the upper abdominal quadrants. Supine x-rays are less sensitive than erect PA chest x-rays. If there is uncertainty, a CT scan will clarify.

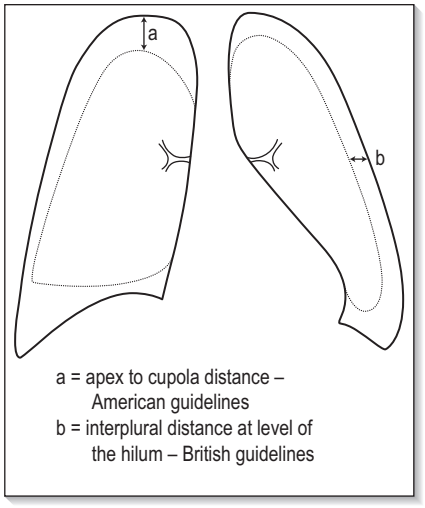

FIG. 6.6.1 Size of pneumothorax. (Reproduced from MacDuff A, Arnold A, Harvey J, BTS Pleural Disease Guideline Group. Management of spontaneous pneumothorax: British Thoracic Society Pleural Disease Guideline 2010. *Thorax.* 2010;65[suppl 2]:ii18–ii31, with permission from BMJ Publishing Group Ltd.)

Digital imaging has supplanted film-based studies in many hospitals. Differences in image size can make estimation of pneumothorax size using previously available methods difficult.

Ultrasound

Ultrasound is increasingly being used to screen for pneumothorax with specific diagnostic features, including the absence of lung sliding and comet-tail artefacts (more detail in Chapter 23.1).

CT scan

CT scanning is the gold standard for the detection of and size estimation of pneumothorax. It can also discriminate large bullae from pneumothoraces and identify dystrophic lung changes in the affected and contralateral lung. The role of these findings in predicting recurrence and defining which patients will benefit from surgery is unclear.

Size estimation

Current therapeutic guidelines divide pneumothoraces into small and large, although the details of the definitions vary. The British Thoracic Society[2] and *Therapeutic Guidelines (Australia): Respiratory*[3] define 'small' as the presence of a visible rim of less than 2 cm between the lung margin and the chest wall on x-ray with the measurement taken at the level of the hilum. A 2-cm rim is estimated to approximate 50% collapse. The American College of Respiratory Physicians[4] defines small pneumothoraces as those with less than 3 cm of apical interpleural distance (Fig. 6.6.1).

Blood gas analysis

The patient's oxygenation is a key determinant of management. Pulse oximetry is acceptable in most patients, but arterial blood gas analysis may be necessary in sicker patients (oxygen saturation <92% on room air, respiratory distress or severe underlying lung disease).

Treatment

There is substantial variation in practice, largely driven by the paucity of high-quality evidence. The respective roles of conservative and invasive treatment are unclear and controversial, although a large clinical trial currently under way may clarify this.

Expert opinion and international guidelines[1–4] stratify patients to treatment options depending on the combination of symptoms and an assessment of the size of the pneumothorax. Important factors to consider in determining the appropriate treatment are as follows:

- Patients with known underlying lung disease respond less well to interventions and require treatment of the underlying condition.
- Clinical evidence of respiratory compromise, in particular significant breathlessness.
- Size.
- Age. Evidence suggests that aspiration is less successful in patients above 50 years of age.
- Cause of pneumothorax. Most iatrogenic pneumothoraces can be treated conservatively or by aspiration. Traumatic pneumothoraces often require continuous catheter drainage because of associated chest wall or lung injuries.

General measures

Patients should initially receive supplemental oxygen, particularly if hypoxic. This increases the rate of pleural air absorption by reducing the partial pressure of nitrogen and increasing the gradient for nitrogen absorption. It is useful for both pneumothorax and pneumomediastinum.

Emergency drainage (MCQ 3)

Patients who present with evidence of tension pneumothorax should be treated with immediate decompression. In the past, needle thoracostomy was advocated. This involves the placement of a large intravenous (e.g. 14-gauge) cannula in the second intercostal space. The safety and effectiveness of this approach has been challenged. In some patients the cannulae are not long enough to reach the pleural space, the needle can cause trauma and the cannulae are prone to dislodgement and kinking. A more reliable approach is insertion of a small-bore catheter by Seldinger technique either in the second intercostal space anteriorly or the fifth intercostal space in the mid-axillary line with connection to free drainage. In emergent situations, there has been a shift away from the use of needles entirely, instead using the technique of simple finger thoracostomy in the fifth intercostal space. Definitive therapy, using catheter drainage, is then required (see later).

Minimal symptoms

Current evidence supports conservative management of patients with minimal symptoms. While this has been the usual practice for small pneumothoraces, some data also support this approach in selected patients with asymptomatic large pneumothoraces, with success rates of up to 90% being reported. It has also been shown that, for small pneumothoraces, recurrence in those managed conservatively is less than in patients treated with intercostal tube drainage. These patients can be treated as outpatients provided they have easy access to medical care should their symptoms worsen.

The rate of resolution/reabsorption of primary spontaneous pneumothoraces has been estimated as 2% of the volume of hemithorax per day, with significant between- and within-patient variations. Based on these data, a prudent follow-up strategy would be to repeat x-rays the next day (to detect deterioration) and weekly until resolution. Clear, specific written instructions about what to do if symptoms worsen or the patient's condition deteriorates are required.

Symptomatic pneumothorax

Simple aspiration

Simple aspiration is recommended as the first-line approach in patients with spontaneous pneumothorax without known underlying lung disease who are not suitable for conservative management. It can be performed as needle aspiration or via a small-bore catheter (<14 Fr) inserted using the Seldinger technique. The aim of this treatment is to convert a larger pneumothorax into one that can safely be managed conservatively. Usually success is defined as reduction to a rim of less than 2 cm measured at the hilum without reaccumulation over 4 to 6 hours and resolution of significant breathlessness. For primary spontaneous pneumothorax, successful reexpansion of the lung after simple aspiration is on the order of 50% to 83%.[1] Available data suggest that success rates for secondary pneumothoraces are lower. Meta-analyses have confirmed that aspiration has similar effectiveness to catheter drainage, with some studies also reporting reduction in admission rate and hospital length of stay.

Successful aspiration has been shown to depend on age (under 50 years 70% to 81% and over 50 years 19% to 31%) and the volume air aspirated (<3 L aspirated: 89% success; >3 L: no success). The latter probably represents the presence of a persistent air leak.

Following successful aspiration, including confirmation that the pneumothorax has not reaccumulated, further management as an outpatient is appropriate provided that the patient has clear instructions on the recognition of deterioration, ready access to medical care and a clear follow-up plan.

Complications associated with aspiration are minor: vasovagal reactions, local subcutaneous emphysema and occasional problems with catheter kinking, blockage or dislodgement.

Catheter drainage

Catheter drainage of spontaneous pneumothorax is required if simple aspiration fails, if an emergency decompression has been performed or if known underlying lung disease makes aspiration unlikely to succeed. Evidence suggests that small-bore catheters (<14 Fr) have similar effectiveness to large-bore catheters and cause less pain. They also allow insertion using a Seldinger technique, which is easier than open insertion techniques and obviates some of the complications seen previously with trocar-based techniques. Catheters may be inserted by an anterior or axillary approach. For practical and cosmetic reasons, an axillary approach is usually favoured. Intercostal catheters are safely inserted in the fourth, fifth, or sixth intercostal space in the mid-axillary line. The fifth intercostal space in the anterior axillary line is most commonly quoted as the 'ideal' location for intercostal catheter insertion. In addition to counting ribs, the use of adjunct techniques such as marking of the mid-arm (humerus) position and/or the axillary hairline are useful to accurately identify the fifth intercostal space.

Success rates of 66% to 97% have been reported. Reported duration of hospital admission ranges from 7 to 9 days; longer for secondary pneumothoraces. There is no evidence that the addition of suction improves outcome. Indeed, the addition of suction early after chest drain insertion may precipitate re-expansion pulmonary oedema, especially in larger pneumothoraces that have been present for a few days.

The use of small-bore catheters also promotes a stepwise pathway of care; they can be used for aspiration and, in the event that this fails, can easily be converted to Heimlich valve or underwater seal drainage (Fig. 6.6.2). Although most patients undergoing catheter drainage are admitted to hospital, some studies are reporting safe and successful management of selected individuals as outpatients by using small-bore catheters and Heimlich valves.

Potential disadvantages of intercostal catheters range from chest and abdominal

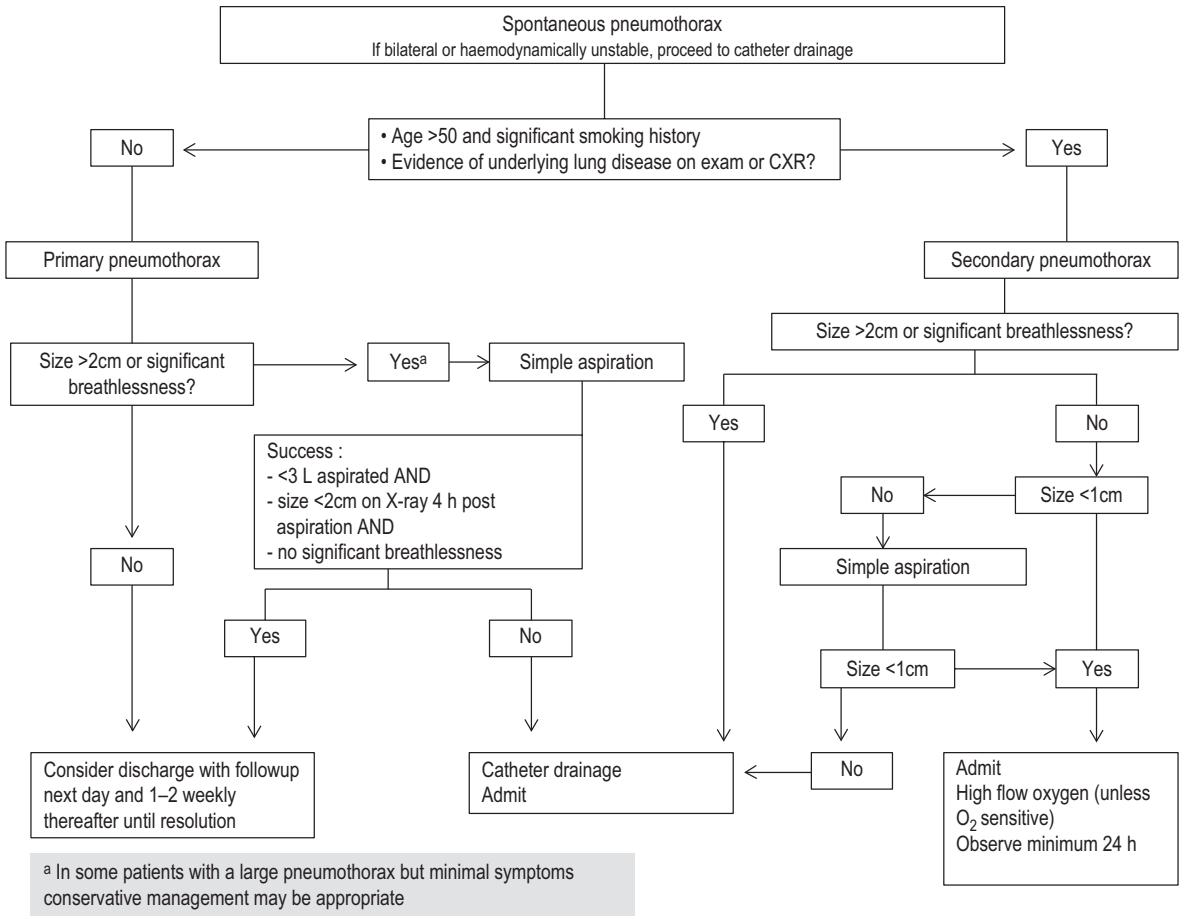

FIG. 6.6.2 Management algorithm for spontaneous pneumothorax. (Adapted from MacDuff A, Arnold A, Harvey J, BTS Pleural Disease Guideline Group. Management of spontaneous pneumothorax: British Thoracic Society Pleural Disease Guideline 2010. *Thorax*. 2010;65[Suppl 2]:ii18–ii31, with permission from BMJ Publishing Group Ltd.)

visceral trauma from sharp trocars (not recommended) to practical management issues such as the bulkiness of the underwater seal bottle system, which must be kept upright. In addition to the risks of aberrant placement, the empyema risk has been estimated at 1%. Other potential complications include bronchopleural fistulae, arteriovenous fistulae, perforation of the internal mammary artery, pulmonary or mediastinal blood vessels, focal lung infections, re-expansion pulmonary oedema and lung infarction. There are insufficient data to quantify the risk of these complications.

Surgery

Approximately 10% of patients require surgical intervention. Indications for surgical referral include persistent air leak after 2 to 7 days; recurrent pneumothoraces; pneumothoraces in airline pilots, frequent plane travellers and divers; contralateral or bilateral pneumothoraces and pregnancy.

Prognosis

Recurrence after a first pneumothorax is up to 50% for primary and secondary pneumothoraces. Half of these occur within 4 months and the risk does not drop substantially until 1 year from the index pneumothorax. This rate increases to 60% to 70% for subsequent recurrences. In patients without underlying lung disease, smoking cessation reduces the risk of recurrence.

There is a growing school of thought that appropriate investigation and risk stratification may be able to identify patients at high risk for recurrence, who could then be offered early targeted use of recurrence prevention strategies.[1]

Other issues

As pneumothoraces will increase in size at altitude owing to changes in atmospheric pressure, flying with a pneumothorax is potentially dangerous. Current guidelines suggest that a pneumothorax should be fully resolved for at least 1 week before flying. Owing to the theoretical risk that higher barometric pressures associated with scuba diving may precipitate recurrence, patients having suffered a primary or secondary pneumothorax are advised not to dive in future unless they have undergone bilateral definitive surgery and have a normal chest CT scan postoperatively.

6.7 Pleural effusion

Shammi Ramlakhan

ESSENTIALS

1 **In the majority of patients, a posteroanterior and lateral chest x-ray will confirm and localize an effusion. Ultrasound, lateral decubitus films and computed tomography scanning are more sensitive in diagnosing and localizing small effusions.**

2 **Pleural fluid analysis is the principal method of determining the underlying cause of an effusion.**

3 **Ultrasound-guided thoracocentesis is the recommended method for diagnostic or therapeutic fluid drainage.**

4 **Treatment is dependent on the underlying disease. Large pleural effusions with cardiorespiratory compromise should be aspirated to provide symptomatic relief.**

5 **Transudates generally respond to treatment of the underlying condition. Exudates usually require further investigative procedures and specific treatments.**

Introduction

A pleural effusion is an accumulation of fluid in the pleural space caused by a disruption of the homoeostatic forces that control normal flow. Massive pleural effusions may produce significant cardiorespiratory compromise requiring urgent attention in the emergency department. However, many are asymptomatic or produce minimal disturbance. In this latter group, the role of emergency department care is assessment to ascertain the aetiology of the effusion, as this dictates the most appropriate treatment. Information regarding the likely cause can be obtained by a thorough history and physical examination. Important adjuvant investigations include chest x-ray (CXR), ultrasound, examination of pleural fluid and biopsies obtained during thoracocentesis. Bronchoscopy and thoracoscopy have a role to play in the small group of patients in whom the mentioned procedures fail to establish a cause; however, their use is beyond the scope of initial emergency department assessment and stabilization.

Aetiology, pathogenesis and pathology

Pathology and pathogenesis

The pleural cavity is normally a small space bordered by the visceral and parietal pleura, both of which are composed of mesothelial lining cells. In normal conditions it contains approximately 0.25 mL/kg of low-protein liquid. The pleura act as semipermeable membranes and fluid movement is determined principally by capillary pressure, plasma oncotic pressure and capillary permeability, governed by the Starling law. The parietal pleura appear to be the more important surface for pleural liquid turnover in the normal physiological state. Current evidence suggests that most pleural fluid drainage occurs via pleuro-lymphatic communications or stomas, augmented by respiratory muscle action and intrinsic lymphatic vessel contractility. Overall absorptive capacity can exceed production by a factor of 10 to 20, allowing maintenance of pleural fluid volume in most cases. Pleural effusions occur due to one of the following:

- Disturbances in the hydrostatic-osmotic pressure gradients, resulting in a transudate
- Pleural inflammation with loss of semipermeable membrane function, resulting in a protein-rich exudate
- Lymphatic obstruction (usually producing a transudate)

Transudates are ultrafiltrates of plasma and arise as a result of relatively few conditions. Exudates are produced by a wider variety of inflammatory conditions and often require more extensive investigation.

Aetiology

Box 6.7.1 lists the causes of transudative and exudative pleural effusions. The commonest causes are congestive cardiac failure, pneumonia, malignancy and pulmonary embolus.

Classification

Pleural effusions are classified by their aetiology as transudates or exudates according to the Light's criteria. This involves measurement of both serum and pleural biochemistry. An effusion is likely to be an exudate if any of the following criteria are met:

- Ratio of pleural fluid Lactate Dehydrogenase (LDH) to serum LDH greater than 0.6
- Pleural fluid LDH greater than two-thirds the upper limit of normal for serum LDH
- Ratio of pleural fluid protein to serum protein greater than 0.5

If the fluid is found to be an exudate, further tests are required to determine the underlying cause.

Clinical features

History

A good history will often identify the cause of a pleural effusion. The initial history should focus on determining the severity and rate of onset of symptoms. Features suggestive of the common causes (e.g. congestive heart failure, pneumonia, malignancy, pulmonary embolism) should be sought. Specific questioning regarding previous occupational exposures, drug treatments, radiation therapy, trauma, tuberculosis exposure and collagen vascular disease may be revealing. Pleural effusions rarely cause symptoms other than dyspnoea. A mild non-productive cough is sometimes described, with a more severe or productive cough suggesting underlying pneumonia or endobronchial pathology. Chest pain in association with an effusion may indicate malignancy, pulmonary embolus or pleural inflammation. Unusually, a chest wall swelling may be due to metastatic cancer or an expanding empyema.

Patients may have associated systemic symptoms due to the underlying pathological process, such as fever, weight loss, or abdominal or joint pain.

Physical examination

Effusions smaller than 300 mL may be undetectable clinically. However, mild hypoxaemia is common and often associated with dyspnoea, which may be due to diaphragmatic distortion, mediastinal shift, reduced chest wall compliance and reduced lung volume. The physical signs of pleural effusion are reduced or asymmetric chest wall expansion, stony dullness to percussion, reduced or absent breath sounds, bronchial breathing above the effusion, pleural rub, diminished or absent vocal resonance and tactile fremitus on the affected side. In large unilateral effusions (>1 L),

tracheal displacement toward the unaffected side may be detected. Ipsilateral tracheal deviation is suggestive of an obstructing endobronchial lesion. In addition, signs of underlying disease should be sought.

Clinical investigations

Investigation and initial management of pleural effusion is shown in Fig. 6.7.1.

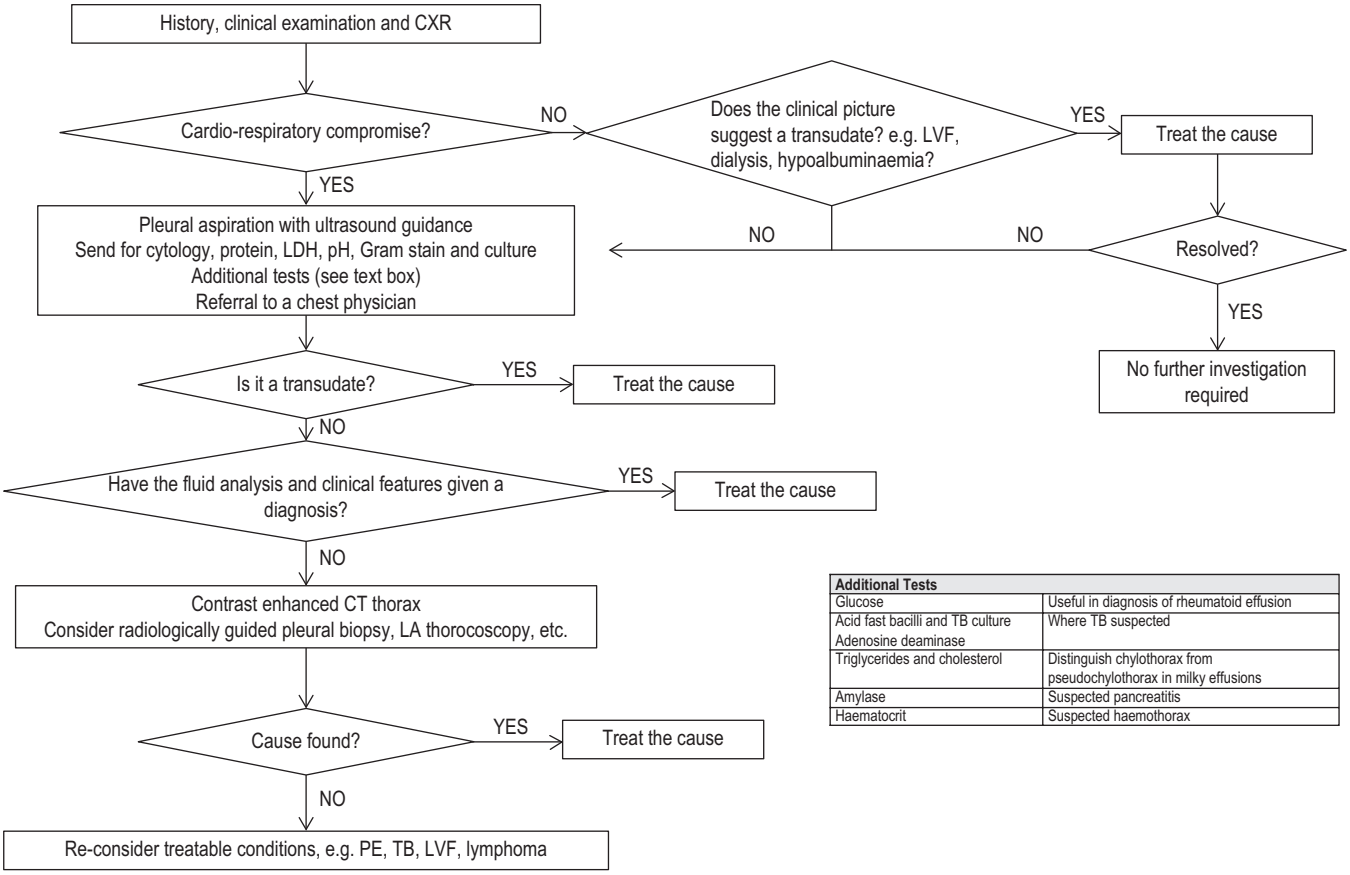
Imaging

In the majority of patients, a posteroanterior (PA) and lateral CXR will provide the required information to confirm and localize an effusion (Figs 6.7.2a and b). The classic radiological features of effusion are of a gravity-dependent homogeneous opacity within the pleural cavity with a concave lateral air-fluid interface (meniscus sign). Effusions larger than 75 mL can obliterate the posterior sulcus on lateral films and 175 mL is needed to blunt the lateral costophrenic angles on erect films (see Fig. 6.7.2b). Occasionally the collection may be subpulmonary. Signs suggestive of this include apparent elevation of the diaphragm, abnormal diaphragmatic contour (lateral displacement of the apex on the PA film, sharp angulation of apparent anterior diaphragm on the lateral film) and more than a 2-cm space between the gastric bubble and the apparent left diaphragm. Very small and/or isolated effusions may not be seen on standard views. Lateral or lateral decubitus films are helpful where a fluid level at least 1 cm deep indicates that the effusion is probably accessible by thoracocentesis and contains at least 200 mL of fluid. If the fluid does not form a uniform level, this may indicate the presence of a loculated effusion, which requires more careful management. Thoracic ultrasound has a higher sensitivity for identifying effusions than CXR. In addition, ultrasound can visualize septa or loculations, pleural thickening or nodularity suggesting malignancy, and areas of consolidation (Fig. 6.7.3). Contrast-enhanced CT can also be helpful in identifying small effusions, underlying pathology or areas suitable for biopsy.

The CXR can also provide other diagnostic clues to the aetiology of the effusion. Large unilateral effusions with lack of mediastinal shift usually indicate a bronchial obstruction, infiltration of the lung with tumour, mesothelioma or a fixed mediastinum (due to tumour or fibrosis). Bilateral effusions with an enlarged heart shadow are usually due to congestive cardiac failure, although they can also be unilateral on the right (30%) or left (10%). Up to half of patients with a pulmonary embolus will have a pleural effusion, which is usually unilateral (85% of patients) and less than one-third of the hemithorax. Pleural plaques and calcification may indicate asbestos exposure, and findings consistent with pneumonia or malignancy may indicate a cause for the associated effusion.

Thoracocentesis

If the diagnosis is known (e.g. congestive heart failure), further investigations are needed only to aid management of the underlying problem. When the diagnosis is still uncertain, the most useful investigation is diagnostic thoracocentesis. A variety of techniques have been reported, but the common underlying principle is the advancement of a needle, trocar or cannula into the pleural space under strict aseptic conditions and the withdrawal of a volume of fluid for analysis. Ultrasound-guided aspiration is recommended, as this reduces both failure and complication rates. Fluid should be procured for biochemical, microbiological and cytological analysis in order to classify the effusion and help to identify the underlying cause (see Fig. 6.7.1). The gross appearance of the pleural fluid can be useful in



Additional Tests	
Glucose	Useful in diagnosis of rheumatoid effusion
Acid fast bacilli and TB culture Adenosine deaminase	Where TB suspected
Triglycerides and cholesterol	Distinguish chylothorax from pseudochylothorax in milky effusions
Amylase	Suspected pancreatitis
Haematocrit	Suspected haemothorax

FIG. 6.7.1 Diagnostic algorithm for the investigation of a unilateral pleural effusion in adults. *CT*, Computed tomography; *CXR*, chest x-ray; *PE*, Pulmonary embolism; *TB*, Tuberculosis; *LVF*, Left ventricular failure; *LA*, local anaesthetic; *LDH*, lactate dehydrogenase. (Modified from Hooper C, Lee YCG, Maskell N. Investigation of a unilateral pleural effusion in adults: British Thoracic Society pleural disease guideline 2010. *Thorax*. 2010;65(Suppl. 2):ii4–ii17, with permission.)

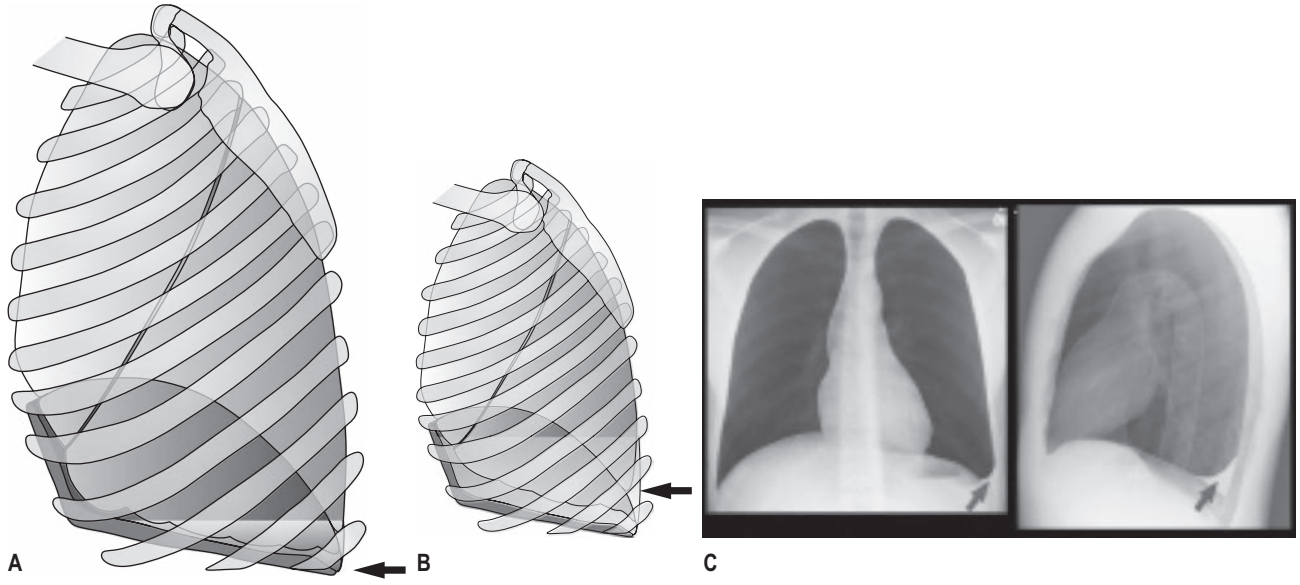


FIG. 6.7.2 (A) Small pleural effusion detected on lateral chest x-ray (*arrow* indicates the effusion). Larger pleural effusion (B). This can be visible on both the lateral and posteroanterior chest views (C) (*arrow* indicates the effusion).

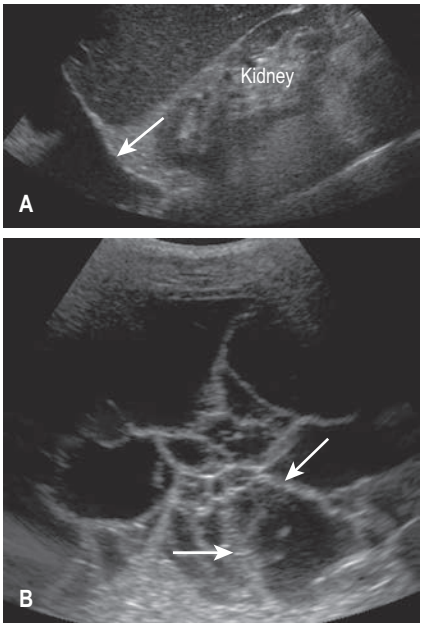

FIG. 6.7.3 (A) and (B) Ultrasound of a parapneumonic effusion showing septations *(arrows)* within the fluid consistent with an empyema. (Reproduced with permission from Seely J, Ayyappan A. Pleural effusion. In: Muller NL, Silva IS, eds. *Imaging of the Chest*. Philadelphia. Saunders/Elsevier; 2008:1341–1342.)

diagnosis (Table 6.7.1). Biochemistry (for LDH and protein), microbiology (for microscopy, culture and sensitivities), and cytology (with a differential cell count) should be requested on all samples. Depending on clinical suspicion, one may also request pleural fluid pH, glucose (in suspected rheumatoid effusions) or acid-fast bacilli, tuberculosis culture and adenosine deaminase (for suspected TB related pleuritis). If a chylothorax or pseudochylothorax is suspected, then triglycerides and cholesterol levels may be useful, while amylase may help distinguish cases of effusion related to pancreatitis or oesophageal rupture. (Fig. 6.7.1)

With respect to exudates, microscopy, Gram stain and cytology should be performed. About 60% of cultures of infected pleural effusion are positive, and this yield is increased with direct inoculation into blood culture bottles. The diagnostic yield in malignant disease ranges from 50% to 90%, with 50 mL of fluid sufficient for cytology. Pleural fluid pH may also be helpful. In parapneumonic effusions, a pH less than 7.2 indicates the need for urgent drainage, whereas a pH greater than 7.3 suggests that treatment with systemic antibiotics should be sufficient. In malignant effusions, a pleural pH below 7.3 indicates more extensive pleural involvement and shorter survival times. A low pleural fluid pH also correlates well with glucose levels. Glucose less than 0.5 times serum is suggestive of bacterial infection, malignancy or rheumatoid arthritis. An elevated amylase in the pleural fluid suggests oesophageal rupture, effusion associated with pancreatitis or malignancy. Pleural fluid antinuclear antibody and rheumatoid factor tests should be ordered when collagen vascular diseases are suspected.

Table 6.7.1 Gross appearance of pleural fluid

Appearance of fluid	*Investigation*	*Interpretation of result*
Bloody	Haematocrit	<1% non-significant 1%–20% malignancy, pulmonary embolus, trauma >50% haemothorax
Cloudy, milky or turbid	Centrifugation Triglyceride level	Turbid supernatant—high lipid levels >110 mg/dL, chylothorax >50 mg/dL, need lipoprotein analysis (Chylomicrons = chylothorax) <50 mg/dL and cholesterol >250 mg/dL, pseudochylothorax
Putrid odour	Gram stain and culture	Possible anaerobic infection
Food particles	Gastrointestinal (GI) imaging	Oesophageal rupture
Ammoniacal odour	Renal function and imaging	Urinothorax

Modified from Light RW. Clinical practice. Pleural effusion. *N Engl J Med*. 2002;346(25):1971–1977.

There are no absolute contraindications to thoracocentesis, but relative contraindications include small fluid volumes (<1 cm on the lateral decubitus film), mechanical ventilation and cutaneous disease over the proposed puncture site. Moderate coagulopathy, thrombocytopaenia or antiplatelet drugs are not associated with increased risk of bleeding when ultrasound is used. The puncture location is chosen based on clinical examination and CXR findings, but ideally with ultrasound guidance.

Additional techniques

Two other procedures deserve consideration when thoracocentesis is not diagnostic. Percutaneous pleural biopsy involves obtaining a closed biopsy of the parietal pleura using an imaging-guided cutting needle. It is relatively easy to perform and improves the diagnostic yield in the presence of tuberculosis and malignancy to 80% and 90%, respectively, when combined with pleural fluid analysis. Thoracoscopy involves pleural biopsy under direct visualization through a thoracoscope. It has a very high yield for diagnosing both benign and malignant pleural disease and can be performed under local anaesthesia. It is usually employed only after other diagnostic procedures have proved non-diagnostic and malignancy is suspected.

Treatment and prognosis

If a pleural effusion is causing respiratory distress, then it should be drained regardless of whether it is a transudate or an exudate (see Fig. 6.7.1); however, treating the underlying cause (e.g. congestive heart failure) may give clinical improvement. Drainage of a relatively small volume of fluid (500 mL) can cause significant relief from symptoms. All patients undergoing this procedure should be well oxygenated, with oxygen saturations monitored and kept above 90%, as thoracocentesis may increase ventilation-perfusion mismatches. There is little evidence that removal of large volumes (usually >1500 mL) of fluid alone causes re-expansion pulmonary oedema. However, rapid removal and larger effusion size (>3 L) may predispose patients to pulmonary oedema; therefore large effusions should be drained slowly and in stages, with at least 12 hours between procedures. The procedure should be stopped if spontaneous drainage, chest discomfort or cough develops.

Transudates should be managed by treating the underlying disease. Large-bore tube thoracostomy should generally be employed for empyema and traumatic haemothorax, although the former may be managed by imaging-guided small-bore drainage. Empyemas tend to loculate early, in which case frequent (every 6 to 8 hours) saline flushing or fibrinolytic (streptokinase, alteplase or urokinase) may be instilled to dissolve the fibrin membranes. Should this fail, surgical drainage or decortication should be performed. Systemic organism-specific antibiotic therapy should also be instituted.

Indwelling pleural catheters are now being increasingly used and are likely to be encountered by emergency department clinicians. These tunnelled catheters can be inserted under local anaesthesia as a day-case procedure, after which fluid is drawn off periodically (usually two or three times a week) using a detachable vacuum bottle system. Drainages can be performed in only a few minutes in the patient's home by community nurses, family members, or even

the patients themselves. When not being used, the indwelling pleural catheter remains concealed under a compact dressing.

Malignant effusions can be managed by thoracostomy and tetracycline pleurodesis, thoracoscopy and talc poudrage or pleuroperitoneal shunt. Chylothoraces should be treated by pleuroperitoneal shunting, as long-term drainage may result in malnutrition and altered immunocompetence.

Prognosis depends on the underlying cause. Patients with parapneumonic effusions have higher morbidity and mortality than those with pneumonia only. Malignant pleural effusions are associated with a mean survival of less than a year.

Complications

Pleural effusions can produce significant respiratory distress, which is alleviated only through drainage. Other complications are those of the underlying pathological process, such as sepsis in the case of parapneumonic effusions.

There are recognized complications associated with thoracocentesis, such as pain at the puncture site, cutaneous or internal bleeding, pneumothorax, empyema and splenic or hepatic puncture. Pneumothorax complicates around 12% of thoracocenteses but this may not always require active treatment. Risk factors include chronic obstructive or fibrotic pulmonary disease, previous chest irradiation, using larger (>20-gauge) thoracocentesis needles, multiple passes to obtain fluid and aspiration of air during the procedure.

Disposition

The requirement for inpatient investigation and management will depend on the degree of respiratory compromise after therapeutic or diagnostic thoracocentesis, the presence of coexisting or underlying disease and the patient's wishes and social circumstances. In many cases, pleural effusions in otherwise stable patients may be investigated and managed on an outpatient basis.

6.8 Haemoptysis

Katie Walker • Christine Jackman

ESSENTIALS

1 **Most patients are stable and can be managed and investigated as outpatients.**

2 **It is essential to differentiate between haemoptysis, haematemesis and bleeding from the upper airway.**

3 **Chest x-ray is normal in 30% of patients with haemoptysis and misses 25% of malignancies.**

4 **High-resolution computed tomography is the investigation of choice if the chest x-ray cannot point to a cause of the bleeding.**

5 **Bronchoscopy is useful if haemoptysis is thought to be due to a lesion in the bronchial tree.**

6 **In 50% of cases, no cause for haemoptysis will be found.**

7 **The priorities in massive haemoptysis are the maintenance of ventilation, oxygenation, circulatory support and the identification and treatment of the source of bleeding.**

8 **If intubation is required, the choice of endotracheal tube type and location of placement will be challenging.**

9 **Embolization of bleeding vessels may provide temporary cessation of bleeding in emergencies, allowing time to stabilize patients prior to surgical procedures.**

Introduction

Haemoptysis is the expectoration of blood from the lungs or tracheobronchial tree. Most patients who present with haemoptysis describe small amounts of blood mixed with sputum or saliva. Most patients are stable and can be managed as outpatients. Rarely, patients present with massive haemoptysis where respiratory and circulatory systems are severely compromised, and death by asphyxiation or exsanguination can be quite rapid. These patients require urgent skilful management of the airways and circulatory systems. A small blood clot may compromise ventilation by obstructing an airway just as effectively as a massive bleed that floods an entire lung.

Aetiology

The causes of haemoptysis are summarized in Table 6.8.1. In up to 50% of cases no cause will be found.[1]

Clinical features

Most patients (95%) with haemoptysis do not present with immediate life-threatening bleeding

Table 6.8.1 Causes and incidence of haemoptysis

and can be managed as outpatients. Massive haemoptysis is any degree of haemoptysis that is immediately life-threatening (usually via respiratory compromise). Haemodynamic compromise is rare, as volumes required to threaten life by ventilatory impairment are as little as 200 mL of blood. Blood lost can also obstruct an airway.

Patients may have difficulty in differentiating between haemoptysis and haematemesis. Bronchial blood is usually coughed out, bright red, frothy and alkaline, whereas gastrointestinal blood is usually darker, may be mixed with food particles and is acidic. Haemoptysis must also be differentiated from nasopharyngeal bleeding, particularly epistaxis.

A targeted history and examination should first seek evidence of airway obstruction as well as respiratory or cardiovascular compromise and then elicit features of potential causes, from the most to the least common. Most patients will have no relevant findings, whereas others will have features of infection (fever, productive cough); possible neoplasm, tuberculosis (TB) and vasculitides (smoking history, other malignancy, chronic cough, weight loss, night sweats, clubbing); chronic or acute respiratory disease; cardiovascular disease and pulmonary embolism. History should also include recent procedures, anticoagulation, TB exposure, possible foreign bodies and past vasculitides. Assessment should aim to differentiate true haemoptysis from gastrointestinal or upper airway causes of bleeding.

Clinical investigations

The patient should be isolated during the course of assessment and management if pulmonary TB or other virulent airborne organisms are considered likely.

Chest x-ray

This is the first investigation to undertake. Between 20% and 30% of patients will have a normal chest x-ray. Chest x-ray may show new alveolar opacity identifying the location of the bleed. It may also show chronic lung disease or new pathology such as infection, masses, cavitation, pulmonary oedema or cardiomegaly. Note that in 25% of patients bleeding from a tumour, the tumour will not be identified on the chest x-ray.[2]

Computed tomography

If no clear cause of bleeding is identified on chest x-ray, consider high-resolution computed tomography (HRCT) of the chest for more detailed information about the pulmonary vasculature, airways and alveoli. It is particularly useful in evaluating for malignancy and will identify the source of the bleed in more than 65% of patients.[3] Consider CT pulmonary angiography in cases of possible pulmonary embolism or vascular malformation.

Bronchoscopy

As CT technology has improved, bronchoscopy has less of a role than previously in determining bleeding sources that have not been identified by chest x-ray or HRCT. In massive haemoptysis, it is used to identify and treat accessible lesions.[4] If haemoptysis in any other patient fails to resolve, then bronchoscopy is usually performed.

In addition to direct visualization of the bronchial tree, bronchoscopy facilitates the collection of sputum and cytological samples for further analysis.

Sputum

Observe universal precautions when pulmonary TB or any other virulent airborne pathogen is being considered. When the origin of haemoptysis is thought to be infective or neoplastic, sputum should be collected for bacteriological and cytological assessment, including Zeihl-Neelsen staining for acid-fast bacilli.

Other

Haemoglobin, platelet count and clotting studies should be undertaken. A raised white cell count may indicate the presence of infection. Assessment of oxygenation by pulse oximetry or venous blood gas analysis is particularly important for a patient with respiratory distress and massive bleeding. Determination of blood group and cross-matching may be needed in the case of massive haemoptysis. Urea and electrolytes provide an assessment of underlying kidney function.

Nasoendoscopy, biopsy, CT or magnetic resonance imaging (MRI) may be indicated if the source of bleeding is from the upper airway (e.g. nasal polyps, laryngeal carcinoma or pharyngeal tumours).

Treatment

Non-massive haemoptysis

In most cases haemoptysis is mild and self-limiting. Treatment is determined by identifying the underlying cause. Malignant disease must also be excluded. If appropriate, patients can usually be discharged on antibiotics and have follow-up as outpatients (both for ongoing investigation and management). A few patients will require inpatient management of the underlying cause.

Massive haemoptysis

Massive haemoptysis is a very different clinical scenario from non-massive haemoptysis and is rare, accounting for less than 2% of all cases of haemoptysis. It has a mortality of over 50% and largely originates from the arterial circulation. It is alarming to the patient and clinically challenging. Massive haemoptysis is usually due to tuberculosis, bronchiectasis, infections (including fungal) and lung malignancies.

The general principles of 'ABCs' apply, as in all serious illness. The immediate threat to the patient is asphyxia and occasionally exsanguination. Early consultation is essential. The team required can include emergency and respiratory physicians, interventional radiologists, anaesthetists, intensivists and thoracic surgeons. An early decision to transfer the patient to a hospital that has the facilities to intervene may be required; hence retrieval services must be notified.

Management involves providing adequate oxygenation and ventilation while identifying and controlling the source of bleeding. To identify the source of bleeding rapidly, immediately obtain a chest x-ray and consider whether the patient is stable enough for a HRCT. Initial management of hypoxia is oxygen by mask or nasal prongs (or both) but may require intubation and positive pressure ventilation. While other evaluation is under way, reversible conditions, such as infection and coagulopathies, should be sought and treated.

Intubation

Clinicians should anticipate a difficult airway with blood obscuring laryngeal views and a poorly oxygenated patient with limited oxygen reserves. Early consultation with the anaesthesia team, if available, is advised. Options for intubation include intubating the trachea only, intubating one lung only and occluding the other or intubating with a double-lumen endotracheal tube (ETT) to allow selective ventilation and suction of each side. Many authors suggest placing the patient with the bleeding lung dependent (down), but there is limited evidence to support this and some feel that it may cause increased bleeding. Intubation allows both suction and oxygenation/ventilation.

The advantages of a large single-lumen ETT include the ability to pass flexible fibreoptic bronchoscopes, suction catheters and occasionally balloon occlusion catheters. In extreme circumstances, the ETT can deliberately be passed into the right main bronchus to selectively ventilate the right lung. It is more challenging to intubate the left main bronchus and higher success rates are achieved when railroading over a fibreoptic scope. A single-lumen tube does not allow for ventilation of one lung while treating the other.

Double-lumen ETTs provide protection for the normal lung and a chance to suction or tamponade the bleeding lung. However, they may not be readily available and take considerably more skill to insert than standard single-lumen ETTs. Tube misplacement has been reported. They can be too narrow to allow the passage of a fibreoptic bronchoscope and hence can limit further assessment of the bleeding source.[5]

Circulation

Attention should be paid to circulation, with transfusion of blood products if required. Coagulopathies should be sought and corrected. Tranexamic acid may have a role in temporarily slowing the bleeding[6]; however, high-quality studies are lacking and there is a low rate of induction of pulmonary embolism.

Interventional radiology procedures

Interventional radiology, if available, is a possible next-line therapy.[1,3,7] The immediate clinical success rate of bronchial artery embolization varies from 70% to 99%. There is a re-bleed rate of 10% to 60% in the short to longer term but the procedure may serve as a temporizing measure to allow the patient to stabilize, after which a semi-elective operation can be considered. Success at angiography is related to the underlying cause. Challenges with angiography include diffuse disease, inaccessible vessels and slow bleeds that do not generate contrast extravasation. Significant complications—such as spinal cord injury and arterial perforation or dissection—have occasionally been reported, but in general the procedure is well tolerated, particularly in patients with respiratory reserve too low to undergo surgery.

Bronchoscopy

Rigid bronchoscopy allows for more complete removal of blood and better ventilation in the case of massive haemoptysis. It does not visualize upper-lobe airways well and the procedure requires sedation or anaesthesia. The fibreoptic bronchoscope is more flexible, of smaller calibre and can be used to visualize areas of the bronchial tree not seen by the rigid bronchoscope. It cannot cope with the large volumes of blood that need suctioning in massive haemoptysis, but it can be passed down the lumen of the rigid bronchoscope once most of the blood has been removed.[5]

Surgery

The place of surgical treatment of massive haemoptysis is controversial. Some authors advocate early surgical resection of the bleeding site and adjacent lung. It may be difficult to identify the source of the bleeding, and most surgeons prefer to operate on a stable patient whose bleeding has ceased. Additionally, some patients will not have the pulmonary reserve to cope with a partial or full lobectomy. Some lesions, such as large vascular malformations, are treatable only by surgery. Surgery is the definitive treatment for intractable recurrent bleeds.[7]

Other approaches

Other authors suggest a more conservative approach, including airway management, suction, endobronchial balloon tamponade, antibiotics, iced saline lavage, topical adrenaline (epinephrine) and bronchial artery embolization; mortality rates of 0% to 25% have been reported. Direct instillation of antifungal agents in cases of massive haemoptysis due to mycetoma has shown greater promise than the use of systemic antifungal agents.

CONTROVERSIES

- What is the appropriate positioning for the patient with massive haemoptysis?
- What method of endotracheal or endobronchial intubation is most appropriate for acute massive haemoptysis in the emergency department?
- Should rigid or flexible bronchoscope be used to assess massive haemoptysis?
- What is the role of tranexamic acid in massive haemoptysis?
- In massive haemoptysis, is conservative management preferred to operative management and what should be the timing of operative management?

SECTION 7

DIGESTIVE EMERGENCIES

Edited by *Biswadev Mitra*

7.1 Dysphagia

Graeme Thomson

ESSENTIALS

1 **Dysphagia is a diagnostic challenge and a broad differential diagnosis should be considered. A carefully taken history will reveal the likely cause in most cases.**

2 **Dysphagia due to a new-onset stroke, pharyngeal or oesophageal disorder will increase the amount of food in the pharynx and may be complicated by aspiration. An assessment of that risk should be made before allowing the patient to take oral fluids or food.**

3 **Patients with moderate- to long-term dysphagia may have significant fluid and electrolyte abnormalities and severe nutritional disturbances.**

4 **Emergency department investigations should be directed to the detection of high-grade obstructions and lesions causing significant risks from airway compromise, haemorrhage or sepsis.**

5 **Dysphagia is very rarely caused by a psychological disorder. There is nearly always a physical cause.**

Introduction

Dysphagia is a broad term encompassing the many forms of difficulty with deglutition (swallowing). The main issues are to determine the likely cause, to identify those patients at risk of significant complications, to treat those causes that are amenable to acute intervention and to refer appropriately for further investigations and treatment.

Dysphagia may be associated with odynophagia (pain on swallowing). *Globus* is a related term meaning the sensation of a lump in the throat. This is rarely of psychological origin. Since the advent of sophisticated investigative techniques, it has been recognized that there is an identifiable physical cause in the great majority of cases.

Aetiology

Problems may occur with any of the three stages of swallowing: oral, pharyngeal or oesophageal. Oral and pharyngeal causes may be grouped under *transfer dysphagia* and oesophageal problems may be referred to as *transport dysphagia*. Passage of food may be obstructed by a physical barrier, such as a tumour, or a disorder of muscle coordination, such as a neurological deficit.

In addition to diseases, many drugs induce dysphagia.[1] These include tetracyclines, non-steroidal anti-inflammatory drugs, ascorbic acid, quinidine, ferrous sulphate and potassium chloride. A careful drug history must be taken.

Clinical features

Symptoms may appear suddenly or develop insidiously. If insidious, there may be an acute precipitating event leading to presentation, often complete or partial obstruction owing to the impaction of a food bolus in the oesophagus. This may present as pain, a feeling of a lump in the neck or central chest, severe retching or drooling and an inability to swallow saliva. Patients may report increasing difficulty swallowing solids and then fluids but, in some cases, there may be no previous history of dysphagia.

When a patient is being screened for dysphagia, the presence of cough or hoarse voice after eating are the historical elements with the greatest sensitivity.[2] It should be assumed that patients with recent cerebrovascular events have dysphagia until formal assessment of swallowing can be undertaken. Desaturation on pulse oximetry is an unreliable indicator of aspiration.[3]

Examination should focus on testing cranial nerve function plus careful examination of the

mouth, neck, chest and abdomen. Hydration and nutritional status should be evaluated.

Perforation may be suspected if there is a history of ingestion of a corrosive substance or sharp object or if pain is a prominent feature. There may be evidence of surgical emphysema in the neck. If presentation is delayed, there may be signs of sepsis.

Clinical investigations

Investigations are directed by the history and likely aetiology. If a food bolus obstruction from a radio-opaque foreign body is suspected, plain chest or neck radiography may be helpful. For non-opaque material or when perforation or mechanical obstruction is suspected, computed tomography (CT) is preferred. Barium swallow may interfere with endoscopy.[4] Semi-elective cases may be referred for endoscopy or video-fluoroscopy.

Laboratory investigations are guided by likely aetiology and complications but should include basic biochemistry and a full blood examination looking for dehydration, electrolyte disturbances and anaemia.

Treatment

Definitive treatment depends on the underlying cause and will rarely be completed in the emergency department (ED). The degree of oesophageal obstruction, the acuity of onset and the presence of complications dictate the need for emergency treatment. Patients with high-grade obstruction should have oral fluids and food withheld and should be given intravenous fluids if the obstruction persists for more than a few hours.

For food bolus obstruction, if the patient cannot swallow saliva or has ingested a sharp object or other material likely to cause local damage, then endoscopic removal should be arranged within 2 to 6 hours. Otherwise endoscopy can be delayed for up to 24 hours.[5] Patients with minor degrees of obstruction may be relieved by medical treatment with drugs such as glucagon, glyceryl trinitrate (GTN) and/or benzodiazepines.[6] However, the obstruction is likely to resolve spontaneously; therefore medical treatment has marginal efficacy.

Bones or similar foreign bodies impacted in the pharynx can often be removed in the ED. Topical anaesthetic sprays may suppress the pharyngeal reflexes adequately to allow direct or indirect laryngoscopy and removal with forceps. Removal may immediately relieve the dysphagia, but symptoms due to local oedema or abrasions may persist.

Oesophageal or pharyngeal perforation is a serious complication requiring cover with broad-spectrum antibiotics and urgent surgical referral.

Odynophagia may be relieved by parenteral or topical analgesia. Oral administration of a viscous preparation of lignocaine will ease the pain caused by luminal inflammatory disorders. The dose should be reduced in the elderly to avoid systemic complications.

Disposition

Appropriate disposition depends on the likely aetiology and the presence of complications. Admission is indicated for patients at risk for airway compromise, severe haemorrhage or sepsis as well as those with high-grade oesophageal obstruction. It will also be indicated when dysphagia is part of a broader disease process. Patients with resolved dysphagia or food boluses should be referred to a gastroenterologist as outpatients for consideration of elective endoscopy.

CONTROVERSIES

- Many ED patients, especially the elderly, have established dysphagia. Recent evidence suggests that modification of the thickness of their diets does not alter the risk of pulmonary complications.
- Long-term management of aspiration may not be beneficial because the apparent severity of aspiration does not correlate with the length of survival.[7]

7.2 Approach to abdominal pain

Rebecca Day • James Fordyce

ESSENTIALS

1 **Abdominal pain accounts for 4% to 10% of all emergency department visits.**

2 **Abdominal pain most frequently arises from pathologies in the gastrointestinal and the genitourinary systems; however, it may also result from cardiovascular, pulmonary, metabolic, infective and/or toxic causes.**

3 **Special consideration should be given towards assessment of abdominal pain in elderly, immunocompromised or obese patients, women of childbearing age and children. These patients require careful assessment to avoid missed diagnoses and poor outcomes.**

4 **In up to 25% to 40% of patients, the exact cause of the abdominal pain may not be determined in the emergency department. Decisions regarding admission, discharge or prolonged observation should be based on degree of symptom control, possible diagnoses, and patient risk profile.**

5 **Patients with abdominal pain should be given adequate analgesia (including the use of opioids). Adequate analgesia can aid diagnosis and does not conceal signs of an acute abdomen.**

Introduction

Abdominal pain is a common emergency presentation and may be caused by a broad range of differentials. Assessment of abdominal pain in the emergency department focuses on the identification of the cause of pain, but further key aims are to identify or exclude acute life-threatening conditions and to consider safe patient disposition. It may not be possible to conclusively diagnose the cause of pain during emergency assessment, so disposition decisions must frequently be made on the basis of risk assessment, patient characteristics and the likelihood of various diagnoses.

The assessment of patients with abdominal pain is challenging because

- symptoms and signs may be non-specific early in the disease process.

- the presentation may be atypical, especially for very young, immunocompromised, obese or elderly patients.
- the degree of pain or abnormal physical findings may not be commensurate with the severity of the disease.

Epidemiology, pathophysiology and differential diagnosis

It has been estimated that abdominal pain accounts for approximately 4% to 10% of all emergency department (ED) visits. A significant proportion (18% to 42%) of these patients will require admission. Older patients presenting with abdominal pain are more likely to require admission (50% to 60%), are more likely to require surgery (18% to 20%) and are at higher risk of death.

Patterns of abdominal pain

- Visceral pain
  - Visceral pain arises by stimulation of nociceptors in visceral structures (gut, heart, renal tract, biliary structures, pancreas). Obstruction and distension of a hollow organ is a frequent cause, with other causes including ischaemia, mucosal irritation and localized inflammation. Pain is often characterized as poorly localized, although it may manifest in the abdominal region that correlates with the embryonic segments of the viscera. Foregut structures will typically produce visceral pain in the upper abdomen, midgut structures in the periumbilical region, and hindgut structures in the lower abdomen (Table 7.2.1).
- Parietal pain
  - Parietal pain arises from nociceptor stimulation in the body wall, including skin, fascia, muscle, parietal peritoneum, pleura and pericardium. Parietal pain is typically well localized to the nociceptive stimulus. Intra-abdominal pathology produces parietal pain through inflammation of the parietal peritoneum. This may be limited to a discrete area, such as the right iliac fossa pain of appendicitis, or may be diffuse, such as that found in generalized peritonitis.
- Referred pain
  - Referred pain is felt at a distance from the site of origin. It is thought that referred pain occurs because afferent pain fibres from areas of high sensory input (e.g. the skin) enter the spinal cord at the same level as nociceptive fibres from an area of low sensory input (e.g. the viscera). The brain, being more used to pain signals from the skin, wrongly interprets the pain signal from the viscera as that from the dermatome. Both visceral and somatic pain may manifest as referred pain. Some examples are
    - shoulder pain due to diaphragmatic irritation
    - pain at the tip of the scapula due to gallbladder pathology
    - epigastric pain due to acute myocardial infarction

Table 7.2.1 Differential diagnosis of pain by location (list is not exhaustive)

Right upper quadrant	*Epigastrium*	*Left upper quadrant*
Hepatobiliary pathology Duodenal ulcer, duodenitis Renal colic, pyelonephritis Retrocaecal appendicitis Pneumonia, pulmonary embolism	Gastritis, peptic ulcer Hepatobiliary pathology Pancreatitis Aortic aneurysm Early appendicitis Myocardial infarction	Gastritis, peptic ulcer Renal colic, pyelonephritis Splenic pathology Pancreatitis Pneumonia
Right lumbar or flank	***Midline or periumbilical***	***Left lumbar or flank***
Renal colic, pyelonephritis Aortic aneurysm Psoas abscess Appendicitis	Visceral pain from midgut structures Early appendicitis Aortic aneurysm	Renal colic, pyelonephritis Aortic aneurysm Psoas abscess
Right lower quadrant	***Suprapubic***	***Left lower quadrant***
Appendicitis Ectopic pregnancy, tubo-ovarian pathology, endometriosis, pelvic inflammatory disease Urinary tract infection, ureteric colic Diverticulitis Hernia Aortic aneurysm Testicular torsion, epididymo-orchitis	Cystitis, bladder pathology Urinary tract infection Prostatitis Ectopic pregnancy, tubo-ovarian pathology, endometriosis, pelvic inflammatory disease	Similar to causes for right-lower-quadrant pain except for appendicitis (very rarely left-sided)
Pain radiating to the back		
Perforated peptic ulcer Acute pancreatitis Abdominal aortic aneurysm, aortic dissection		

Note: Pain from inflammatory bowel disease, diverticulitis, colitis, gastroenteritis, volvulus, intestinal obstruction, adhesions, ischaemic colitis and constipation may localize to any part of the abdomen.

Generalized abdominal pain

Generalized pain of the entire abdomen has a broad differential, with both benign and life-threatening aetiologies (Box 7.2.1).

Extra-abdominal causes of abdominal pain

There are a number of extra-abdominal causes of abdominal pain that must be considered along with abdominal causes (Box 7.2.2).

Box 7.2.1 Some potentially life-threatening causes of generalized, diffuse abdominal pain

Haemoperitoneum from any cause (e.g. ruptured abdominal aortic aneurysm, ruptured ectopic pregnancy, trauma)
Mesenteric ischaemia
Perforated viscus
Peritonitis (any cause)
Pancreatitis
Bowel obstruction
Diverticulitis
Inflammatory bowel disease
Metabolic disorders (e.g. diabetic ketoacidosis), sickle cell crisis
Infective (e.g. typhoid fever, malaria)

(Adapted with permission from Gray-Eurom K, Deitte L. Imaging in the adult patient with non-traumatic abdominal pain. *Emerg Med Pract.* 2007;9:2).

Clinical features

Assessment of patients with abdominal pain

An accurate, focused history often highlights the likely aetiology of abdominal pain. Clinical impression derived from the history and examination will direct decisions regarding further diagnostic work-up. Simultaneous assessment and treatment is frequently necessary in time-critical conditions. Appropriate analgesia should be given early and does not compromise the accuracy of abdominal examination findings.

Patient history

- Key points to identify in the history are as follows:
  - Factors that may influence likelihood of disease (such as risk factors for embolic disease, alcohol, use of non-steroidal anti-inflammatory drugs [NSAIDs])
  - Factors that may influence the assessment of abdominal pain (such as altered anatomy from prior surgeries or body habitus, impaired sensation, or renal impairment that alters medication dosing or contrast administration)

- Factors likely to influence treatment of causes of abdominal pain (such as anticoagulants, anaesthetic risks, fasting status)

Patient demographics and background history

- Age and sex: The likelihood of certain conditions is higher in patients of a specific age and sex (Table 7.2.2).

Box 7.2.2 Extra-abdominal causes of abdominal pain

Thoracic
Myocardial infarction/unstable angina
Pneumonia
Pulmonary embolism
Herniated thoracic disc (neuralgia)

Genitourinary
Testicular torsion

Systemic
Diabetic ketoacidosis
Alcoholic ketoacidosis
Uraemia
Sickle cell disease
Systemic lupus erythematosus
Vasculitis
Hyperthyroidism
Porphyria
Glaucoma

Toxic
Methanol poisoning
Heavy metal poisoning
Spider bite

Abdominal wall
Muscle spasm
Muscle haematoma
Herpes zoster

Infections
Strep pharyngitis (more often in children)
Mononucleosis

(Adapted with permission from Purcell TB. Nonsurgical and extraperitoneal causes of abdominal pain. *Emerg Med Clin North Am.* 1989;7:721–740.).

- A thorough history should be taken, including known medical issues, social history, menstrual history, family history, medications, use of cigarettes, alcohol and other recreational drugs and also history of allergies.
- It is important to ascertain the presence or absence of pregnancy in all potentially pregnant female patients, with specific consideration of risk of ectopic pregnancy.
- Always consider the possibility of trauma, even if not immediately evident on history.

Pain attributes

The nature and time course of pain are key clues to diagnosis. The following attributes should be noted:

- Onset and progression of abdominal pain over time (Box 7.2.3): Acute vascular events and rupture of a hollow viscus typically present with maximal pain at the onset. Ureteric and biliary colic also often presents with severe pain in the early stages. This is in contrast to pain from inflammatory processes, such as acute appendicitis, which tend to progress and 'mature' over hours.

Box 7.2.3 Temporal characteristics of abdominal pain

Sudden maximal pain at or near onset
Perforated peptic ulcer
Ruptured abdominal aortic aneurysm
Ruptured ectopic pregnancy, ruptured ovarian cyst
Ovarian/testicular torsion
Mesenteric infarction
Pulmonary embolism
Acute myocardial infarction

Progression to maximal pain within minutes
Acute pancreatitis
Renal and ureteric colic
Biliary colic
Strangulated hernia
Volvulus
Intussusception

Gradual onset (increased pain over hours)
Appendicitis
Strangulated hernia
Inflammatory bowel disease
Chronic pancreatitis
Salpingitis/prostatitis
Cystitis

(From White MJ, Counselman FL. Troubleshooting acute abdominal pain. Emedmag 2002. with permission.).

- Location of pain (see Table 7.2.1), migration of pain and radiation of pain: Location of pain helps to identify the area of pathology, although occasionally this may be misleading, especially if the pain is referred. Migration of pain over time gives a clue to possible underlying aetiology—for example, pain from appendicitis typically starts at the umbilicus or epigastrium and later localizes to the right iliac fossa.
- Radiation of pain may suggest specific conditions (see Table 7.2.1) (e.g. pain from acute pancreatitis and perforated peptic ulcers often radiates to the back).
- Severity of pain: Severity of pain experienced is dependent on a number of factors in addition to the underlying pathology. Severity of pain is not always commensurate with the severity of the underlying illness. The elderly in particular often have a diminished sense of pain. Nonetheless, patients in severe pain should be assessed early and given pain relief. Pain scores may be used to record and monitor progress.
- Character of pain: Colicky abdominal pain usually results from obstruction of a hollow viscus (e.g. the gallbladder). Constant non-colicky pain usually denotes an inflammatory or vascular process.
- Precipitating and relieving factors: Pain from peritonitis worsens with movement, deep breathing, coughing or sneezing. Pain from peptic ulcer disease classically increases with hunger and decreases with food, antacids or milk. Pain from biliary colic tends to occur after full or fatty meals. Pain from acute pancreatitis classically worsens with supine posture and is relieved by sitting up.
- Recurrent episodes of abdominal pain: This suggests chronic recurrent conditions, for example peptic ulcer, biliary colic, renal colic or diverticulitis. Mesenteric ischaemia and testicular torsion may also present with recurrent episodes.

Associated symptoms

Patients with abdominal pain often have other associated symptoms that may give a clue to the possible cause. These include

- Constitutional symptoms—for example, fever, chills, rigors, weight loss or arthralgia.
- Gastrointestinal tract symptoms—for example, anorexia, nausea, vomiting, diarrhoea or constipation. Nausea and vomiting are

Table 7.2.2 Common causes of abdominal pain according to age group and gender

Causes	*Age group*	*Gender*
Biliary tract disease	Peak age 35–50 yrs; rare in those <20	Female:male 3:1
Ruptured ectopic pregnancy	Childbearing age	Female
Appendicitis	All ages and both genders, peak at young adulthood; there is a higher risk of perforation in the elderly, women, and children.	
Mesenteric ischaemia	Elderly, those with vascular, thrombotic or embolic risks	
Abdominal aortic aneurysm	Increased with advancing age	Men more common
Diverticulitis	Increased with advancing age	Men more common

non-specific and may result from intra- and extra-abdominal causes. However, faeculent vomitus is highly indicative of intestinal obstruction. Both the vomiting of fresh or altered blood as well as the passage of black tarry stools indicate gastrointestinal haemorrhage. Failure to pass stools and flatus over a 24- to 48-hour period suggests possible intestinal obstruction.

- Genitourinary tract symptoms—for example, dysuria, frequency, urgency or haematuria—suggest urinary tract pathologies. Dyspareunia, abnormal bleeding or vaginal discharge may suggest gynaecological pathology. Penile discharge, scrotal swelling, or testicular pain may indicate either genital or abdominal pathologies.

Box 7.2.4 lists some of the historical high-yield questions that the patient with abdominal pain may be asked.

Physical examination

A systematic, directed and thorough physical examination can help strengthen the clinical impression formed from the history or to uncover unexpected abnormalities. Physical findings typically help to rule in but not rule out the underlying diagnosis.

General

Consider the patient's general condition and appearance. Patients who appear drowsy or unwell need urgent attention. The posture of the patient may give a clue to the possible underlying disease. Patients with renal colic typically roll about in pain, whereas those with peritonitis lie still as movements aggravate the pain. Inspect for pallor, jaundice, hydration status, enlarged lymph nodes and signs of chronic liver or renal disease.

Vital signs

Initial examination should always include a review of the vital signs. Patients with abnormal vital signs should be given priority. However, it is not possible to rule out life-threatening causes of abdominal pain by the absence of abnormal vital signs. It has been estimated that up to 7% of patients with abdominal pain but normal vital signs may have an underlying life-threatening process and this percentage increases in the elderly. Tachycardia may be absent in patients with autonomic dysfunction, in the elderly and in patients on medications that may blunt the cardiac response to illness or volume loss. Similarly, the elderly, the immunocompromised or those in severe septic shock may sometimes not mount a febrile response. Even in the immunocompetent, fever may not always accompany acute inflammatory conditions.

The abdomen

Abdominal examination is ideally carried out with the patient lying supine and the abdomen exposed from the costal margins to the pubic symphysis.

- Inspection: Look for movement with respiration, shape (e.g. distended or scaphoid), the presence of any surgical scars and external lesions (e.g. bruises, distended veins, hernias). Sometimes, markedly enlarged organs (especially the liver or spleen) or a distended bowel may be seen.
- Palpation and percussion: Palpation is usually the most informative part of the abdominal examination. Start with the abdominal region away from the area of pain. Perform systematic palpation over all regions of the abdomen, starting with light palpation, followed by deep. Palpate for tenderness, guarding, rebound, and masses. The area of abdominal tenderness helps to localize the pathology. The presence of involuntary guarding (or rigidity) indicates peritoneal irritation. Findings of abnormal abdominal masses may help point to the possible diagnosis. Finally, palpate and percuss for hepatosplenomegaly, palpate bimanually for renal masses or tenderness and examine for costovertebral angle tenderness. Percussion for shifting dullness may be performed in patients with suspected ascites.
- Auscultation: This is traditionally performed to listen for abnormal or absent bowel sounds and for vascular bruits. Findings from auscultation are generally neither sensitive nor specific, and the role of abdominal auscultation is very limited.
- Specific abdominal signs (Table 7.2.3): Distinctive signs have been described that are associated with specific diagnoses. Some of these signs have not been studied and their sensitivity and specificity remain unknown.

Rectal examination

This is useful in cases of gastrointestinal haemorrhage, perianal or perirectal diseases, stool impaction, prostatic pathologies and rectal foreign bodies.

Examination of hernial orifices

All hernias should be examined for signs of strangulation. Hernias are most commonly present in the inguinal or femoral area, along the midline or arising from old surgical scars. Rarely, they may be present in the paramedian, lumbar or gluteal areas.

Examination of the genitalia

Genital examination is frequently an important part of the assessment of lower abdominal pain in both men and women. In women, vaginal examination allows viewing and sampling of vaginal discharge, quantification of bleeding, and assessment of the cervix. In men, testicular abnormalities may be found as a cause of abdominal pain, or abdominal pain may refer to the testes.

Limitations of the abdominal examination

A proportion of patients with serious intra-abdominal conditions, such as ruptured aortic abdominal aneurysm and mesenteric ischaemia, may present with non-specific abdominal findings. The area of tenderness does not always correlate with the anatomical location of the disease, and signs of peritonism may not always be present, especially in the elderly and the immunocompromised. Abdominal examination in an obtunded patient may be unreliable, and other assessment modalities such as imaging have to be considered.

Box 7.2.4 High-yield historical questions

1. How old are you? Advanced age means increased risk.
2. Which came first—pain or vomiting? Pain first is more likely to be caused by surgical disease.
3. How long have you had the pain? Pain for less than 48 hours is more likely to be caused by surgical disease.
4. Have you ever had abdominal surgery? Consider adhesion or obstruction in patients with previous abdominal surgery.
5. Is the pain constant or intermittent? Constant pain is more likely to be caused by surgical disease.
6. Have you had this before? No prior episode suggests a greater likelihood of surgical disease as the cause.
7. Do you have a history of cancer, diverticulosis, pancreatitis, kidney failure, gallstones or inflammatory bowel disease? All are suggestive of more serious disease.
8. Do you have human immunodeficiency virus (HIV)? Consider occult infection or drug-related pancreatitis.
9. How much alcohol do you drink per day? Consider pancreatitis, hepatitis, cirrhosis.
10. Are you pregnant? Test for pregnancy; consider ectopic pregnancy.
11. Are you taking antibiotics or steroids? These may mask infection.
12. Did the pain start centrally and migrate to the right lower quadrant? High specificity for appendicitis.
13. Do you have a history of vascular or heart disease, hypertension or atrial fibrillation? Consider mesenteric ischaemia and abdominal aneurysm.

(Adapted with permission from Colucciello SA, Lukens TW, Morgan DL. Assessing abdominal pain in adults: a rational, cost-effective, and evidence-based strategy. *Emerg Med Pract*. 1999;1:1).

Table 7.2.3 Specific abdominal signs

Sign	*Description*	*Association*
Murphy sign	Cessation of deep inspiration due to pain on palpation of right hypochondrium	Acute cholecystitis (sensitivity 97%; specificity 50%)
Kehr sign	Severe left shoulder tip pain, especially when the patient is lying supine	Haemoperitoneum, e.g. from ruptured spleen or ectopic pregnancy
Cullen sign	Ecchymosis around the periumbilical area	Retroperitoneal haemorrhage (haemorrhagic pancreatitis, abdominal aortic aneurysm rupture)
Grey–Turner sign	Ecchymosis of the flanks	Retroperitoneal haemorrhage
McBurney sign	Tenderness localized to a point at two-thirds distance on a line drawn from the umbilicus to the right anterior superior iliac spine	Appendicitis
Iliopsoas sign	Extension of right hip causes abdominal pain	Appendicitis (sensitivity 16%; specificity 95%)
Obturator's sign	Internal rotation of the flexed right hip causes abdominal pain	Appendicitis
Rovsing sign	Right lower quadrant (RLQ) pain with palpation of the left lower quadrant	Appendicitis
Heel-drop sign	RLQ pain on dropping heels on the ground after standing tiptoes; alternatively RLQ pain from forcefully banging the patient's heel with the examiner's hand	Appendicitis (sensitivity 93%)
Cough test	Post-tussive abdominal pain	Peritonitis (sensitivity up to 95%)

(Reproduced with permission from White MJ, Counselman FL. Troubleshooting acute abdominal pain Emedmag, 2002.)

Examination of extra-abdominal systems

Directed examination of the cardiovascular, respiratory and other systems as needed is necessary when patient with abdominal pain is being assessed.

- Abdominal pain may be caused by extra-abdominal pathology (see Box 7.2.2).
- Systemic signs may provide clues to the possible intra-abdominal pathology—for example, the presence of atrial fibrillation or peripheral vascular disease suggests possible mesenteric ischaemia.
- Abdominal conditions may cause extra-abdominal sequelae—for example, associated chest infection.

Serial examination

Physical signs may often be non-specific in the early phases of disease. Serial examinations over a period of hours can help to distinguish a surgical from a non-surgical abdomen and improve the diagnostic yield.

Clinical investigations

Investigations are used to identify, quantify or rule out pathology, to assess patient condition and response to treatment and to screen for coexistent disease. An investigation should be ordered to answer focused clinical questions, and interpretation of results must take in the clinical context and the limitations of the test. Negative test results may not fully rule out serious pathologies in patients with high pre-test probabilities.

Bedside tests

- Blood gas analysis provides rapid and repeatable measures of acid-base status, as well as a variety of other important parameters (dependent on the assays used), such as haemoglobin, electrolytes, creatinine, glucose and lactate. Elevated lactate is a marker of tissue hypoxia; lactate and may be elevated either in systemic hypoperfusion or as a result of localized tissue ischaemia. Serum lactate measurements have sensitivities as low as 70% for intestinal ischaemia, and a normal lactate level does not always rule out ischemic bowel.
- Urine analysis: This provides useful early information for patients with suspected urinary tract infection and ureteric colic. However, it is important to interpret urine analysis results in the context of the patient's clinical presentation. About 30% of patients with acute appendicitis may present with blood and leucocytes in their urine and about 30% of patients with ruptured aortic abdominal aneurysm may have haematuria. Conversely, up to one-third of patients with urolithiasis may be negative for haematuria.
- Urine pregnancy tests: Bedside urine tests are rapid and accurate. Most are able to detect β-human chorionic gonadotropin (HCG) to a level as low as 25 mU/mL of urine. It has been estimated that up to 1% of ectopic pregnancies are associated with β-hCG values lower than this.
- Electrocardiography (ECG): ECG should be routinely performed in older patients presenting with abdominal pain and to assess for cardiac ischaemia or arrhythmia. Acute coronary events may manifest with abdominal symptoms—for example, epigastric pain, nausea and vomiting. ECG may also suggest the possible cause of the abdominal pain in some cases—for example, mesenteric ischaemia from atrial fibrillation, abdominal pain and vomiting from digoxin toxicity.

Laboratory tests

Most laboratory tests do not aid in differentiating surgical from non-surgical causes of abdominal pain.

- Full blood count: This study is routine in the assessment of abdominal pain, but the significance of white cell levels must be interpreted with caution. A normal white count (including normal absolute neutrophil count) does not rule out a surgical cause of pain. Ten to 60% of patients with surgically proven appendicitis have a normal initial white cell count and only about 50% of patients with severe intra-abdominal pathology have an elevated white cell count. On the other hand, an elevated white cell count is a non-specific measure of generalized inflammatory response, which may be due to a variety of pathologies.
- Electrolytes: Measurements of electrolytes and renal function is also routine in assessment of abdominal pain, although this rarely provides a diagnosis. An exception is hypercalcaemia, which can present as abdominal pain.
- Liver function test: This may be abnormal in hepatobiliary disease, sepsis or a number of other conditions. Liver impairment may influence treatment options.
- Lipase: An elevated lipase level three times the upper limit of normal is the hallmark of acute pancreatitis, however, it may be caused by other pathologies, such as other pancreatic pathologies, renal disease or salivary gland pathology. Lipase may be normal in patients with computed tomography (CT)–proven pancreatitis, especially in those with recurrent disease.
- C-reactive protein (CRP): CRP is an acute-phase reactant, its level is often elevated in inflammation. Serial CRP measurements have been used to monitor inflammatory processes. In emergency medicine, CRPs have been utilized in the assessment of inflammatory conditions such as appendicitis, with varying results.

Imaging

Plain x-rays

The value of plain radiographs in the evaluation of patients with abdominal pain is limited. Plain x-rays (erect chest, supine and erect abdomen) may still have a role as a first-line investigation in patients with suspected bowel obstruction, bowel perforation and foreign body. X-ray findings for bowel obstruction and perforation are fairly specific but not sensitive—that is, they help to establish, but not exclude, these diagnoses.

Ultrasound

Ultrasound has broad utility in the assessment of abdominal pain in the emergency department, both as a point-of-care investigation at the bedside and as a formal diagnostic test performed by specialist sonographers. Ultrasound is also utilized to aid diagnostic and therapeutic procedures such as peritoneal aspiration or suprapubic catheterization as well as to increase success rates and safety. Ultrasound is operator-dependent and appropriate training is necessary to ensure competence.

- Haemoperitoneum from abdominal trauma: The FAST examination (Focused Abdominal Sonography in Trauma) is now considered to be an essential evaluation in unstable patients who have sustained abdominal trauma. (Also see Chapter 3.5 and 23.1.) The presence of free intraperitoneal fluid implies the development of haemoperitoneum. FAST is highly specific (99%), although its overall sensitivity is about 66% compared with CT. FAST is almost 100% sensitive in the hypotensive patient. The sensitivity of FAST improves with serial examination.
- Abdominal aortic aneurysm: Ultrasound allows the rapid bedside identification of abdominal aortic aneurysm (defined as an aortic diameter >3 cm). This has specific utility in the unstable patient who may not be suitable for transfer to a CT scanner. Ultrasound cannot reliably identify rupture, but the detection of an abdominal aortic aneurysm in a hypotensive patient with symptoms suggestive of rupture (abdominal pain, backache or flank pain) is an indication for urgent intervention.
- Ectopic pregnancy: In a patient with a positive pregnancy test, an empty uterus (especially in the presence of free intraperitoneal fluid), implies ectopic pregnancy until proven otherwise. On the other hand, identification of an intrauterine pregnancy essentially reduces the risk of an ectopic pregnancy to less than 1:5000 (1:50 for women undergoing assisted reproduction). Transvaginal ultrasound is more sensitive than transabdominal ultrasound in detecting early intrauterine pregnancy.
- Assessment of suspected gallbladder disease: Ultrasound is the recommended imaging study of first choice for suspected gallbladder disease.
- Tubo-ovarian pathologies: Ultrasound is the first-line investigation for patients with suspected pelvic inflammatory disease or tubo-ovarian pathology. Transvaginal ultrasound provides detailed visualization of the pelvic organs and trans-abdominal ultrasound provides a complementary global view.
- Ureteric colic: Ultrasound combined with abdominal radiographs may be used to screen patients with suspected ureteric colic. The diagnostic sensitivity of ultrasound alone for nephrolithiasis is about 63% to 85%, fairly similar to that for intravenous urography, which has a sensitivity of 64% to 90%. The use of ultrasound avoids potential risks associated with radiation exposure.
- Detection of free peritoneal fluid in non-traumatic abdominal pain: In the appropriate clinical context, this may suggest the presence of ascites, intraperitoneal haemorrhage, pus or leakage of gut contents.
- Appendicitis: Ultrasound may be used to evaluate for the presence of appendicitis if there are contraindications to the use of CT (e.g. pregnancy) or if CT is unavailable. Ultrasound is not as sensitive as CT and helps to rule in but not to rule out this diagnosis.

Computed tomography

With the advent of helical and multidetector scanning technology, CT has become the imaging modality of choice for the evaluation of abdominal pain in the non-obstetric patient. CT allows for detailed visualization of intra-, extra- and retroperitoneal structures and has a high degree of accuracy, establishing diagnoses in more than 95% of cases in one study. It identifies the exact site of disease as well as its impact on the surrounding structures, thereby guiding further management.

CT may be performed with or without intravenous and oral contrast agents. The use of oral contrast in the emergency setting is no longer routine, although it has utility in some specific circumstances—for example, obstruction of the small bowel or surgically altered bowel anatomy.

The main limitations to CT use are the risks of ionizing radiation and the potential nephrotoxicity of radiocontrast, although recent studies have shown this to be less of a risk than previously thought. Risks of radiation decrease with increasing age of patient but risks of nephrotoxicity increase. Other limitations include the need for potentially unstable patients to be transferred to the scanning facility and poor diagnostic accuracy for some pathological conditions, such as cholelithiasis or traumatic perforations of the small bowel.

In the patient with very high suspicion for conditions that require immediate surgical intervention (e.g. unstable patient with obvious peritonitis), the use of CT may result in a delay of definitive treatment.

Although the sensitivity of CT is close to 100% for many conditions, clinical decisions should not be based on CT results alone. If initial CT findings are negative but clinical suspicion is high, further evaluation with serial examination and potentially repeat scans may be needed. For the patient in whom the clinical suspicion for serious abdominal pathology is very low, urgent CT scan is likely to have a low yield and the cost and potential side effects of CT outweigh the benefits.

Magnetic resonance imaging

With the introduction of high-speed techniques, magnetic resonance imaging (MRI) protocols for patients with acute abdominal pain can now be reduced to below 15 minutes.

MRI does not involve ionizing radiation and offers better soft tissue visualization than CT. The high intrinsic contrast resolution of images rendered by MRI may allow for contrast-free scanning in certain cases. Compared with CT, MRI is able to provide more information for hepatobiliary disease, pancreatitis and mesenteric ischaemia. MRI has also demonstrated promising accuracy for the diagnosis of appendicitis, diverticulitis, small bowel obstruction and abdominal and pelvic venous thrombosis.

Currently the use of MRI in ED patients presenting with acute abdominal pain is still relatively limited. MRI is significantly more costly than CT, takes longer to perform and has a number of contraindications.

Imaging for the pregnant patient

Ultrasound is the modality most commonly used in the assessment of abdominal pain in pregnancy and is considered safe for use throughout pregnancy. MRI is also considered a safe modality for use in pregnancy, although gadolinium-based contrast agents are not recommended. CT, although avoided if possible, remains an option in certain clinical circumstances. The doses of ionizing radiation involved in CT studies are below the level thought to lead to developmental or neurological deficits. Risk of foetal carcinogenesis is very low but correlates to radiation dose with no lower dose threshold. Iodine-based CT contrast has not been demonstrated to cause harm to the foetus, but it crosses the placenta and should be avoided unless clearly necessary.

Special patient groups

The elderly

Elderly patients presenting with abdominal pain are more likely to have conditions requiring surgical intervention, are harder to diagnose, are more likely to suffer complications of treatment as well as of delayed diagnosis and have higher mortality. Therefore geriatric patients with abdominal pain must be carefully evaluated

and the threshold for imaging studies, surgical consultation and admission should be lowered.

- Challenges to diagnosing elderly patients
  - The elderly often present atypically or with non-specific complaints—for example, poor appetite, lethargy, constipation, vomiting, loose stools, falls.
  - Pain perception in the elderly may be blunted.
  - Vital signs may be normal in spite of serious underlying illness.
  - Signs of peritonism may not be present in cases of a surgical abdomen and other physical findings may be non-specific or subtle.
  - Laboratory tests, such as full blood count, may be normal.

The immunocompromised

Immunocompromised patients are at higher risk of intra-abdominal sepsis and may have a suppressed inflammatory response. Abdominal signs from peritoneal irritation may be absent. Progression of disease may rapidly become life threatening. Common causes of immunosuppression in an emergency setting are iatrogenesis (organ transplant patients, chemotherapy) and chronic disease.

Women of childbearing age

Numerous gynaecological and pregnancy-related conditions may precipitate a presentation with abdominal pain. Establishing the possibility of pregnancy is crucial, as ectopic pregnancy can rapidly become life threatening. Common gynaecological causes of abdominal pain are ovarian pathologies, pelvic inflammatory disease and endometriosis. Possible obstetric causes of abdominal pain vary by semester of pregnancy.

Pregnancy may modify the presentation of other intra-abdominal pathologies. A second- or third-trimester gravid uterus may displace structures in the lower abdomen away from their usual position—for example, the appendix may migrate to a higher position in the right hypochondrium or the right flank, thus changing symptoms and signs. Clinical signs of peritonism may be obscured due to loss of musculature elasticity in the abdominal wall.

Obese patients

Obesity rates are climbing rapidly in the developed world, and the assessment of the obese patient with abdominal pain poses specific challenges. Abdominal examination of a patient with obesity or morbid obesity is less sensitive and specific. Plain x-ray resolution is decreased when x-rays need to pass a greater distance through tissues. Ultrasound examination is more technically challenging, with decreased image quality in the morbidly obese patient. CT and MRI facilities have limitations relating to the weight and dimensions of patients who can be imaged. Obese patient have higher morbidity and mortality from severe illness.

Chronic abdominal pain

Some patients present to the emergency department with abdominal pain that has been present without diagnosis for many weeks or months. Many of these patients may have had extensive investigations by other health practitioners. They may be very frustrated at the lack of a unifying diagnosis. Assessment of such patients should be comprehensive while also avoiding repetitive, harmful or extensive investigations. Social and psychiatric history is very important, as chronic pain may be both a precipitant and a symptom of significant psychosocial pathology. It is important to show empathy and to thoroughly assess the patient while setting early realistic expectations regarding the likelihood of definitive diagnosis or cure in an emergency setting.

Treatment

Resuscitation

Prompt resuscitation should take precedence over diagnosis in unstable patients. Appropriate fluid therapy and inotropic support should be instituted early to prevent further deterioration and end-organ dysfunction.

Symptom relief

Analgesics should be started early in the patient's presentation and their effectiveness assessed with a pain score pre- and post-administration. It is important to ensure that titrated rather than one-off analgesics are provided during the patient's ED stay. Oral agents should be avoided if absorption is likely to be compromised, as in bowel obstruction. Patients with severe pain should receive titrated parenteral opiates such as fentanyl or morphine in preference to oral medications, as enteric absorption can be slow and unreliable. The previously widely held dogma that opiates mask signs of serious pathology (in particular peritonism) has been disproved in many studies. In fact, the use of opioids in abdominal pain is not only safe but actually aids diagnosis by facilitating physical examination and relaxing the abdominal musculature.

Paracetamol

Paracetamol should be charted regularly for all patients with abdominal pain unless a specific contraindication exists. Oral bioavailability, at 70% to 90%, is reasonable. Rectal or intravenous paracetamol is useful if oral ingestion or absorption is not possible.

Non-steroidal anti-inflammatory drugs

The NSAIDs are a diverse group of medications that have analgesic, antipyretic and anti-inflammatory properties. Agents in this range can be administered enterally, topically, or parenterally. NSAIDs are highly efficacious in renal colic and musculoskeletal pain. However, they may have gastrointestinal and renal side effects and should be avoided in patients who are dehydrated, have renal failure or who have a gastric mucosal cause for their pain—for example, reflux oesophagitis or peptic ulcer disease.

Opiates

Opiate analgesia is the mainstay of symptom relief for acute abdominal pain in the emergency setting. Oral, intranasal, intramuscular or intravenous routes can be used. Oral agents include codeine, oxycodone, and tramadol. Codeine is an inactive precursor requiring metabolism to morphine, leading to potential treatment failure in non-metabolizing patients. Oxycodone may provide more reliable analgesia. Its use in Australia is increasing rapidly and concerns exist regarding the potential for addiction. Tramadol is a moderate-strength agent, which may have less gastrointestinal side effects compared with the other oral agents. Fentanyl can be titrated as an intravenous agent and is also efficacious intranasally, which can be useful if intravenous access is delayed. Morphine is usually used as titrated intravenous aliquots. Intramuscular or subcutaneous morphine has variable bioavailability and effect and has limited use in acute abdominal pain.

Hyoscine butylbromide

Hyoscine butylbromide is a poorly absorbed anticholinergic agent used to relieve intestinal spasm by local action on gut smooth muscle muscarinic receptors. Evidence seems to support a limited role for hyoscine butylbromide for mild to moderate colicky abdominal pain.

Proton pump inhibitors

Although proton pump inhibitors (PPIs) can be useful in the longer-term treatment of gastric mucosal disease, they are of unproven benefit in relieving acute dyspeptic pain in the emergency department setting; therefore they have an unfavourable cost-benefit ratio.

Antiemetics

Ondansetron, metoclopramide, and prochlorperazine are commonly used antiemetics. Ondansetron, a serotonin receptor antagonist, has largely superseded metoclopramide as the first-line antiemetic in Australian emergency departments owing to its better side-effect profile, longer duration of action and possibly greater efficacy.

Antibiotics

Antibiotics should be used early for suspected intra-abdominal sepsis. Choice of antibiotic will

depend on local bacterial resistance profiles and the diagnoses under consideration. In general antibiotics for suspected intra-abdominal sepsis should cover gram negative aerobes as well as anaerobes. Additional coverage for gram positive aerobes is required in patients with spontaneous bacterial peritonitis.

Disposition

A patient may be discharged from the emergency department if the following criteria are met and symptoms have been controlled:

- No diagnosis has been identified or strongly suspected that requires acute inpatient care.
- Social circumstances are favourable.
- The patient has the ability to return if symptoms progress.
- Sudden deterioration is not anticipated.

Patients who do not meet these criteria should remain in hospital for observation and further treatment. This may involve admission to an inpatient setting or, alternatively, observation in an emergency short-stay unit if a benign diagnosis is anticipated. The main aims of observing the patient with abdominal pain are to improve diagnostic yield with serial examination, to monitor progress after treatment, to detect the development of signs of acute abdomen and for further diagnostic workup if indicated.

Discharge advice

It is important to give discharge advice, as some conditions develop over time. The patient should be advised to return if

- pain is persistent (>24 hours) or worsening
- they develop incessant vomiting or are unable to retain fluids
- vague pain has become localized—for example, to the right iliac fossa
- they develop high fever or chills or feel increasingly ill, weak or unwell
- they develop fainting episodes
- abdominal distension develops
- there is blood in the stools or vomitus
- they develop new medical problems requiring urgent consultation

Non-specific abdominal pain

A large proportion of stable patients with abdominal pain will not have a definitive diagnosis on discharge from the ED. In patients under 50 years of age, non-specific abdominal pain may be as high as 40%. This figure is lower in the elderly, at about 15%.

Most younger patients may be safely discharged from the ED once their symptoms have resolved with treatment and a period of observation. They should be clearly informed that the cause of their pain has not been determined and appropriate discharge advice, as well as an instruction to return to the ED if symptoms recur or worsen, should be given. Referral to a specialist for further evaluation may be indicated.

Non-specific abdominal pain in younger patients tends to have a benign course. However, about 10% of the elderly thus labelled are subsequently found to have an underlying malignancy. It is also important to rule out extra-abdominal causes in the elderly.

Developments in the next 5 to 10 years

Early recognition and surgical management of acute mesenteric ischaemia greatly improves patient outcomes. However, clinical diagnosis of acute mesenteric ischaemia, especially in the early stages, remains challenging and largely still relies on CT imaging. Lactate is often used in the emergency department when mesenteric ischaemia is suspected, but it is non-specific. Other biomarkers—for example, citrulline—have been investigated and been shown to improve diagnostic accuracy, but further research around clinical cut-offs and marker combination panels is still required before these tests will be ready for widespread clinical application.

CONTROVERSIES

- Clinical scoring systems for abdominal pain. Various clinical scoring systems (e.g. the Alvarado score for acute appendicitis) have been proposed. They help to ensure a more systematic approach to the evaluation of a patient, but none has been shown prospectively to improve on the physician's judgement.
- Conservative antibiotic management of uncomplicated appendicitis. The two largest recent meta-analyses came to opposite conclusions regarding whether antibiotics were as effective and safe for the treatment of uncomplicated appendicitis.

7.3 Bowel obstruction

Kim Yates

ESSENTIALS

1 **Small bowel obstruction is most often caused by adhesions, hernias or neoplasms. Large bowel obstruction more commonly results from neoplasms, volvulus or strictures.**

2 **The common clinical features of bowel obstruction are paroxysms of poorly localized abdominal pain, constipation/obstipation, abdominal distension, nausea, vomiting and hyperactive or high-pitched bowel sounds. Examination for hernias is essential.**

3 **On abdominal x-rays, dilated loops of bowel with multiple air-fluid levels can confirm the diagnosis of bowel obstruction. Where clinical suspicion is high and plain radiography is negative, a computed tomography scan is recommended.**

4 **Initial treatment consists of correction of dehydration and electrolyte abnormalities, decompression, analgesia and further assessment (particularly to identify strangulating bowel obstruction).**

5 **Strangulating bowel obstruction and/or perforation are indications for urgent surgery.**

Introduction and pathophysiology

Bowel obstruction is the interruption of the normal progression of intestinal contents. It can result from a mechanical obstruction or from a failure of intestinal motility without obstruction. It can affect the small or large bowel, may be partial or complete and can be strangulating or non-strangulating.[1,2]

The 'ABC' mnemonic—Adhesions, Bulge, Cancer/Crohn's—can be used to remember the common causes of small bowel obstruction (SBO): adhesions (60% to 85%), hernias (2% to 3%), neoplasms (2% to 5%), and Crohn disease (5% to 7%). Less common causes include gallstones, foreign bodies, strictures, radiation, diverticulitis, endometriosis and abscesses. Ninety percent of large bowel obstructions (LBOs) are

caused by adenocarcinoma of the colon and rectum, volvulus or strictures from diverticulitis.

The pathophysiology of mechanical bowel obstruction relates to rising intraluminal pressure, mucosal injury, bacterial overgrowth and inflammatory response. Bowel proximal to the obstruction distends with gas, fluid and electrolytes; thereafter hypersecretion escalates, bowel absorptive ability decreases and progressive systemic volume losses occur. Vomiting ensues more quickly the more proximal the bowel obstruction is and worsens the dehydration and electrolyte disturbances.

If obstruction persists, then the intraluminal pressure rises and local vascular compromise can occur, especially venous stasis. As pressures rise and blood flow diminishes, the bowel can strangulate and necrosis may follow, with consequent perforation and sepsis. A closed-loop obstruction implies both proximal and distal obstruction (e.g. strangulating hernia or volvulus) and, typically, leads to vascular compromise more quickly and therefore to a higher risk of strangulation, ischaemia and perforation.

Functional obstruction, where there is failure of intestinal motility but no mechanical cause, is seen postoperatively as adynamic ileus and may occur with the use of opiates. Acute colonic pseudo-obstruction (Ogilvie syndrome), which is also a functional obstruction, can also produce small bowel dilatation; risk factors for this include antikinetic drugs (e.g. calcium channel blockers, anticholinergic drugs, phenothiazines, or anti-parkinsonian medications), severe electrolyte disturbances, neurological disorders, thyroid disorders and major acute medical illnesses or recent surgery.

Clinical features

History

In early bowel obstruction, abdominal pain is poorly localized and colicky; later it may become more constant and, if severe, suggests ischaemia, strangulation, perforation or peritonitis. Patients with proximal SBO tend to have more profuse vomiting, more frequent paroxysms of pain and less abdominal distension than those with more distal obstructions. With LBO, periumbilical or hypogastric pain and abdominal distension are the most common presenting features. Vomiting is more common in SBO and is a late symptom in LBO. Faeculent vomiting suggests a more high-grade SBO. Obstipation (inability to pass flatus and stool) was formerly thought to be typical, but the passage of flatus and stool may continue[1–3].

The gastrointestinal and surgical history helps differentiate causes of mechanical obstruction and drug history and systems enquiry may identify potential causes of functional obstruction.

Examination

Classical examination findings are abdominal distension and absent, reduced or 'tinkling' bowel sounds. Abdominal tenderness may be present but is not a reliable indicator of site of obstruction. A mass may or may not be palpable. The presence of fever, tachycardia, guarding or peritonism suggests strangulating obstruction or perforation; however, vascular compromise can occur in their absence. Signs of dehydration are often present. Abdominal distension is more commonly present in LBO or distal SBO. On auscultation, rushes or high-pitched tinkles may be heard but are not absolute indicators of obstruction. Surgical scars suggest adhesions as a cause of obstruction, and examination for hernias is essential. Rectal examination may be normal, but the presence of faecal impaction, blood or a mass may assist with diagnosis of cause. Pelvic examination may be useful if abscesses or inflammation are suspected[1–3].

A focused medical examination should also be performed to exclude causes of functional obstruction and to assess for anaesthetic risk.

Clinical investigations

Laboratory tests

Laboratory findings are often nonspecific but help in the assessment of severity and guidance of resuscitation. Haematocrit may be raised if dehydration is present. The commonly measured inflammatory markers, such as white blood cell count and C-reactive protein, cannot distinguish inflammation due to obstruction from other inflammatory syndromes. Electrolyte abnormalities—such as hyponatraemia, hypokalaemia and impaired renal function—are common. Metabolic acidosis and rising lactate levels suggest bowel ischaemia. Coagulation studies are indicated for patients on anticoagulants or when urgent surgery may be needed. A blood or urine pregnancy test, where appropriate, and urine microscopy are important in excluding other causes of abdominal pain[1–4].

Imaging studies

Abdominal x-rays (AXRs) are readily available and the presence of dilated loops of bowel with multiple air-fluid levels on AXR is highly suggestive of bowel obstruction. When enlarged, the small bowel (>3 cm), caecum (>9 cm) and colon (>6 cm) are considered dilated. Free air under the diaphragm on an upright chest x-ray or AXR that includes the lung bases indicates that perforation has complicated the obstruction. Colonic volvulus can be diagnosed on AXR in 85% of cases, so AXRs should be checked for the 'bent inner-tube' of sigmoid volvulus and the dilated caecum or 'kidney bean' of caecal volvulus. Studies have reported variable sensitivity of AXR for the diagnosis of SBO (59% to 93%). Specificity appears better for SBO than LBO (83% vs. 72%), but 20% to 30% of patients with proven SBO may have normal or equivocal AXR. AXR may appear normal with closed-loop or strangulated obstructions; however, intramural gas suggests necrosis[1,2,5–8].

Initial studies of bedside ultrasound, looking for dilated fluid-filled small bowel or decreased peristalsis, have shown better sensitivity than AXR for diagnosing SBO, but larger prospective studies are needed.

Abdominal computed tomography (CT) especially multi-detector CT, has a high sensitivity and specificity for detecting SBO (90% to 95% and 96%, respectively) and LBO (96% and 93%, respectively). CT can determine the level and cause of obstruction and identify emergent causes, such as volvulus and strangulation, as well as distinguish functional obstruction. CT findings such as intramural gas, abnormal bowel wall thickening/enhancement, mesenteric oedema/fluid or gas in mesenteric or portal veins all suggest ischaemia in SBO, but studies show variable sensitivity and specificity, so the use of CT to rule out ischaemia is controversial.

Magnetic resonance imaging has similar sensitivity and specificity to CT, but limited availability, and long scan times mean limited usefulness in the Emergency Department (ED) setting unless minimizing radiation exposure is paramount.

Endoscopy[1]

Careful sigmoidoscopy is safe in LBO and therapeutic in sigmoid volvulus when it is used to place a rectal tube. In some centres, endoscopy is performed acutely to decompress LBO by inserting drainage tubes or self-expanding metal stents[1].

Treatment and prognosis

General measures

Most patients with bowel obstruction are dehydrated, so treatment with crystalloid intravenous fluid is required and electrolyte disturbances should be corrected. Urinary catheterization and monitoring of urine output, vital signs and electrolytes should guide ongoing fluid and electrolyte therapy. Nasogastric decompression is customary to reduce discomfort and risk of aspiration but also to monitor output. Analgesia is often required, with titrated increments of intravenous opiates being the most appropriate option. There is no evidence that antibiotics are useful for non-operative management, but they are indicated before laparotomy[1–3,8].

Patients with bowel obstruction associated with haemodynamic compromise, shock or

sepsis require combined, ongoing management by surgical and intensive care teams. Patients with suspected strangulating bowel obstruction or perforation should have urgent surgery. Stable patients and those with partial bowel obstruction can be started on conservative therapy and monitored closely as inpatients for signs of deterioration.

Conservative therapy

Ongoing IV fluid therapy, electrolyte management and bowel rest are the mainstay interventions. Monitoring of vital signs, urine and nasogastric output and clinical state should continue, and deterioration or failure to improve are indications for surgical therapy. In some centres, water-soluble contrast agents such as Gastrografin are administered via nasogastric tube to patients with adhesive SBO, as this has been shown to reduce length of stay and the need for surgery as well as helping to predict the likelihood of resolution using serial AXR[1–3,8,9].

A non-strangulating sigmoid volvulus can be temporarily decompressed by a rectal tube inserted via a sigmoidoscope. Endoscopic placement of self-expanding metallic stents can relieve malignant LBO, either prior to elective surgical resection or as definitive palliative therapy if the malignancy is inoperable. Reported complications of metallic stents include perforation, stent migration and re-obstruction.

Surgical therapy

Bowel obstruction due to hernias and complete SBO usually require surgery. Strangulating bowel obstruction is an indication for urgent surgery and should be suspected in the presence of severe pain and localized tenderness. Additional suggestive features include a fever, tachycardia, shock, acidosis, raised lactate, sepsis and confirmatory CT findings. It can, however, occur without these features. Broad-spectrum parenteral antibiotics are indicated preoperatively and when sepsis is suspected[1,2,8].

Mortality escalates dramatically the longer surgery is delayed in strangulating bowel obstruction or perforation (30% compared with 3% in uncomplicated SBO), so prompt surgery is vital. The surgical approach adopted will depend on the suspected pathology and operative findings. Laparoscopic adhesiolysis is becoming more common for SBO in stable patients who fail conservative therapy, but it may require conversion to laparotomy. In LBO caused by benign or malignant strictures, endoscopically placed stents can allow definitive surgery to be deferred; if it is unsuccessful, however, patients usually undergo the appropriate segmental colectomy with either an ostomy or primary anastomosis. Owing to the risks of anastomotic dehiscence or contamination, stomas may be preferred for very sick patients or when non-viable colon is found.

CONTROVERSIES

- Clinical features and plain radiography may not be helpful in the diagnosis of strangulating bowel obstruction.[1,2,4,8] When progression to ischaemia occurs, lactate dehydrogenase and creatine kinase may rise, but they are nonspecific. D-dimers may be an exclusionary indicator. Rising lactate levels and worsening metabolic acidosis are strong indicators of ischaemia. Serum markers—such as intestinal fatty acid binding protein and alpha-glutathione S transferase—of damaged enterocytes are promising for early detection but are not readily available. CT is useful for identifying established strangulation, but early diagnosis remains challenging.
- Tube decompression therapy in SBO has not been associated with a reduction in need for surgery or bowel resection but is commonly practised.[1,2,8] Both short nasogastric and long naso-intestinal tubes have been used in the treatment of adhesive SBO, but long tubes have not shown a definite advantage.
- Non-operative therapy.[1,2,8,9] In adhesive SBO without signs of strangulation, a trial of non-operative therapy with frequent reassessment for 48 hours appears safe, but the safe duration beyond this is controversial. There is increasing evidence that water-soluble contrast agents such as Gastrografin have diagnostic and therapeutic value in adhesive SBO. Administration usually begins in the ED, but a robust multidisciplinary protocol is necessary for its safe implementation.

7.4 Hernia

Neil A. Goldie

ESSENTIALS

1 **A diagnosis of symptomatic herniae mandates early surgical repair to avoid life-threatening complications.**

2 **Herniae may present as a reducible lump or may incarcerate, strangulate and/or present as bowel obstruction.**

3 **Femoral herniae are often misdiagnosed and, when complicated, are associated with high morbidity.**

4 **All herniae presenting with a complication should undergo prompt surgical repair.**

Introduction

A hernia is defined as the protrusion of a viscus or part of a viscus through a weakness in the wall of the containing cavity. It has an aperture, coverings (usually peritoneum and abdominal wall layers) and contents, which may be any intra-abdominal organ but are usually omentum or small bowel. Surgical treatment requires reduction of the contents and closure of the aperture, with reinforcement to prevent recurrence. The reinforcement may be sutures or mesh.

There are a number of described sites for herniae. This chapter focuses on the more common of these, but the principles of assessment and treatment apply to herniae at other sites.

Aetiology, pathology and clinical features

Inguinal hernia

Inguinal herniae are extremely common and account for 75% of all abdominal wall herniae. There is a lifetime risk of occurrence of 27% for men and 3% for women and an annual incidence of 130 per 100,000 population. Up to 9% of hernia repairs are performed urgently. Emergency repairs are more common in the elderly and carry greater morbidity than elective repairs.

As their name implies, direct inguinal herniae bulge directly through the posterior wall of the inguinal canal. They are caused by weak abdominal musculature, are common in the elderly and are frequently bilateral. They have large necks and hence seldom become irreducible or strangulate until they are of considerable size.

For indirect inguinal herniae, the hernial sac comes through the internal inguinal ring, travels the length of the inguinal canal and emerges from the external inguinal ring. Thus it usually lies above and medial to the symphysis pubis. Later the internal inguinal ring may stretch and the hernial sac and its contents may descend to and fill the scrotum, occasionally becoming very large. Because the internal inguinal ring is usually narrow, irreducibility is common. Indirect inguinal herniae occur throughout life (e-Fig. 7.4.1).

Direct and indirect inguinal herniae may be distinguishable by simple clinical tests. When an indirect hernia is reduced, finger pressure over the site of the internal ring may hold it reduced; however, a direct inguinal hernia will flop out again unless several fingers or the side of the hand props up the entire length of the inguinal canal.

Femoral hernia

Femoral herniae appear lateral and inferior to the symphysis pubis. They are formed by the peritoneal sac and contents, which occupy the potential space of the femoral canal, medial to the femoral vein. They are proportionately more common in women and rarely large. Symptoms usually occur early and complications are common.

Both femoral canal areas should be closely examined in any patient presenting with abdominal pain or signs of bowel obstruction, as femoral herniae are frequently overlooked, especially in patients who are elderly and obese. Diagnosis of a femoral hernia mandates early surgery. Morbidity from emergency femoral hernia repair increases with the presence of small bowel obstruction. Mortality with emergency surgery can be as high as 5%.

Umbilical hernia

Umbilical and periumbilical herniae protrude through and around the umbilicus. They are very common in the newborn, but most resolve by 4 years of age. As they have a broad neck, emergency complications are uncommon. They can be difficult to diagnose in very obese people. If complicated, their presentation can resemble that of abdominal wall cellulitis.

Epigastric hernia

Epigastric herniae appear in the midline above the umbilicus. A small extraperitoneal piece of fat may be stuck in this hernia, causing pain.

Other herniae

Obturator hernia

Rarely, viscera may pass through a defect in the obturator foramen and present as a small bowel obstruction. This occurs most commonly in elderly emaciated women with chronic disease. Diagnosis of this internal hernia and the hernia of the foramen of Winslow is seldom made preoperatively.

Spigelian hernia

Spigelian herniae are rare and are due to a defect in the anterolateral abdominal wall's musculature. They usually present as a reducible lump in the elderly male, lateral to the rectus muscle in the lower half of the abdomen. Complications are rare.

Incisional hernia

These may occur at the site of any previous abdominal wound, as from an appendicectomy or laparotomy. The wound area becomes weak, allowing the protrusion of a viscus or part of a viscus.

Sportsman's (athlete's) hernia

This term designates herniae that present with painful symptoms in the groin following exertion. The sportsman's or athlete's hernia is defined as an occult hernia caused by weakness or a tear of the posterior inguinal wall without a clinically recognizable hernia. Generally, by the time of diagnosis, non-operative treatment options have failed and surgery often results in a return to sport. Ultrasound can be a useful diagnostic tool to detect herniae that are intermittently symptomatic but without clinical signs.

Complications

In the early stages, herniae are usually reducible, producing only intermittent pain in the groin, but reducible herniae may become irreducible

(incarcerated). Incarcerated herniae may lead to a bowel obstruction. Strangulation and interruption of the blood supply to the contents of the hernia (usually small bowel) may supervene. In this case, there will be increasing local pain, tenderness, warmth and overlying erythema. This is accompanied by signs of bowel obstruction and a leucocytosis.

Rarely, only part of the bowel wall is caught in a hernial constricting ring. Bowel wall necrosis, which ensues, is not circumferential; this is termed a Richter hernia. In this case, there may be signs of strangulation without signs of obstruction.

Very rarely, neglected herniae can fistulate, with bowel contents appearing at the abdominal wall or through the hernial orifices.

Treatment

Reduction

It may be possible to reduce a hernia that initially appears irreducible in the emergency department, but caution must be exercised. If the skin over the hernia is already inflamed and pain is severe, the contents may be compromised and urgent surgical exploration will be required. Reduction of the contents in this circumstance can be dangerous, as false reassurance can occur, followed by the later development of peritonitis due to intra-abdominal perforation of the hernial contents.

As a general rule, if the hernia has been irreducible for less than 4 hours, vital signs are normal and there are no symptoms of bowel obstruction, reduction of an incarcerated hernia may be attempted. This is achieved by giving adequate analgesia to relax the patient and applying gentle pressure, manipulating the hernia site for several minutes. Elevating the foot of the bed may be helpful. Successful reduction relieves pain, may prevent strangulation and reduces the urgency of surgical intervention. Notwithstanding, all herniae that have undergone a complication require surgical consultation with view to definitive treatment at the time of presentation.

Surgical repair

Inguinal hernia repair is a very common operation in general surgery. Rates of repair range from 10 per 10,000 population in the United Kingdom and 28 per 10,000 in the United States to 33 per 10,000 per year in Australia.

Timely repair of herniae reduces the incidence of complications and avoids the greater risks associated with emergency surgery. Until the introduction of synthetic mesh, inguinal hernia repair had changed little for over 100 years. Mesh is used to reinforce the repaired defect and can be placed by an open method or laparoscopically. Laparoscopic transabdominal preperitoneal hernia repair takes longer than open surgery and has a more serious complication rate with regard to visceral injuries, but it is being increasingly performed because it reduces postoperative pain and significantly reduces time off work. It is also much more operator dependent, more difficult to learn and has higher overall hospital costs.

Patients requiring emergency surgery for bowel obstruction or strangulation should be prepared with adequate fluid resuscitation and analgesia.

CONTROVERSIES

- The diagnosis and management of 'sportsman's hernia'.
- The role of laparoscopy in hernia repair.
- The use of mesh (polymer versus biological). A number of mesh products have been recalled by the US Food and Drug Administration.

E-FIG. 7.4.1 Common inguinal herniae.

7.5 Gastroenteritis

Arun Ilancheran

ESSENTIALS

1 **Gastroenteritis is usually a benign, self-limiting disease that can be diagnosed clinically, warrants no specific investigation and settles spontaneously with symptomatic treatment and oral fluid therapy.**

2 **The cardinal clinical feature of gastroenteritis is diarrhoea, which may be accompanied by varying degrees of nausea and vomiting, abdominal cramping and pain, lethargy and fever.**

3 **The clinical examination is directed at confirming the diagnosis of gastroenteritis, excluding alternative diagnoses and determining the degree of dehydration.**

4 **A wide variety of viruses, bacteria and protozoa may cause gastroenteritis. In developed countries, common viral agents include rotavirus and norovirus. Common bacteria include *Campylobacter jejuni, Staphylococcus aureus, Escherichia coli, Shigella dysenteriae* and *Salmonella enteriditis*. Common protozoa include *Giardia lamblia*.**

5 **The principles of treatment of gastroenteritis are to replace the fluid losses orally or intravenously, minimize the patient's symptoms by the use of antiemetic therapy and, in some circumstances, administer specific antimicrobial agents.**

6 **Introduction of rotavirus vaccine in Australia in 2007 has led to the reduction of both rotavirus and non-rotavirus gastroenteritis.**

Introduction

Gastroenteritis is a common clinical syndrome. It poses one of the world's major clinical and public health problems and, in developing countries with poor-quality drinking water and low levels of sanitation, it is a major cause of morbidity and mortality, especially among children and the elderly.

Gastroenteritis is caused by infection of the gastrointestinal tract by various viruses, bacteria and protozoa. Transmission is most commonly by the faecal-oral route. The syndrome consists of diarrhoea, abdominal cramping or pain, nausea and vomiting, lethargy, malaise and fever. Each of these features may be present to a varying degree and may last from 1 day to more than 3 weeks.

In developed countries, even though serious morbidity and mortality are low, gastroenteritis may be an extremely painful and unpleasant event, causing disruption to daily life and significant loss of work and school days. Patients often seek emergency medical care because of the acuteness of onset of symptoms, the frequency of the diarrhoea, the severity of abdominal pain and cramps or because of concerns regarding dehydration.

Pathogenesis and pathology

Microorganisms of all descriptions are constantly entering the gastrointestinal tract through the mouth. Extremely few of these progress to cause clinical illness. The natural defences of the gastrointestinal tract against infection include gastric acid secretion, normal bowel flora, bile salt production, bowel motility, mucosal lymphoid tissue and secreted immunoglobulin A. People with disturbances in any of these defences are more prone to develop a clinical infection. For example, patients with achlorhydria, bowel stasis or blind loops, immunodeficiency states or recent antibiotic therapy that has disturbed bowel flora are prone to develop gastroenteritis. Some organisms, such as rotavirus, occur principally in children, as previous infection confers immunity.

Microbiology

A wide variety of viruses, bacteria and protozoa may cause gastroenteritis, and the list is continually growing. Viral agents include rotavirus, enteric adenovirus, astrovirus, calicivirus, norovirus, coronavirus and cytomegalovirus. Bacteria include *C. jejuni*, *S. aureus*, *Bacillus cereus*, *E. coli*, *Vibrio cholerae*, *S. dysenteriae*, *S. enteriditis*, *Yersinia enterocolitica*, *Clostridium perfringens* and *C. difficile*. Protozoa include *G. lamblia*, *Cryptosporidium parvum* and *Entamoeba histolytica*.

Micro-organisms cause gastroenteritis by a number of mechanisms. They may release preformed toxins prior to ingestion, multiply and produce toxins within the gastrointestinal lumen, directly invade the bowel wall or use a combination of toxins and invasion.

S. aureus and *B. cereus* produce a variety of toxins in stored food that are subsequently ingested. These toxins are absorbed and, within hours, act on the central nervous system to produce an illness characterized predominantly by vomiting and mild diarrhoea.

Invasive bacteria are characterized by *Salmonella*, which invades the mucosa (primarily of the distal ileum) producing cell damage and excessive secretion. *Shigella* likewise invades the mucosa but also produces toxins that have cytotoxic, neurotoxic and enterotoxic effects.

The many strains of *E. coli* have been divided into five groups, depending on the pathology of the diseases they cause. These are enteropathogenic, enterotoxigenic, enteroinvasive, enteroaggregative and enterohaemorrhagic. Enterohaemorrhagic *E. coli* is associated with haemorrhagic colitis and the haemolytic-uraemic syndrome, whereas enterotoxigenic *E. coli* is associated with traveller's diarrhoea. The protozoan *G. lamblia* adheres to the jejunum and upper ileum, causing mucosal inflammation, inhibition of disaccharidase activity and overgrowth of luminal bacteria.

Rotavirus is estimated to be the cause of 50% of gastroenteritis admissions in Australia prior to the introduction of rotavirus vaccine. Rotavirus vaccine was introduced into the funded Australian National Immunization Programme in July 2007.[1] A comparison study of gastroenteritis prior to the vaccine's introduction against the 30 months following it showed a marked reduction in emergency department (ED) encounters as well as hospitalization for rotavirus and non-rotavirus gastroenteritis. There also appears to be an indirect population-protective effect of the vaccine as older children who were ineligible for the rotavirus vaccine have also demonstrated reduced hospitalization and positive rotavirus tests.

Epidemiology

In Australia the estimated incidence of gastroenteritis is 17.2 million cases per year. Thirty-two percent of these cases are food-borne, which is equivalent to 0.3 episodes per person per year.

Altogether, food-borne gastroenteritis causes 15,000 hospitalizations and 80 deaths annually. The economic impact on the health care system is estimated at $30 million per year.

Norovirus, enteropathogenic *E. coli*, *Campylobacter* and *Salmonella* are the leading causes of gastroenteritis in Australia, with norovirus considered to be the leading cause worldwide. Norovirus outbreaks are commonly reported in aged-care facilitates, health care facilities and child care centres, causing immense disruption to the systems meant to be looking after this vulnerable populations.[2]

Gastroenteritis may occur in many settings. It may be a sporadic isolated event; a small outbreak either within a family or other close living group, such as in a geriatric residential facility; or part of a larger community epidemic. It may occur in travellers, either while still overseas or on their return home. It is important to be aware of the circumstances and context in which the illness occurs, as these will often dictate the course of investigation or management.

Clinical features

History

The clinical history and examination are directed at confirming the diagnosis of gastroenteritis, excluding other diagnoses and determining the degree of dehydration.

The principal clinical manifestation of gastroenteritis is diarrhoea. There is a lack of standardized definition of gastroenteritis. The World Health Organization syndromic definition of gastroenteritis is 'three or more abnormally loose or fluid stools over 24 hours'. The diarrhoea of gastroenteritis is often watery and profuse in the early stages of the illness and may last for up to 3 weeks. It is important to determine the frequency, volume and characteristics of the stool. Some organisms—such as enterohaemorrhagic *E. coli*, *Shigella*, *Salmonella*, *Campylobacter* and *Entamoeba histolytica*—may cause acute and bloody diarrhoea, whereas others, such as *Giardia*, may cause loose, pale, greasy stools.

Abdominal pain is common and is most often described as a diffuse intermittent colicky pain situated centrally in the abdomen. It may occur just prior to a bowel action and be relieved by that. Severe pain is often caused by *Campylobacter*, *Yersinia* and *E. coli*. Abdominal pain is also the hallmark of many other forms of intra- and extra-abdominal pathology. Diagnoses other than gastroenteritis should be seriously considered if the pain is well localized, constant and severe or if it radiates to the back or shoulder.

Vomiting may be present, particularly early in the illness, and can be variable in severity and persistence. The amount of vomiting and the ability to keep down clear fluids should be determined, as this will dictate the management of dehydration. Severe vomiting often occurs with organisms that produce preformed toxin, although it does not usually persist for longer than 24 hours. Anorexia, nausea and lethargy are common. Fever and systemic symptoms, such as headache, are prominent with organisms such as *Yersinia*, that invade the bowel wall and enter the systemic circulation. Lethargy may be related to the dehydration or merely the strain of constant and persistent diarrhoea from any aetiology.

Specific inquiry regarding fluid status is essential. The aim should be to determine the amount of fluids that have been taken orally and kept down over the course of the illness, along with the estimated urine output. It is also important to ascertain pre-existing or intercurrent illness, such as diabetes or immunosuppression, which may alter management.

Physical examination

Suitable infection control procedures should be instituted prior to the examination to prevent spread to the examining doctor and hence to other patients. Where possible, the patient should be in an isolation cubicle. Hand hygiene procedures before and after the consultation, the use of gloves and prompt disposal of soiled clothing and linen are important.

A careful clinical examination should be performed, concentrating on the abdomen and the circulatory state of the patient. The vital signs, temperature and urinalysis should be obtained.

In mild to moderate gastroenteritis, the clinical examination is often unremarkable. There may be some general abdominal tenderness, active bowel sounds and facial pallor but little else. In more severe disease, the abdominal tenderness may be pronounced and signs of dehydration present. Of note, uncomplicated gastroenteritis is extremely unlikely if the abdominal examination reveals localized tenderness or signs of peritoneal irritation.

Fluid losses through diarrhoea, vomiting and fever, together with poor oral fluid intake, can lead to clinically apparent dehydration. This may be manifest as tachycardia, tachypnoea, reduced tissue turgor, delayed capillary return, reduced urine output and, in its more severe stages, hypotension, impaired conscious state and death.

Extra-abdominal signs of a primary gastroenteritis can occur. *Campylobacter* has been associated with reactive arthritis and Guillain-Barré syndrome. The clinical features, course and complications for various causative agents are summarized in Table 7.5.1.

Diarrhoea in certain circumstances

Traveller's diarrhoea

Millions of travellers each year are affected by diarrhoea. Southeast Asia, the Middle East, the Mediterranean basin, Central and South America are areas of frequent occurrence. The incidence of diarrhoea in travellers to these areas is as high as 30% to 50%. Bacteria are the most common cause of traveller's diarrhoea. Pathogens include enterotoxigenic *E. coli*, enteroaggregative *E. coli*, *Salmonella*, *Shigella* and *Campylobacter*. Protozoans, such as *Giardia*, *Cryptosporidium* and *Entamoeba histolytica*, account for 10% of cases. Rotavirus and norovirus are the principal viral pathogens but account for less than 10% of traveller's diarrhoea. Many cases do not become symptomatic until after travellers return home. Antibiotic prophylaxis for traveller's diarrhoea, although effective, is not usually recommended as, in most instances, the illness will be self-limiting.[3]

The immunocompromised patient

Patients with impaired immunity (AIDS, IgA deficiency, immunosuppressive therapy following organ transplantation and long-term corticosteroid usage) are not only more susceptible to the common causes of gastroenteritis but are also vulnerable to the less common organisms, such as *Cryptosporidium*, *Microsporidium*, *Isospora* and *Cytomegalovirus*. Infections are often more severe, have a higher incidence of complications and may be more resistant to conventional therapy. Isolation of the causative organism and determination of antibiotic sensitivity are essential to guide management.

Hospital-acquired diarrhoea

Clostridium difficile is the most common cause of antibiotic-associated and nosocomial diarrhoea. It may range from a mild disease to life-threatening pseudomembranous colitis and can follow treatment with almost any antibiotic but particularly cephalosporins and clindamycin. Methods of laboratory detection include stool culture, polymerase chain reaction (PCR), cell-culture cytotoxicity assay and enzyme immunoassays. Patients should be treated empirically with oral metronidazole, reserving oral vancomycin for severe disease or subsequent recurrences.[4]

Differential diagnosis

Many pathological conditions, especially early in their course, may present with a clinical picture similar to that of gastroenteritis. Appendicitis, mesenteric adenitis, small bowel ischaemia and inflammatory bowel disease can all present in a similar fashion. Conversely, *Campylobacter* may cause severe abdominal pain with little diarrhoea and may be misdiagnosed as appendicitis or inflammatory bowel disease. Medical conditions—such as toxic ingestions, diabetic ketoacidosis, hepatitis and pancreatitis—may also present with vomiting, abdominal pain, tenderness and 'loose' stools.

Table 7.5.1 Pathogen-specific syndromes

Causative agent	*Incubation period*	*Duration of illness*	*Predominant symptoms*	*Foods commonly implicated*
Bacteria				
Campylobacter jejuni	1–10 d (usually 2–5 d)	2–5 d occasionally >10 d	Sudden onset of diarrhoea, abdominal pain, nausea, vomiting	Raw or undercooked poultry, raw milk, raw or undercooked meat, untreated water
E. coli enterohaemorrhagic	2–10 d	5–10 d	Severe colic, mild to profuse bloody diarrhoea can lead to haemolytic uraemic syndrome	Many raw foods (especially minced beef), unpasteurized milk, contaminated water
E. coli enteropathogenic, enterotoxigenic, enteroinvasive	12–72 h (enterotoxigenic)	3–14 d	Severe colic, watery to profuse diarrhoea, sometimes bloody	Many raw foods, food contaminated by faecal matter, contaminated water
Salmonella serovars (non-typhoid)	6–72 h	3–5 d	Abdominal pain, diarrhoea, chills, fever, malaise	Raw or undercooked meat and chicken, raw or undercooked eggs and egg products
Shigella spp.	12–96 h	4–7 d	Malaise, fever, vomiting, diarrhoea (blood and mucus)	Foods contaminated by infected food handlers and untreated water contaminated by human faeces
Yersinia enterocolitica	3–7 d	1–21 d	Acute diarrhoea sometimes bloody, fever, vomiting	Raw meat, especially pork, raw or undercooked poultry, milk and milk products
Vibrio cholerae	A few hours to 5 d	3–4 d	Asymptomatic to profuse painless watery diarrhoea, dehydration	Raw seafood, contaminated water
Vibrio parahaemolyticus	4–30 h (usually 12–24 h)	1–7 d	Abdominal pain, diarrhoea, vomiting and sometimes fever Illness of moderate severity	Raw and lightly cooked fish, shellfish, other seafood
Viruses				
Norovirus (and other viral gastroenteritis)	24–48 h	12–60 h	Severe vomiting, diarrhoea	Oysters, clams, foods contaminated by infected food handlers and untreated water contaminated by human faeces
Rotaviruses	24–72 h	Up to 7 d	Malaise, headache, fever, vomiting, diarrhoea	Foods contaminated by infected food handlers and untreated water contaminated by human faeces
Parasites				
Cryptosporidium	1–12 d	4–21 d	Profuse watery diarrhoea, abdominal pain	Foods contaminated by infected food handlers and untreated water contaminated by human faeces
Giardia lamblia	1–3 wk	1–2 wk to mo	Loose pale greasy stools, abdominal pain	Foods contaminated by infected food handlers and untreated water contaminated by human faeces
Entamoeba histolytica	2–4 wk	Weeks to months	Colic, mucous or bloody diarrhoea	Foods contaminated by infected food handlers and untreated water contaminated by human faeces
Toxin-producing bacteria				
B. cereus (toxin in food)	1–6 h (vomiting) or 6–24 h (diarrhoea)	<24 h	Two known toxins causing nausea and vomiting or diarrhoea and cramps	Cereals, rice, meat products, soups, vegetables
C. perfringens (toxin in gut)	6–24 h	24 h	Sudden onset colic, diarrhoea	Meats, poultry, stews, gravies, (often inadequately reheated or held warm)
Staphylococcus aureus (toxin in food)	30 min–8 h	24 h	Acute vomiting, and cramps, may lead to collapse	Cold foods (much handled during preparation) milk products, salted meats

Clinical investigations

In most circumstances, no investigations are necessary to make the diagnosis of gastroenteritis or to manage the patient effectively.

Identification of the infective agent may be useful when there is an outbreak of gastroenteritis to ensure that adequate public health measures are instituted in an attempt to limit spread of the disease. Additionally, in a patient who has a persistent illness or clinical features of a specific illness (such as *Campylobacter*, *Giardia* or *Salmonella*), identification of the organism may be helpful in directing antimicrobial therapy or identifying a carrier state. Although the history and examination may give clues as to the aetiological agent, they are unreliable, as many similarities exist between the clinical syndromes produced by each organism. Laboratory identification is the only accurate method.

The infective agent may be identified by microscopy and culture of faeces, looking specifically for pathogenic bacteria, cysts, ova or parasites. A fresh specimen of faeces will assist in detection. Occasionally multiple specimens are required, especially for organisms that may shed into the faeces only sporadically.

Rotavirus infection is detected by looking for rotavirus antigen in the stool by electron

microscopy, PCR, enzyme-linked immunosorbent assay (ELISA) or latex agglutination.

If a patient is dehydrated or systemically unwell, a full blood examination, serum electrolyte determination and serum glucose are warranted. In rare cases, where there are signs suggestive of septicaemia or severe systemic illness, blood cultures and liver function tests may be indicated.

Abdominal x-rays are useful only if it is necessary to exclude a bowel obstruction or free intra-abdominal gas.

Treatment

The principles of treatment for gastroenteritis are to replace fluid and electrolyte losses, minimize symptoms if possible and, in selected cases, administer specific antimicrobial therapy.[5] Clear fluids for 24 hours are often recommended, with the rationale that keeping the stomach empty, which will minimize vomiting. If the patient wishes to eat, it should be allowed. Strictly withholding feeding, especially from children, is not necessary. In hospital settings, these patients are usually isolated with contact precautions to prevent spread of nosocomial infections.[6]

Replacement of fluid losses may be achieved enterally, either by mouth or via a nasogastric tube or intravenously. The method selected will depend on the cooperation of the patient, the degree of dehydration, the rate at which rehydration is desired and the presence of other diseases, such as diabetes.

Specific oral rehydration solutions are the most appropriate for oral or nasogastric use. There are a number of commercial preparations available through pharmacies without prescription. These consist of a balanced formula of glucose, sodium and potassium salts and, in worldwide trials, have been shown to be extremely effective and safe, even when used in the most primitive of conditions. Although many commonly available fluids may be used and will probably be effective in mild disease, fluids that contain large amounts of glucose, such as degassed lemonade or undiluted fruit juice, should not be encouraged in adults and are contraindicated in children. These fluids are hyperosmolar and deficient in electrolytes, thus promoting further fluid losses. Glucose-containing electrolyte solutions use the gut's co-transport system for glucose and sodium, thereby facilitating the absorption of water as well. Caffeine-containing products should also be avoided as caffeine increases cyclic levels of adenosine monophosphate (AMP), thereby promoting the secretion of fluid and worsening diarrhoea.

Intravenous rehydration is necessary in patients who are in shock or who are becoming progressively dehydrated despite oral or nasogastric fluids. Resuscitation should be commenced with normal saline at a rate that accounts for ongoing losses along with replacement of the estimated fluid deficit. Patients should also be encouraged to take oral fluids unless vomiting is prohibitive. As soon as an adequate intake is achieved, the intravenous fluids can be scaled back and ceased.

Close monitoring of serum electrolytes is necessary during intravenous rehydration. In particular, it is important to monitor serum sodium, as the exclusive use of normal saline for rehydration can lead to hypernatraemia. Potassium should be added to the fluid as determined by the serum potassium, remembering that low serum potassium in this circumstance is indicative of low total body potassium.

In adults, parenterally administered antiemetic drugs—such as metoclopramide, prochlorperazine or ondansetron—may be useful in the management of severe vomiting. Although antimotility agents, such as loperamide, have been shown to reduce the number of diarrhoeal stools and duration of illness, they have significant side effects and should be used only if essential. There is growing evidence that oral ondansetron in children is useful for those that fail initial oral rehydration therapy.[7,8]

Even though many bacteria that cause gastroenteritis respond to antibiotics, they are rarely indicated. In the majority of these cases, the illness will be short-lived and mild. Diarrhoea and vomiting for more than 3 days and persistent fever suggest a bacterial cause for the gastroenteritis. However, many isolates of *Campylobacter jejuni*, *Shigella* and *Salmonella* are resistant to many antibiotics. Choice of antibiotics should be based on antibiotic sensitivity patterns and local therapeutic guidelines. Antibiotics may be indicated in *Giardia* infections, *Shigella* causing severe disease, *Salmonella* in infants, the immunosuppressed or the elderly, *Campylobacter* in food handlers and in traveller's diarrhoea. Antibiotics are contraindicated in uncomplicated *Salmonella* infections as they may prolong the carrier state. Recommended antibiotic regimens are summarized in Box 7.5.1.[9]

Box 7.5.1 Antibiotic treatment regimens

Giardia lamblia
Tinidazole 2 g (child: 50 mg/kg up to 2 g) orally as a single dose
OR
Metronidazole 2 g (child: 30 mg/kg up to 2 g) orally qd for 3 d

Amoebiasis
Tinidazole 2 g (child: 50 mg/kg up to 2 g) orally qd for 3 d
OR
Metronidazole 600 mg (child: 15 mg/kg up to 600 mg) orally q 8 h for 7–10 d
PLUS
Paromycin 500 mg (child: 10 mg/kg up to 500 mg) orally q 8 h for 7 days (to eradicate cysts and prevent relapse)

Shigellosis
Ciprofloxacin 500 mg (child: 12.5 mg/kg up to 500 mg) orally q 12 h for 5 d
OR
Norfloxacin 400 mg (child: 10 mg/kg up to 400 mg) orally, q 12 h for 5 d
OR
Co-trimoxazole 160/800 mg (child: 4/20 mg/kg up to 160/800 mg) orally q 12 h for 5 d

Campylobacter
Azithromycin 500 mg (child: 10 mg/kg up to 500 mg) orally daily for 3 d
OR
Ciprofloxacin 500 mg (child: 12.5 mg/kg up to 500 mg) orally q 12 h for 3 d
OR
Norfloxacin 400 mg (child: 10 mg/kg up to 400 mg) orally q 12 h for 5 d

Salmonella
Azithromycin 1g (child: 20 mg/kg up to 1 g) orally on the first day, then 500 mg (child 10 mg/kg up to 500 mg) orally qd for a further 6 d
OR
Ciprofloxacin 500 mg (child: 12.5 mg/kg up to 500 mg) orally q 12 h for 5–7 d
If oral therapy not feasible, bacteremic patients or children <3 mo old:
Ceftriaxone 2 g (child 1 month or older: 50 mg/kg up to 2 g) IV qd
OR
Ciprofloxacin 400 mg (child 10 mg/kg up to 400 mg) IV q 12 h

7.6 Haematemesis and melaena

Kevin K.C. Hung • Colin A. Graham

ESSENTIALS

1 Resuscitation is the priority, with particular attention to restoring perfusion of vital organs by replacing intravascular volume.

2 Upper gastrointestinal (GI) endoscopy is the key investigation and frequently allows definitive therapy. It should be performed at the earliest opportunity.

Introduction

Upper gastrointestinal bleeding (UGIB) is a common medical emergency with substantial morbidity and mortality. Over the last two decades, there have been advances in drug therapy for peptic ulcer disease and varices, improvements in endoscopic techniques, interventional radiology and surgical management, in addition to advances in resuscitation and supportive care. Mortality for patients presenting with UGIB remains around 6% to 10%, although there is some evidence that mortality has declined in the United Kingdom and the United States. Fewer patients (approximately 2%) now require emergency surgery. Patients with UGIB are increasingly elderly and have more co-morbidity than in the past, which may explain the slow improvement in mortality despite the many technical advances in management, particularly endoscopy. Patients now rarely die of exsanguination but more commonly of multiple organ failure secondary to pre-existing co-morbidities.

Definitions, epidemiology and pathogenesis

UGIB is defined as any bleeding within the GI tract proximal to the ligament of Treitz. Any bleeding arising distal to that point is a lower GI bleed. Haematemesis is the vomiting of bright red blood. 'Coffee-ground vomiting' is the vomiting of digested blood clot, whereas melaena is the passage of black, tarry stools as a result of the bacterial degradation of haemoglobin within the gut. Melaena usually represents a source of UGIB, but it can rarely occur due to a lower GI source of bleeding. Haematochezia is the passage of bright red blood per rectum and, in the context of UGIB, represents a briskly bleeding source of haemorrhage. Melaena of itself is not associated with poorer outcomes in UGIB, but haematochezia due to an upper GI source is associated with double the risk of death.

Peptic ulceration remains the most common cause of UGIB despite the recognition and treatment of *Helicobacter pylori* infection as a primary cause of peptic ulcer disease (accounting for 36% of cases in a recent UK audit). The pathogenesis of peptic ulcer disease is complex but is closely related to a variety of risk factors, including *H. pylori* infection, use of non-steroidal anti-inflammatory drugs (NSAIDs) including aspirin, smoking and alcohol use.

Gastroduodenal erosions and oesophagitis make up a further 15% of cases. Oesophagogastric varices, resulting from portal hypertension, are the source of 11% of episodes of UGIB and up to 20% in patients less than 60 years old. Mallory-Weiss tears, the result of repeated vomiting, reportedly account for less than 5% of cases (although patients with a typical history often do not undergo endoscopy) and usually do not require specific treatment. The remaining causes (all <2%) include vascular lesions, such as angiodysplasia, a Dieulafoy lesion and aortoenteric fistula.

Prevention

The development of peptic ulcer disease is closely related to management of the risk factors. The effective identification and eradication

of *H. pylori* has led to a significant reduction in the incidence of peptic ulcer disease as the cause of UGIB.

There is little doubt that restricting the prescription of NSAIDs in the elderly (the highest-risk group for the development of UGIB from NSAIDs and the age group with the highest risk of mortality from UGIB) could prevent a significant number of episodes of UGIB. This is particularly relevant to emergency medicine practice, where NSAIDs are often prescribed as analgesia for musculoskeletal conditions. Care should be taken to prescribe the safest drugs (ibuprofen is the most common NSAID with a low risk profile) for the shortest possible time at the lowest effective dose. Cyclo-oxygenase (COX)-2 selective NSAIDs have been found to cause reduced GI injury, but their use is limited by their increased cardiovascular risks. If patients are assessed as at high risk for possible UGIB, NSAIDs should be avoided or, if unavoidable, a proton pump inhibitor (PPI) should be prescribed with the NSAID to maximize gastric mucosal protection.

Clinical features

It is usually necessary to determine whether the blood loss is from a GI source. Blood from the nose or oropharynx can be swallowed, resulting in haematemesis and/or melaena. If bleeding is thought to be from the upper GI tract, then a number of diagnoses must be considered (see later).

The following historical clues and caveats must be considered:

- A history of epigastric pain or dyspepsia suggests peptic ulcer disease. However, peptic ulcer disease may be painless, particularly in the elderly and in those taking NSAIDs and corticosteroids.
- A positive history of gastric or duodenal ulcer disease or reflux oesophagitis is associated with an approximately 50% chance of finding the same diagnosis at endoscopy.
- The risk of UGIB in patients taking NSAIDs is double that of patients not taking NSAIDs and is still higher than baseline in patients taking PPIs as gastric protection.
- The classic history of nausea and repeated vomiting prior to bleeding occurs in approximately one-third of cases of Mallory-Weiss tear.
- UGIB with a history of alcohol abuse and the stigmata of portal hypertension is suggestive of varices. However, up to 40% of patients with cirrhosis who present with GI bleeding are bleeding from causes other than varices (commonly from gastric erosions).
- Conditions associated with stress ulcers include burns, major trauma, head injury, sepsis and hypotension.
- Patients with chronic renal failure have a high incidence of angiodysplasia, peptic ulcer disease and oesophagitis.
- A history of aortic surgery and GI bleeding raises the possibility of an aortoenteric fistula, even if the initial bleeding episode is not significant (the first bleed is often the 'herald bleed').
- Clinical evidence of a coagulopathy should be sought, as this will influence subsequent investigation, treatment and prognosis.
- Current drug treatment should be identified, particularly the use of anticoagulants (traditional or novel), antiplatelet drugs, and NSAIDs.
- Stool examination, by rectal examination if required, is essential. As previously described, stool colour has prognostic significance. Testing for occult blood further increases the sensitivity of this examination as commercial kits are able to detect as little as 6 mg of haemoglobin per gram of stool. A positive test is dependent on the time of onset of bleeding in relation to GI transit time. False positives may be produced by certain bacterial and vegetable peroxidases, such as bananas and horseradish. False negatives may result from ferrous salts.

Clues to the speed or acuity of blood loss include the following:

- The most likely diagnosis. Varices produce large amounts of dark (venous) blood; aortoenteric fistulae produce massive bright red haematemesis and haematochezia, with profound circulatory collapse.
- Signs of haemodynamic instability and response to initial resuscitation. If there is a poor response, there is likely to be significant haemorrhage.
- The character of the vomitus. Ongoing haematemesis is associated with large blood loss; 'coffee-ground' altered vomiting or clear fluid is often associated with a slower rate of bleeding.
- The colour of the stool (see earlier).
- The nasogastric aspirate if a tube is already in the stomach (commonly 'old age home' residents receiving enteral nutrition). Note that the practice of inserting a nasogastric tube in the emergency department (ED) to assess the aspirate is no longer recommended, as the absence of blood does not exclude significant bleeding.

The key message is that if there is haemodynamic instability or other evidence of significant ongoing UGIB, fluid resuscitation should continue but arrangements should be made to expedite emergency upper GI endoscopy. The accuracy of diagnosis is not important at this stage but the identification of major ongoing bleeding is.

Severity scores

Over the last decade, several scoring systems have been introduced to assist in the assessment of the severity of UGIB. The best known of these is the Rockall score, which can be a pre-endoscopy score (admission Rockall) or a post-endoscopy score (full Rockall), and the Glasgow-Blatchford score (GBS), which utilizes clinical criteria only. The GBS is very sensitive and can be used to identify patients who may be suitable for outpatient care. Recent studies have found the GBS to be the best at predicting intervention or death at 30 days, and various cut-offs have been proposed for outpatient management. The current European Society of Gastrointestinal Endoscopy (ESGE) guideline recommends that patients with GBS of 0 to 1 do not require early endoscopy or hospital admission.

Clinical investigations

Blood tests

Blood should be drawn for full blood count, coagulation studies (International Normalised Ratio (INR) prothrombin time (PT) INR/PT, activated partial thromboplastin time (APTT) and fibrinogen), electrolytes, urea, creatinine, glucose level, liver function tests and urgent cross-matching. The initial haemoglobin is of limited value, as 24 to 48 hours are required for the intravascular volume to equilibrate. Thrombocytopenia and leucocytosis are associated with increasing morbidity and mortality. UGIB may also result in an elevation of the urea level (relative to the creatinine), as there is a combination of an increased protein load in the gut and intravascular hypovolaemia. Blood should be taken for blood gas analysis to assess acid-base balance in those with significant bleeds. Venous blood gas analysis is appropriate unless coexisting respiratory failure is suspected. Similarly, a serum lactate level can help to identify patients with clinically occult hypoperfusion who are at high risk of significant haemorrhage.

Imaging

A chest x-ray may be indicated where aspiration is suspected, in the elderly or in patients with cardiopulmonary co-morbidities. It should also be performed if perforation is suspected; however, perforation associated with significant UGIB is rare.

Endoscopy

Although clinical and historical features can point towards the most likely diagnosis, they are not specific. The admission Rockall score (pre-endoscopy) and the GBS can help predict the need for endoscopy. There is no empirical therapy that effectively treats all causes of UGIB. As a result, a specific endoscopic diagnosis must almost always be made. Exceptions may include patients with a classic history suggestive of a Mallory-Weiss tear with no ongoing

UGIB symptoms and stable haemoglobin and haemodynamic status and the very elderly with major co-morbidity and poor health status (e.g. patients with advanced dementia). Most centres rely on endoscopy to

- Provide information on the source of bleeding with a high degree of specificity (90% to 95%).
- Allow prediction of the likelihood of re-bleeding and mortality, according to the nature and location of the lesion and stigmata of recent haemorrhage. These factors help in deciding the level of patient monitoring or whether they may be treated as outpatients.
- Provide therapy. Endoscopy facilitates haemostasis through sclerotherapy, coagulation techniques and banding of varices and allows histological or microbiological diagnosis. In high-risk peptic ulcers, endoscopic therapy has been shown to decrease re-bleeding by 75% and mortality by 40%.
- Diagnose with safety (morbidity <0.01%). Safety is further maximized if endoscopy is delayed until the patient is haemodynamically stable and the airway patent and protected.

Endoscopy should be performed within 24 hours of presentation. Urgent endoscopy should be performed in patients with active or recurrent bleeding, bright red blood on haematemesis, large bleeds (>2 units of blood required) and when variceal bleeding is suspected. However, there is no evidence that early endoscopy (<12 hours) is associated with reduced mortality, although it is associated with a reduced length of hospital stay. Pro-motility agents, such as erythromycin, promote gastric emptying pre-endoscopy but have not been shown to have any benefits on mortality, need for surgery or length of stay. They are not routinely recommended in the ED prior to endoscopy.

Treatment

Resuscitation

Continuous electrocardiogram (ECG) monitoring, non-invasive blood pressure monitoring and pulse oximetry should be instituted, with frequent clinical reassessment. Urine output should also be measured and recorded hourly. Invasive arterial and central venous pressure monitoring may be necessary in massive bleeds, intubated patients and those with co-morbidities.

Oxygen should be administered to patients who are hypoxaemic (oxygen saturation <92%) or have evidence of significant ongoing bleeding. Massive ongoing bleeding may compromise the airway to the extent that tracheal intubation may be required to secure and protect it. Intubation in these circumstances can be both difficult and hazardous and high-volume effective suction is essential. The extent of bleeding is often underestimated and, under these conditions, doses of induction agents should be dramatically reduced from normal levels.

The intravascular volume should then be optimized. The presence of shock (in most studies this was defined as systolic blood pressure <100 mm Hg) places the patient at high risk for re-bleeding, requirement for surgery and death. Note that among the elderly, patients with autonomic neuropathies (frequently found in those with diabetes) and those taking β-blockers or calcium channel antagonists the vital signs, including postural hypotension, may not be reliable indicators of the degree of blood loss. Propranolol is a commonly used (and effective) prophylaxis for the prevention of variceal bleeding in cirrhotic patients, and this may blunt the haemodynamic responses of patients with acute massive variceal bleeding.

Intravascular volume should initially be replaced with isotonic crystalloid (saline or Hartmann solution) or colloid. There is no evidence of superiority for either class of intravenous fluid in UGIB. Blood should be given promptly if there is persistent haemodynamic instability despite 1 to 2 L of crystalloid or colloid if the initial haemoglobin level is below 7 mg/dL, if there is a significant risk of re-bleeding and in those patients with co-morbidities (e.g. chronic obstructive pulmonary disease, coronary artery disease) making them unable to tolerate periods of anaemia. The thresholds for transfusion continue to be questioned, as early transfusion has been associated with increased mortality in UGIB. However, a higher haemoglobin level (>9 mg/dL) is generally accepted as desirable if there is a history of severe underlying cardiorespiratory disease (e.g. ischaemic heart disease). A restrictive red blood cell transfusion strategy that aims for a target haemoglobin between 7 and 9 g/dL is usually recommended. The initial haemoglobin level may be unreliable in the setting of critical bleeding and the transfusion requirement should be guided by haemodynamic status rather than haemoglobin level.

Correction of coagulopathy

Transfusion of fresh frozen plasma and platelets should be considered early to prevent and treat coagulopathy associated with massive haemorrhage. Fresh frozen plasma should be given when the prothrombin time is 3 seconds greater than the control or when large transfusions are required. In all patients requiring massive transfusion, attempts should be made to avoid hypothermia by using blood warmers, heating blankets and overhead heaters.

Endoscopy
